RELATIVE DETERMINATION OF THE ATOMIC WEIGHT OF CHLORINE IN BAMLE APATITE

By Margot Dorenfeldt Received October 3, 1922

Introduction

This work was undertaken at the suggestion of Dr. Ellen Gleditsch in connection with an investigation carried out by Gleditsch and Samdahl, the object being to determine whether, in an old mineral which has not been in contact with water, the two chlorine isotopes of atomic weights 35 and 37 occur in the same proportion as in ordinary chlorine. The mode of attack was to compare the specific gravities of saturater colutions of sodium chloride, one solution being made from ordinary sodium chloride and the other from Bamle apatite, the method being similar to that described by Fajans and Lembert.²

Apparatus and Materials

The pycnometer was an exact copy of one described by Fajans and Lembert, a modified Sprengel-Ostwald type. The temperature variations of the thermostat cannot be given accurately but a 0.1° thermometer showed no change. The glass test-tubes in which the solutions were rotated in the thermostat were of thick glass, 14 cm. long, and of 22 mm. internal diameter. The clean tubes and the rubber stoppers were soaked in warm brine solution for 12 hours, after which treatment they were carefully rinsed. The balance was a Bünge with a sensitiveness of 0.4 mg.; no mirror was used but ½ divisions could easily be read.

The "ordinary sodium chloride" was a commercial highly purified preparation which was further purified. A saturated solution was treated with chlorine, the excess chlorine removed by boiling, the salt precipitated with hydrogen chloride, recrystallized

¹ Gleditsch and Samdahl, Compt. rend., 174, 746 (1922). Arch. Math. Naturvidensk., 38 (1923).

² Fajans and Lembert, Z. anorg. Chem., 95, 297 (1916).

evaporated to dryness, ignited, and recrystallized thrice. Weighing value No. 4, 1.202791, which agrees with that found for "ordinary sodichloride," 1.202791 and 1.202790.

After the work had been abandoned for a time the "apatite sodung chloride" solution was evaporated, ignited, recrystallized two or three times, and the specific gravity again determined (No. 5). Another evaporation, ignition and recrystallization gave value No. 6, the specific gravity of "ordinary sodium chloride" being determined at the same time.

The slight difference between the first and the last determinations of "ordinary sodium chloride" may be accounted for by a new setting the thermostat regulator. The measurements taken at the same te under identical conditions are in good agreement. Thus the averager "ordinary sodium chloride" under the earlier conditions agrees precise with the value for the purest "apatite sodium chloride" (No. 4), while later value, 1.202867, for "ordinary sodium chloride" agrees closs with the average, 1.202855, of the later values for the still further purifice "apatite sodium chloride."

A sample was then taken from each of the two solutions by means of the pycnometer and ignited to constant weight in platinum, all precautions being observed. When corrected to vacuum the "ordinary sodium chloride" weighed 3.31262 while the "apatite sodium chloride" weighed 3.31267 or 0.05 mg. more, a difference less than the errors of weighing (0.1 mg.). It follows that the atomic weight of the apatite chlorine does not differ from that of ordinary chlorine by an appreciable amount. Even if the solubilities found (26.357% at 18° or 35.790 g. per 100 g. of water) were not absolutely correct, the atomic weight 35.46 calculated from the relative values would still hold good.

Incidentally, we have compared the solubilities we found with those calculated from the formula of Andreae³ which are in good agreement with many recent determinations.⁴ The calculated value is 26.363%, while we found 26.357% which is in excellent agreement.

Summary

The chlorine isotopes in Bamle apatite occur in the same proportion as in ordinary sodium chloride.

Every method of measuring activity, except by the speed of reaction, depends upon the number of molecules passing through or reacting at a surface, which may be the surface of contact of the solution with a gas, with another liquid, with the solid form of the solute, or with an electrode. Since the activity is independent of the extent of this surface, it must be proportional to the number of molecules which collide with a unit surface. To account for different degrees of attraction of different surfaces, this may be expressed as the number which would collide with a unit standard surface multiplied by a coefficient for the particular surface. Also, the activity must be proportional to the fraction of colliding molecules that pass through or react at the surface, either of which we will call the fraction of reactive molecules. This may be summarized in mathematical form: activity = proportionality constant × number of collisions against unit standard surface × specific surface coefficient × fraction of reactive molecules.

In an ideal solution the fraction of the molecules that are reactive is independent of the composition, and the activity of each component is proportional to its mole fraction. So the number of collisions of each component is proportional to its mole fraction, and not in general to its concentration.

In collisions between 2 molecules, let us picture the molecules of the first type as colliding with those of the second. Then the number of collisions will be proportional to the mole fraction of the molecules of the first type. For a single molecule of the second type the factor of proportionality will be its surface expressed in equivalents of a unit standard surface, which will certainly depend upon the size and nature of its surface, and perhaps also on its motion through the solution. In an ideal solution, however, this factor will be independent of the composition. The total number of collisions in a liter will be proportional to the concentration of the molecules of the second type, the number per mole of each component to its mole fraction. In either case the number of collisions will be proportional to the mole fraction of the molecules of the first type.

Collisions per mole =
$$K \times N_1 \times N_2$$
 (1a)
Collisions per liter = $K \times N_1 \times C_2 = K \times \Sigma C \times N_1 \times N_2 = K/\Sigma C \times C_1 \times C_2$ (1b)

The kinetic theory assumes that the speed of a bimolecular reaction is proportional to the number of collisions between reactive molecules of each sort. In an ideal solution, where the fraction of the molecules which are reactive is constant, the speed is proportional to the number of collisions between all the molecules. Using the two values of speed defined above, and recalling that in an ideal solution activity is proportional to mole fraction

$$-dN_1/dt = K' \times N_1 \times N_2 = K'' \times a_1 \times a_2$$
(2a)
$$-dC_1/dt = K' \times \Sigma C \times N_1 \times N_2 = K'/\Sigma C \times C_1 \times C_2 = K'' \times \Sigma C \times a_1 \times a_2$$
(2b)

The general equations are obvious. If m represents the number of molecules of each kind which react, they are

$$-dN_1/dt = K'' \times a_1^{m_1} \times a_2^{m_2} \times \dots \times a_n^{m_n}$$
(3a)
$$-dC_1/dt = K'' \times \Sigma C \times a_1^{m_1} \times a_2^{m_2} \times \dots \times a_n^{m_n}$$
(3b)

This derivation holds only for ideal solutions, but it does show that, if its logic is correct, the term s for ideal solutions when the equation is written in terms of activities is the quantity transformed in unit time per single mole of all components.

For the purpose of integration, the activities which change during the course of the action must be expressed in the same units as the differential. For an apparently unimolecular reaction⁵ the ΣC 's cancel in the second form, and the value of K is the same whether the speed is expressed in terms of mole fractions or of concentrations. In general $K_C = K_N(\Sigma C)^{1-n}$ where n is the apparent order of the reaction. A dilute solution, as ordinarily considered, is one in which ΣC is constant and independent of the composition. For such a solution K_C is proportional to K_N for a reaction of any order.

To extend this treatment to semi-ideal solutions, in which all the deviation from ideality is due to chemical action, it is necessary and sufficient to express the mole fraction of each reactant as it exists in solution and not as moles added.

The extension to solutions in general must be made by analogy, but it is rendered more probable by the fact that most solutions do not deviate much from semi-ideality. At present we cannot apply the theory of the speed of reaction unless the activity of each reactant whose concentration changes during the course of the reaction is proportional to its mole fraction: so the extension need not be too general. We know that in a reversible reaction near equilibrium the speed of each of the two opposing reactions must be proportional to the activities of the reactants, regardless of the nature of the environment. From the above argument it is evident that the reaction speed is proportional to the activities of the reactants in any reaction in ideal or semi-ideal solutions. The only generalization which will include both these special cases is that the speed of all reactions is proportional to the activities of the reactants: that Equations 3a and 3b hold for all reactions. This is further justified by the conclusion that the activity contains factors for both the proportion of reactive molecules and the frequency of collision.

This interpretation of activity offers an explanation of the conclusions of Brönsted² concerning the salt effect on the speed of reactions, particularly between ions. Brönsted considers that every reaction takes place by the formation of an intermediate complex of extreme instability, whose activ-

⁵ The order of a reaction is the number of molecules that react according to the equation; the apparent order is the number of those whose activity changes.

ity corresponds to its electrical charge which must equal the algebraic sum of the charges of the reactants. The speed of reaction is proportional to the activities of the reactants and inversely proportional to the activity coefficient (a/C) of this critical complex.

The formation of a complex which reacts immediately is synonymous with reaction on collision. The salt effect on reaction speed might be due to a change in the proportion of reactive molecules or to a change in the collision frequency. The effect on the activity coefficient might be due to either of these same causes. The fact that these effects depend only on the ionic type indicates that it is the latter which is changed, for the fraction of the ions which are already active must vary greatly for ions of the same valence type. Both salt effects are probably due to a change in the medium which alters the effect of the electrical charges upon each other, the nature of which is such that, when the frequency of collisions between oppositely charged ions is increased, that between similarly charged ions is decreased, and vice versa. Since the effect on the speed of reaction is due to the same cause as that on the activity, it should be inversely proportional to the activity coefficient of the complex formed during collision. This factor represents a true catalytic action in the salt effect, distinct from and superposed on the change in activities of the reactants.

Brönsted's conclusions are based on results with solutions 0.1 N or more dilute, which may be considered as dilute solutions by the definition given above; in such solutions the activity coefficients are approximately equal for ions of the same valence type. To apply this theory to concentrated solutions, the activity coefficient of the complex should be defined as the activity divided by the mole fraction: $f_C = a_C/N_C$. Moreover, in concentrated solutions the activity coefficient is not the same for all ions of the same valence type. Since the activity coefficient of an extremely unstable substance can never be measured directly, this introduces a new source of uncertainty into the study of concentrated solutions. In ideal or semi-ideal solutions f_C is a constant. The general equations become

$$-dN_1/dt = K''/f_C \times a_1^{m_1} \times a_2^{m_2} \times \dots \times a_n^{m_n}$$

$$-dC_1/dt = K''/f_C \times \Sigma C \times a_1^{m_1} \times a_2^{m_2} \times \dots \times a_n^{m_n}$$
(4a)
(4b)

Viscosity and Speed of Reaction

Those who have assumed that the viscosity of a medium affects the reaction speed have generally assumed also that the speed of any reaction is inversely proportional to the viscosity, which seems to imply that the viscosity is a symptom of an inertia in the medium which affects anything happening in it. Others^{6,7} have maintained that the effect of viscosity is at most very much smaller than that calculated by this assumption.

⁶ Arrhenius, Z. physik. Chem., 28, 317 (1899).

⁷ von Halban, *ibid.*, **67**, 129 (1909).

Moran and Lewis³ consider that the frequency of collision is a function of the viscosity, and that it is only through influencing this frequency that the viscosity affects the reaction speed. Then the viscosity should have no effect on a unimolecular reaction. In the case of the reaction of sucrose with hydrogen ion, the heavier sucrose molecule moves so much more slowly that it may be considered as motionless, and the effect of viscosity on the reaction speed is proportional to its effect on the mobility of hydrogen ion as measured by conductivity: it is approximately inversely proportional to the square root of the viscosity.

I believe that the speed of reaction is independent of the viscosity. My conception of the influence of viscosity is essentially that of Arrhenius, 6 which deserves restatement and emphasis and requires some minor modifications. Since the influence of a substance on the viscosity of a medium depends largely upon the size of its molecule, we will simplify the discussion by neglecting other factors and defining size as effect on viscosity.

Conductivity is not proportional to fluidity (the reciprocal of viscosity) but to some fractional exponent of it. The usual explanation of this smaller exponent is that the ions are too small to obey Stokes's law and that, when the individual molecules are considered, a solution is heterogeneous. The fluidity measures the mobility of all the molecules, large and small, while the conductivity measures the mobility of the smaller ions past the larger molecules. The effect of the larger molecules on the average mobility, when they themselves take part in the motion, is greater than their blocking effect upon smaller molecules or ions. 8,9,3

To extend this reasoning to the speed of reaction we must consider that both fluidity and conductivity depend upon the ordered motion of migration. Both are measured by the linear velocity over distances very large compared to the free path of the molecules. The speed of reaction, on the other hand, depends upon the frequency of collision and, therefore, upon the chaotic motion of thermal agitation. Although the free path in liquids is extremely small, an ion, when the direction of its motion is changed by collision, has exactly the same probability of colliding with a reactive molecule as though it had continued its motion in the original direction.

According to the theory of the equipartition of energy and the kinetic molecular concept of temperature, the speed of thermal motion is a function only of the temperature, and is independent of the viscosity or any other property of the medium. In fact, the kinetic explanation of viscosity considers that viscous resistance is exerted by means of the change of energy of ordered linear motion to that of chaotic thermal

⁸ Green, J. Chem. Soc., 93, 2049 (1908).

⁹ MacInnes, This Journal, 43, 1217 (1921).

agitation. Since the frequency of collision and the speed of reaction depend only on this latter type of motion they cannot be influenced by viscosity.

The experimental study of the effect of viscosity on reaction speed is inconclusive because of the failure to eliminate other factors. The viscosity of a medium cannot be changed without changing the medium, which may also change the activity coefficient of any reactant or the specific catalytic effect of the medium. The effect on activity coefficients may be determined by measuring the activities, and that on the catalytic effect only by measuring the speed of several reactions in the same media. The fact that viscosity and speed of reaction change together cannot show how the two are related, or even that they are related.

Very dilute solutions of agar-agar or of gelatin have very great viscosities, while the effect of these solutes on other properties is small. It has been found that the speed of hydrolysis of methyl acetate by hydrochloric acid in such solutions, even when set to a jelly, is almost as great as in water. ^{10,11} The small change can probably be accounted for by a change in the activity of the hydrogen ion. This eliminates the possibility of a general inertia due to viscosity. It cannot decide between the two other theories, for the conductivity and diffusion are also nearly the same in these jellies as in water.

Arrhenius⁶ believed that the fact that non-electrolytes have a very small effect on the speed of sucrose inversion compared to their effect on viscosity¹² proves that the reaction speed is very nearly independent of viscosity. But there may be a compensating increase in the activity of one of the reactants; witness the effect of sucrose itself on the hydrogenion activity.

The same objection applies to the measurements of reaction speed in water-alcohol mixtures.¹³ There must be a great change in the activity coefficients of most substances as the solvent changes, for the solubilities change greatly. The activity coefficients of ions apparently change also. The measurements of Pearce and Hart,¹⁴ calculated for 0.1 mole in a liter of solvent, show that the mean activity of lithium and chloride ions is 5 times as great in methyl alcohol, and 8 times in ethyl alcohol, as in water; but no activities have been measured in connection with the speed of reaction measurements. Moreover, although the viscosities of mixtures of water-alcohol pass through a maximum, the speed of re-

¹² Arrhenius, Z. physik. Chem., 4, 226 (1889).

¹³ This objection applies also, as regards the activity of the acid, to the work of W. H. Garrett and W. C. M. Lewis [This Journal, 45, 1091 (1923)] on the formation of valerolactone in solutions containing sucrose.

¹⁴ Pearce and Hart, This Journal, 44, 2411 (1922).

action sometimes increases, sometimes decreases, and sometimes passes through a minimum, which does not, however, correspond to the viscosity maximum.¹⁵

Particularly interesting are the results of Kistiakowsky on the reaction of formic acid with ethyl alcohol and that of ethyl formate with water. When the reactions are catalyzed with hydrochloric acid the speeds of both decrease slowly as water is displaced by alcohol to a minimum at about 60% alcohol, and then increase rapidly. Without a catalyst both decrease much more rapidly and continuously to 90% alcohol. The difference in the reactions with and without catalyst is very possibly a measure of the hydrogen-ion activity.

The only measurements in which all the activities have been measured are those of Buchböck16 on the hydrolysis of carbonyl sulfide in aqueous solutions of various salts and acids, published soon after the first suggestion of the activity theory, under the name of solubility theory, by Van't Hoff. 17 Probably the speed of this reaction should not be affected by the viscosity according to any kinetic theory of viscosity, since the reaction is unimolecular or with the solvent which is in large excess. The constants quoted do show that, corrected or not by multiplying by any power of the viscosity, the concentration theory, the simple activity theory, and the unmodified theory of Brönsted all fail to give constants. The modified theory of Brönsted explains the results if the speed is independent of the viscosity and the activity coefficient of the critical complex increases linearly with some function such as the "ionic strength" of Lewis and Randall. 18 The concentrations of the ions may be estimated roughly from the molality of the solution necessary to give the same freezing-point depression as does N hydrochloric acid.

The Inversion of Sucrose

Most of the assumptions necessary to the application of this theory to the inversion of sucrose were discussed in my previous paper,⁴ but some require reconsideration in the light of new work. The numbers following the subtitles refer to the pages of the previous paper.

Activity of Sucrose (2391-2, 2399-402).—There seems no reason to change the conclusions that the reaction is unimolecular with respect to

¹⁸ Lewis and Randall, This Journal, 43, 1112 (1921).

sucrose, and that the activity of sucrose is proportional to its mole fraction.¹⁹

Constancy of k (2391–2, 2399–402).—Fales and Morrell²⁰ claim that k, the constant for a unimolecular reaction, is not always constant during the course of a single reaction. Unfortunately, their experiments were not carried out in duplicate, and it is difficult to determine what part of their variation should be attributed to a real lack of constancy and what part to experimental error. The more complete details in Morrell's dissertation indicate two types of variation from constancy.

The first is abnormally high values of k for the first 1 or 2 minutes. This is noticeable only in the $0.1\ N$ or more concentrated solutions, for in the more dilute solutions the total change in so short a time is negligible. The abnormality is irregular and bears no apparent relation to the acid or sugar concentration. Two probable causes are: (1) an error in the measurement of time, which is unavoidable when the time interval is not great compared to the time of delivery of the pipets; and (2) an increase in temperature for the first few minutes due to the heats of dilution. Fales and Morrell have discarded these abnormally high values in calculating their average constants. They probably do not indicate a real abnormally high initial speed.

The second is a gradual increase of the reaction speed, which appears only in the solutions more concentrated in hydrochloric acid than $0.3\ N$. Their solutions of $0.3\ N$ acid have about the same hydrogen-ion activity as the upper limit in the solutions studied by Lewis. 21,3 We are, therefore, justified in assuming that such an increase does not exist in these solutions. Moreover, such a gradual variation would appear in their method. 22

Activity of Water (2392-6).—The activity of the water cannot be determined directly, since it changes materially during the course of inversion. It is determined from the activity in solutions without acid, and corrected for the effect of the acid by two assumptions which seem to give the minimum and maximum probable values. For $0.1\ N$ sulfuric acid the greatest correction is 0.6% and the greatest difference between the two assumptions is 0.4%; for $0.1\ N$ hydrochloric acid the corresponding values

¹⁹ In their statement that this question involves a difficulty to which attention had not hitherto been drawn, Moran and Lewis³ apparently overlook the discussion in my previous paper referred to above.

²⁰ Fales and Morrell, This Journal, 44, 2071 (1922). Morrell, Dissertation, Columbia University, 1921.

²¹ Jones and Lewis, J. Chem. Soc., 117, 1120 (1920).

²² The agreement between the results of Moran and Lewis and of Fales and Morrell noted by Lewis, Merriman and Moran [This Journal, 45, 711 (1923)] does not depend on the form of constant used by the authors, but arises through agreement of the two observations in both k and $a_{\rm H}+$.

are twice as great. The two assumptions lead to practically the same conclusions as to the number of water molecules taking part in the reaction.

Activity of Hydrogen Ion (2392).—It was previously assumed that the hydrogen electrode with saturated potassium chloride bridge gave an accurate measure of the hydrogen-ion activity. The discussion in another paper²³ indicates that this cannot be true with varying acid concentration, but that it is probably true with varying sucrose concentration. However, this must be recognized as an assumption with some theoretical justification. Without it, the measurements of sucrose inversion are worthless as a test of theories of the mechanism of reaction.

Fales and Morrell²⁰ claim that the reaction speed is not exactly proportional to the hydrogen-ion activity with varying acid concentration. Their results can be explained by the error in the determination of the hydrogen-ion activity and by the theory of Brönsted.

Activity Coefficient of Critical Complex.—If Equations 4a and 4b are correct, the activity coefficient of the critical complex must be taken into account, but it cannot be measured directly and cannot be assumed to be equal to that of the hydrogen ion. It was shown²³ to be probable that the two most important reasons for the change in activity coefficients are the change in the fraction of unhydrated ions and the effect of electrical charges on one another. In the case of a critical complex the first is already taken into account in the activities of the reactants. With varying sucrose concentration the total ionic concentration is probably unchanged, so we will assume that the activity coefficient of the critical complex is constant. This assumption has about the same degree of substantiation as the one that the saturated potassium chloride bridge gives constant liquid-junction potentials with these solutions.

For varying acid concentration the best we can do is to assume that the activity coefficient of the critical complex is the same as that of the potassium and chloride ions, which appear not to be greatly affected by varying water activity but to depend on the changing concentration of ionic charges. Frankly discarding the experimental determinations of hydrogenion activity, and taking the activities of hydrogen ion and of chloride ion in the dilute sucrose solutions as the same as in water solutions of the same molality, we find for the results of Fales and Morrell constants within the variation of their two series from each other, except for the 0.001 N solutions, where the concentration of acid may well be reduced by some side reaction.²⁴ It is not worth while publishing the details with so many approximate assumptions involved.

²³ Scatchard, This Journal, 45, 1716 (1923).

²⁴ A similar treatment of the results of Harned and Pfanstiel [This Journal, 44, 2193 (1922)] on ester hydrolysis gives less constant values than those quoted and explained in their article. This may be due to the uncertainty about the activity of the ester and about the number of water molecules which enter into the reaction.

Equation for Sucrose Inversion.—It is convenient to collect here the definitions of the various symbols.

N= mole fraction; C= concentration in moles per liter; $\Sigma C=$ total moles of all components per liter; a= activity, on a scale such that it is unity for pure water or for solutions without sucrose; f=a/N; $\eta=$ viscosity; x=0.52 at 20° and 25°, 0.55 at 35° and 40°; n= an integer (trial values = 5, 6, 7); subscript wapplies to water, H to hydrogen ion, S to sucrose, and S to the critical complex; S = S to Moran and Lewis.

Since the reaction is unimolecular with respect to sucrose and hydrogen ion and the activity of the sucrose is the only one that changes enough to need consideration, Equation 4b becomes;

$$-dC_{S}/dt = K''/f_{C} \times \Sigma C \times a_{S} \times a_{H} \times a_{W}^{n} = K''/f_{C} \times \Sigma C \times 1/\Sigma C \times f_{S} \times C_{S} \times a_{H} \times a_{W}^{n}$$

$$K'' = f_{C}/(f_{S} \times a_{H} \times a_{W}^{n}).1/C_{S}.dC_{S}/dt = f_{C}/(f_{S} \times a_{H} \times a_{W}^{n}).k$$
(5)

We have assumed that $f_{\mathbb{C}}$ and $f_{\mathbb{S}}$ are constant; by Brönsted's theory we might make the less sweeping assumption that their ratio is constant. By the simple activity theory $f_{\mathbb{C}}$ should be replaced by 1. In any case the ratio may be incorporated in the constant, and we reach a result identical with that of the previous paper.

$$K_{\rm S} = \frac{k}{a_{\rm H} \times a_{\rm W}^n} \tag{6}$$

Other Constants.—Lewis and his co-workers have proposed two constants for this action, which we will designate by the initials of the authors.

$$K_{\rm J+L} = \frac{k}{a_{\rm H} \times C_{\rm W}} \qquad (7) \qquad K_{\rm M+L} = \frac{k \times (C_{\rm W} - 4C_{\rm S}) \times a_{\rm W}^2 \times \eta^2}{a_{\rm H}} \qquad (8)$$

 K_{J+L} differs from K_S only in the replacement of the activity of water by its concentration. It depends upon all the assumptions mentioned above except those concerning the activity of water. It must be rejected, however, unless the activity theory is correct for some substances but not for others.

 $K_{\rm M+L}$ differs in the definition of reaction speed and in assuming that the speed is inversely proportional to η^x . For these solutions $(C_{\rm W}-4C_{\rm S})$ is approximately equal to $a_{\rm w}^{10}$, and η^x to $a_{\rm w}^{-18}$, when all are expressed on such a scale that they are unity for pure water. Then the insertion of these terms makes a difference corresponding to + 10 and - 18, respectively, molecules of water reacting with each molecule of sucrose. Obviously, no conclusions can be drawn regarding the mechanism of the reaction until both of these two factors are settled. $K_{\rm M+L}$ depends upon all the other assumptions that does $K_{\rm S}$.

Experimental Results.—The work of Moran and Lewis with hydrochloric acid as catalyst offers another check of the theory. In calculating the activity of water its activity in $0.1\ N$ hydrochloric acid is taken as 0.9965 (determined from freezing-point measurements). $K_{\rm J+L}$ is 55.55 times as great as the value given in the formula. The values of $K_{\rm M+L}$

are taken directly from the paper of Moran and Lewis and also differ from the value given by the formula by a constant factor, different for each temperature. These differences arise from different units for activities and concentrations, but they can make no difference for a comparison of relative values.

The values of the constants are given in Table I. Table II contains the relative root-mean-square deviations of the experimental values from their averages for both $0.1\ N$ sulfuric and hydrochloric acids, and the last column gives the average of the 4 series. These values are equal, within 1%, to the relative probable error of a single determination, and offer the simplest means of comparing the constancy of the constants.

Examining first the application of my formula to the inversion catalyzed

by hydrochloric acid, it is evident that the constancy is not so good as with sulfuric acid and that all the results show a minimum for medium concentrations. Remembering that the second assumption for determining $a_{\mathbf{w}}$ is more probable than the first, we see that these results confirm those with sulfuric acid in indicating that n is 6, although the possibility that it is 7 is not eliminated.

To compare the three formulas we will take $K_{\rm S}$ for the second assumption with n equal to 6. Of the three formulas, $K_{\rm J+L}$ fits the experimental data best, in spite of the fact that $K_{\rm S}$ contains an arbitrary integer and $K_{\rm M+L}$ an arbitrary non-integral constant, both chosen to give the best agreement with experimental data. The difference between the latter two is small and may be accounted for by the greater flexibility of the arbitrary constant in $K_{\rm M+L}$. It is doubtful if any of the variations exceed the sum of the experimental errors. The experimental results certainly cannot serve as a criterion to choose between the several formulas; this choice must be based on the accuracy and reasonableness of their assumptions. Only after the formula is established can the experiments determine the number of water molecules which react with one molecule of sucrose.

The Hydration of Sucrose.—Moran and Lewis find confirmation of their formula from their conclusion that osmotic-pressure measurements prove that sucrose exists in water solution entirely as a tetrahydrate. I have already discussed the accuracy of the various methods of determining the extent of hydration, the fact that all methods point to decreasing hydrate formation with increasing concentration, and that the most accurate results (from vapor pressures) are best accounted for by the formation of a hexahydrate in accordance with the law of mass action.

The Critical Increment.—Moran and Lewis claim further confirmation of their theory from the fact that it gives probable values of the critical increment, that is values which agree with Lewis's radiation theory. The critical increment is a function of the fraction of reactive molecules. The activity must be a function of the same quantity, whether the nature of that function is correctly derived above or not. It follows that the critical increment cannot be derived from the reaction speed in terms of activities, but must be in terms of concentrations or mole fractions. Since the volume changes very little with the temperature, the difference between these last two is negligible. A detailed discussion of this complicated question is out of place here, but the critical increment, calculated from concentrations or mole fractions, is practically the same for the two theories of the reaction mechanism.

Summary

1. A kinetic interpretation of activity is given which justifies the expression of reaction speed in terms of activities and which demands that the

25 Scatchard, This Journal, 43, 2406 (1921).

speed so expressed be defined as moles transformed in 1 mole of all components.

- 2. This interpretation offers a possible explanation of the salt effect on reaction speed. The expression of Brönsted must be modified for concentrated solutions.
- 3. An analysis of experimental work shows that it is of little value for determining the relation of reaction speed to viscosity. The kinetic theory, however, demands that reaction speed be independent of viscosity.
- 4. These conclusions lead to the formula for the inversion of sucrose previously presented when the concentration of electrolyte is unchanged.
- 5. The experimental measurements cannot serve as a criterion for choice between the various theories of the mechanism of the reaction, for the difference in agreement between the formulas is too small.
- 6. Any interpretation of the experiments depends upon the assumption that the liquid-junction potential with saturated potassium chloride is independent of the sucrose concentration.
- 7. Interpreted by the formula previously presented, the speed of inversion catalyzed by hydrochloric acid adds confirmation that 6 molecules of water react with each molecule of sucrose. The agreement is not quite so good as with sulfuric acid.

THE SEPARATION OF ISOTOPES. APPLICATION OF SYSTEMATIC FRACTIONATION TO MERCURY IN A HIGH-SPEED EVAPORATION-DIFFUSION APPARATUS

By Robert S. Mulliken¹

Received February 9, 1923

Introduction

Important Factors for Rapid Operation of Diffusion Methods.—In the separation of isotopes, the small separating power of the diffusion methods (including evaporation) must be compensated by very rapid operation, if large separations are to be obtained in a reasonable time. The apparatus described below was designed to accomplish this object for mercury. In the course of the work, systematic fractionation as applied to diffusion methods has been rather thoroughly studied.

The most important factors for maximum speed of separation fall into two classes: those of operating speed and those of operating efficiency.²

¹ National Research Fellow in Physical Chemistry.

² By the efficiency of any given operation is meant the ratio of actual separation to the separation obtained under *ideal* conditions. The separation obtainable under ideal conditions by a process either of evaporation or of molecular diffusion, is given by Equations 7, 16 and 19 of a previous paper [(a) Mulliken, This Journal, 44, 1034 (1922)].

These two factors are usually opposed so that a compromise has to be sought. It will be shown later under "Systematic Fractionation" that about the best compromise is obtained, for the present apparatus,³ at such a rate of output D and efficiency E that E^4D is a maximum.

The total rate of output is obviously proportional to the number of operating units, and to the output of each unit. For molecular diffusion the latter is proportional, other things being equal, to the diffusion area and to the permeability of the diffusion membrane. High permeability goes with minimum thickness. In the present apparatus filter paper is used to give maximum permeability.

Efficiency is needed both in each individual operation and in the mode of division and combination of fractions in systematic fractionation. Efficiency of the individual operation depends on the design of the units. The same effect as that of increased efficiency is secured when two different methods of separation can be combined as successive steps in one operation. This principle is used in the present apparatus by the superposition of an efficient molecular diffusion on an inefficient evaporation. Closely related to the efficiency factor is the variation from one element to another, or especially among compounds of a single element, in the degree of separation obtainable in a given operation. The element mercury here used is decidedly unfavorable from this point of view, but is unusually good from the points of view of practicable speed of turn-over, and of general convenience of handling.

Description of Apparatus in Present Form

In the following paragraphs the apparatus as now set up, its operation, and the results obtained will be described. In a later section the subject of systematic fractionation will be discussed.

The method consists essentially in systematically repeated operations in each of which mercury vapor at low pressure (probably about 5 mm.), generated under such conditions that a partial separation of isotopes occurs, is diffused molecularly, giving a further separation. The chief advantage of the method is the relatively very high speed at which it can be operated without great sacrifice of efficiency, combined with the facts that the apparatus requires only tap water for perfect cooling, and that a high vacuum is not needed.

Vacuum System.—The apparatus consists of 6 similar upright units used independently but in cooperation. They are set up on a table and

³ In general, maximum E^3D is a more appropriate criterion.

⁴ See table of separation coefficients, Mulliken and Harkins, This Journal, 44, 55 (1922).

⁵ A set of connected units was at first considered, but was rejected for several reasons, one of which is that in such a set the evaporation effect would be nullified, as far as separation of isotopes is concerned:

each is connected through a 3-way stopcock to 2 vacuum lines, evacuated by a Cenco Hyvac pump. A McLeod gage is used to read the pressure. The units are ordinarily all connected to the same line. Any unit that needs to be repaired or emptied is switched to the other line, and air is admitted. To bring such a unit again into operation, the second line is opened to the pump and the first line shut off. As soon as the unit is evacuated, it is switched to the first line with the other units, and all are again connected to the pump. Several stopcocks are used to make these operations possible. Little trouble was experienced from leakage, especially since an air pressure of 0.2 mm. is as good as the highest vacuum, and even 0.5 mm.

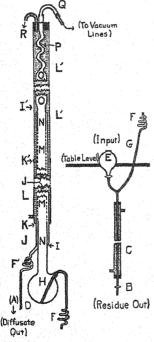

Fig. 1.—Section of type I unit

lowers the efficiency only slightly. There is little or no leakage in the units themselves, so that they can be shut off from the pump for considerable periods.

Design of Units.—The best design for the individual units, as now worked out, is shown in Fig. 1. They are made entirely of Pyrex glass.

In the operation of the apparatus the mercury is evaporated from the 500cc. flask H. A dirty evaporating surface improves the efficiency, as noted in a previous paper.6 The mercury is fed into the evacuated flask from the 100cc, funnel E through the capillary tube G, the highest point of G being about 34 cm. above the stopcock on E. The inner end of tube G touches the bottom of the flask H, so that at the end of a run the entire residue in the flask can be removed except for a few drops. To remove the residue it is necessary to admit into the flask sufficient air pressure to drive the mercury over the highest point in G.7 This is considerably more than 760 mm. above the exit stopcock B, so that a vacuum is automatically produced in the upper part of G if the mercury stops flowing. The flow of cold water in C completely cools the hot mercury on the way out.

The neck N of the flask H is sealed at I inside of a 40 mm. tube J, which is sealed in turn at K inside the 50mm. condenser jacket L. The distance IK, about 7 cm., is required for safety in making the seal I. Cold water flows continually between J and L, leaving by way of the tube R. For purposes of construction and repair, the tube L is in two sections, L and L', which are held together at K' by a thick sealing-wax joint. The tube N is continuous with the filter-paper membrane M, which has a diameter of 30 mm.

⁶ Mulliken, This Journal, 44, 2388 (1922).

⁷ It was originally hoped that the mercury would siphon out without interruption of the vacuum, but in practice the column in G usually breaks. The use of a capillary is to reduce to a minimum the volume of mercury not in action.

and a length of one meter. Moverlaps N for a distance of about 2 cm, at each end, and is fastened with water glass. The tube M is made by rolling a long strip of filter paper (one cross seam being needed if the paper is cut from a large sheet) and sticking the edges together, with a 3mm. overlap, by means of water glass. The paper turns brown on heating where it has been wet with water glass but this does not affect its strength. A number of small pieces of cork are fastened on the surface of the paper membrane to prevent it from coming into contact with the condenser wall.

Mercury vapor flows rapidly through N and M. Part of it diffuses through M, is condensed on the inner walls of J, and gathers into drops which collect in the exit from the inclined seal I. As soon as the height of the mercury in the 3mm. tube F exceeds 760 mm. the mercury flows when A is opened. The coils F reduce danger of breakage, but are perhaps unnecessary; they increase the volume of mercury not in action. The vapor which does not diffuse through M is directly exposed to condensation above I in the 20cm residue condenser O, and falls back into the flask through the stream of rising vapor. The coil P, 15 cm. long, is necessary to complete the condensation, because of the rapid upward motion of the vapor. 10

⁸ Preliminary experiments showed that the rate of diffusion is, for a given evaporation rate, directly proportional to about the 1.3 power of the length, and *inversely* proportional to about the 1.3 power of the diameter. Decrease in diameter or increase in length of the membrane, especially the former, involves increased pressure inside the membrane, which decreases the operating efficiency as well as the life of the membrane, so as to neutralize the value of the increased rate of production. The dimensions given in the text represent a fairly good—doubtless not the best—compromise between speed and efficiency for the paper here used (Whatman No. 5). The best dimensions depend in general on the permeability and efficiency-speed curve (compare Fig. 3) of the paper used. The use of a similar paper half as thick, and so twice as permeable, would double the rate of production. Resistance to heat is an all-important consideration in the choice of paper; that here used was the best of several in that respect, although not the most permeable.

⁹ It was thought that the efficiency could be improved by avoidance of this contact of the diffusion residue with undiffused vapor of different composition. Accordingly, a

type of unit (Type 2) was constructed in which I was made with an annular catch, as shown in Fig. 2, by means of which the diffusion residue was led outside the unit on its way back to the flask. (Samples of the diffusion residue could be removed through suitably placed stopcocks, so that the fraction of vapor diffusing, as well as the separate efficiencies of the diffusion and evaporation processes, could be determined; this could not be done with the Type I unit.) As will be seen from Fig. 3, this type of unit gave a lower efficiency than the simpler Type I unit, except at low rates of evaporation. The most probable explanation of this result is that the falling drops of diffusion residue obtained in Type I units serve a useful function by slowing down and mixing the central core of the rising stream of vapor with the lateral portions, thus improving the diffusion efficiency, and that this beneficial effect more than compensates the bad effect of partial establishment of equilibrium between the condensed diffusate and vapor. Both causes of inefficiency are probably always present in Type I, that of imperfect vapor mixing increasing rapidly with increase in speed of operation, and nearly disappearing at low speeds.

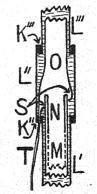

Fig. 2.—Diffusion residue catch of type II unit

10 In constructing a unit, the 96cm. outer condenser tube L is first sealed at K to the inner tube J extending from I' to I. The end I is made with a slant and the en-

The flask H rests directly on a special iron tripod with a cup-shaped piece of Nichrome wire gauze. The tripod for each unit stands in an iron pan (30 x 20 cm.) which rests on a sheet of Transite asbestos wood that extends the length of the table. To secure effective heating without causing the burner to strike back, a rather roomy asbestos hood is built over the flask and tripod, provided with an ample opening at the back for admission of air, and another near the top at the front for the exit of the burner gases. A Transite asbestos board along the front of the table keeps the heat from E, so that the next lot of material for any operation can be kept there.

The units are supported (or guided) by a single clamp placed about at K'. They are easily taken down for repair or replacement by breaking the tubes D and G, and removing the U-shaped piece Q, which is fastened in place with sealing wax. The height of the top of the unit above A and B, which are just above the floor, is about 2.8 meters.

Conditions of Operation.—The most economical evaporation rate is about 450 cc. per hour per unit. This is equal to 36 kg. per hour for the entire 6 units. The rate of diffusion in each unit is then about 70 cc. per hour. Under these conditions the efficiency of the evaporation process¹¹ is about 21%, and that of the diffusion¹² about 80%, the combined efficiency being about 96%. The combined process is outwardly completely analogous to a simple distillation having an efficiency E, which may considerably exceed 100% (but cannot exceed 200%), given by, $E = E_e + E_d((1 - F_d)/F_d) \ln(1/1 - F_d)$. Here F_d is the fraction of the generated vapor which diffuses, and E_d and E_d are the individual efficiencies (compare Ref. 2) of the evaporation and diffusion processes, respectively. 13 The curve (Fig. 3) for Type I unit trance of F is attached to it. The paper tube M is next prepared and cemented at each end to a 16cm. section of 30mm. glass tubing, closed at the outer end which later forms part of the tube N. The paper tube with its glass end-pieces is now placed inside of I. so that each end piece projects for about half its length. The seals are now made at I and I'. The operations of sealing on the section OP, and the flask H are then fairly easily accomplished. L' is attached with sealing wax at the top and bottom and the unit set up. The seals at K, I and I' require very considerable care. A distance of 6-7 cm. from I or I' to the junctions of M with N is sufficient to prevent seriously scorching the paper during the glassblowing.

¹¹ It is thought that the evaporation efficiency cannot be substantially improved at the stated speed of operation (Ref. 6).

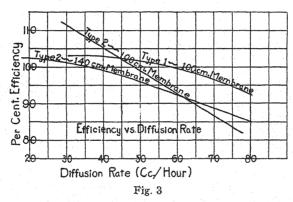

¹² The diffusion efficiency is limited by the two factors referred to in Ref. 9, and also by the fact that the interstices between the fibers of the filter paper are, except at very low rates of evaporation, relatively too large as compared with the mean free path in the vapor (compare Ref. 4 for discussion). This of course varies with the paper used. The effect of back pressure, due to the vapor pressure of mercury at the temperature of the cooling water used, is negligible in all cases.

By using an apparatus somewhat like Type II (Ref. 9), a diffusion efficiency probably approximating 100% was obtained in several of the slower runs, where the pressure of mercury vapor is estimated to have been less than 2 mm. These runs have been used as the basis for a new value of the separation coefficient. This was reported in a previous paper (Ref. 6), and is here used as the basis for all calculations of efficiency.

¹³ The adjustment of F_d is an important problem of design. Low F_d means increased E, but decreased D, and vice versa.

shows the relation of efficiency E to speed D for the present type of unit. 14

With all 6 units operating effectively and continuously, a spread of 0.10 units of atomic weight, with a set of 50cc. fractions at equal intervals of about 0.004 units between —0.05 and +0.05 could be produced in about 80 hours of diffusion. The time required for any spread (so long as complete separation of the individual isotopes is not approached) is about proportional to the cube of the difference between the atomic weights of the extreme fractions, as is shown by a study of the theoretical course of the fractionation. This will make a very slow process of obtaining a large separation, such as one unit of atomic weight. A complete set of intermediate fractions or working stock, of volume and distribution about as described above is necessary in increasing the separation of extreme fractions. Any separation can, however, be readily increased by about

0.05 units by evaporating the final extreme $50 \, \mathrm{cc.}$ fractions to $0.5 \, \mathrm{cc.}$ each in a small apparatus.

The actual number of working hours required for any separation will be about twice or thrice the time of diffusion as given above. This is due to the considerable time needed for repair and replacement of units, to loss of time when the units are not in operation together, to time required

 14 E is determined by determining the relative density of a sample of diffusate and one of residue for a run at the desired speed, and applying Equation 19 (Ref. 2). The difference in their densities is usually about 36 parts per million for 100% efficiency, and can be determined, if desired, to about 2%.

¹⁵ This corresponds to E = 0.92, and a cut (see Ref. 4) of 2 in each operation.

¹⁶ The time required for a given extreme separation is directly proportional to the size of the stock fractions. The minimum practicable size of fraction is determined chiefly by the falling off of efficiency with small volumes, and by the increased heating of the vapor and consequent effect on the life of the membrane. The loss of value by mixing during refilling also becomes increasingly important with small volumes. An improvement in the present apparatus which would permit smaller operating volumes without decrease of speed, would be most valuable.

in starting and stopping the apparatus and in emptying and refilling units, and to low efficiency in operation for various reasons. The last two factors are particularly important in the case of the light fractions; a given amount of progress takes about 50% longer for them than for the heavy fractions. To avoid loss of time by too frequent replacement of units, the diffusion rate should not be allowed to exceed about 70 cc. per hour for any considerable period (a much lower speed limit is necessary at *small volumes*; compare Ref. 19), as the life of the membrane is limited by the temperature to which it is subjected. The actual rate of progress is lowered very little if the diffusion rate falls as low as 60 cc. per hour, since the increased efficiency nearly compensates the decreased production rate, the E^4D curve being nearly flat for some distance near its maximum.

Method of Operation and Accounting System.—In filling a unit at the beginning of a run, the lightest fraction of sufficient size previously produced is introduced into the apparatus. As the diffusion proceeds, the density of the residue in the flask increases. Previously produced fractions of progressively increasing density are successively introduced at appropriate times, while the diffusate is removed in successive fractions equal in volume to about 30% of the flask contents (but compare below). The process continues until after the last of the earlier series of fractions has been introduced, and the residue in the flask has become too small for efficient operation. Air is then admitted to expel the residue through G. The unit can be emptied, re-evacuated and refilled in 30 minutes under favorable conditions. With each repetition of such a series of operations the lightest and densest fractions produced become more widely separated. At a given time the different units are in general at different states in their passage through the series.

An essential part of the operation is a method for rapidly calculating and recording the composition of each fraction as it is produced, for keeping account of the volume and composition of the material in the units, and for calculating the proper times to add more material. This last is done whenever the composition of a previously produced fraction is identical with that of the contents of a unit, except that the contents of a unit at any time is limited to 300–350 cc., or unless it is desired to reduce the volume of the contents before emptying a unit and starting on the retreatment of a lighter fraction. A pad of record sheets is kept on a

¹⁷ Efficiency is lost (1) by mixing of partly separated fractions (a) whenever the diffusion rate changes suddenly, as when the air pressure suddenly rises, (b) in the normal procedure of combining fractions on the shelves if they differ by less than 6 parts per million, (c) whenever a unit is emptied and refilled (about 2 cc. of diffusate and diffusion residue remains on condenser walls, etc., and a little in the flask); (2) when the volume in the flask is less than 150 cc. (See Ref. 19). Effects 1c and 2 influence the light more often than the heavy fractions.

¹⁸ The reconstruction of a unit with a new membrane takes about 20 hours.

small shelf projecting from the front of each unit, and on this the "credits." "debits" and "balance," both volume and composition, are recorded. For rapid calculation of the composition of any diffused fraction, a table has been prepared showing the decrease in density of the diffusate over a range of efficiency of 72-110%, and over a range of the fraction of the balance diffused of 0-62%. In order to determine the composition of a given diffused fraction its volume is measured and divided by that of the previous balance to give the proportion diffused; the diffusion rate is calculated from the time, and the efficiency is then read from a previously determined plot (like those in Fig. 3) of efficiency against speed for that unit;19 the density change (decrease) is recorded, and to it is added the composition figure (expressed as parts per million of density greater or less than that of ordinary mercury); the product is then transferred to a properly labeled bottle on a storage shelf. The change of density of the residue is read from another chart on which efficiency is plotted against diffused fraction, and the density and volume of the residue (balance) in the flask are recorded. The volume and density of the fraction newly added are at the same time recorded, together with the resulting new balance. The volume which must diffuse, in order to bring the contents of the flask to the composition of the next lightest fraction on the storage shelf, is then calculated, and diffusion allowed to proceed to this point, when the fraction in question is added, the diffusate removed, and the calculations described above are repeated. To avoid indefinite subdivision of fractions, any two fractions on the shelves differing by 6 parts per million or less are combined to give a single fraction. This means no great loss since the value of a separation between two fractions is proportional to the square of that separation (see Systematic Fractionation), and since a separation of about 35 p. p. m. between diffusate and residue is produced in normal operation. Similarly there is no great loss in value (only 1.3%) in the collection together of diffused fractions totaling as much as 30% of

¹⁹ The efficiency curve should be the same for all units of the same type. If the curve for that type has been determined, it is necessary only to determine 2 or 3 points for each new unit, to make certain that the unit has no defect or unusual characteristic. This can be done rapidly by comparing the densities of a diffusate and residue for each of 2 or 3 rates of diffusion. It is also necessary to check occasionally the results obtained with each unit to make sure that it is still in good condition.

The efficiency of a unit at any speed is lower, and the vapor temperature much higher, when the flask contains less than 100 cc.; the efficiency drop is roughly 2% at 100 cc. and 5% at 50 cc. Low volumes occur mostly with fractions near the extremes, thus increasing difficulties there.

High pressure (more than about 0.5 mm.) increases the fraction which diffuses. The loss in efficiency under such conditions is about the same as if the increased diffusion rate were due to an increase in the evaporation rate. (High pressure may be caused by air admitted accidentally through the stopcock below E, after a fraction has been added, or by breakage or leakage in the apparatus, etc.)

the previous balance (cut = 10/7), although the first and last portions of such a fraction differ in density by 10 p. p. m. The corresponding figures for a 50% fraction (cut of 2) are 4.0% loss, and 22 p. p. m. A great number of very small fractions would require an impossible amount of attention from the operator. The number of fractions removed per hour, at 70 cc. per hour per unit, is 6×70 divided by Q_d , or $420/Q_d$, where Q_d is the average size of the fractions as removed. The work of taking 10 fractions per hour, inspection of the apparatus, and occasionally emptying and refilling a unit, is enough to keep one man busy. When a unit is refilled, allowance has to be made, in recording the composition of the first fraction added, for the fact that about 2 cc. of the previous contents still remains in the units, chiefly adhering to the condenser walls.

Except in the early stages of operation, the best method is, all things considered, to make a series of cuts of 2, that is, diffusion of 50% of the flask contents between refillings. The changes of composition are thus equal and opposite for the two fractions produced in each stage of the operation. This method has the advantage of ease of arithmetical calculation; it involves the handling of a minimum number of fractions, and requires *no* mixing of fractions of differing composition except as a result of irregularities in operation. 20

Results.—The work up to the present has been largely of a preliminary nature, but the features of design and operation have now been so far developed that additional radical changes are not to be anticipated. It seems desirable, therefore, to describe the method and apparatus at this time, as considerable time will be required to effect a large separation. The present preliminary separation, 0.01016 units of atomic weight on 22cc. (300g.) samples, was obtained in a few weeks of irregular operation with an incomplete set of units.²¹

Systematic Fractionation

A detailed study of systematic fractionation was found to be of prime importance in the design and operation of the apparatus. The most important results, given below, are applicable not only to the present

 20 These factors are enough to offset the slightly greater loss of diffusion value during collection, and the 17% greater capital stock required, as compared with the use of 30% fractions. The advantage of the use of 30% fractions in regard to amount of stock needed can be obtained only by constantly mixing fractions. The separation into 50% fractions involves a higher average flask-content, and so a somewhat higher efficiency, than the use of 30% fractions for operation at a fixed minimum volume of the residue.

²¹ The extreme samples consist of 22 cc. of material for which $\Delta M = +0.00504$ and 22 cc. for which it is -0.00512. The best result previously reported is that of Brönsted and Hevesy [Z. physik. Chem., 99, 189 (1921) and Phil. Mag., 43, 31 (1922)] who obtained 0.2 cc., $\Delta M = +0.0046$, and 0.3 cc., $\Delta M = -0.0052$. A far greater quantity has therefore been obtained in the present work although the quality of separation obtained in the two researches is about the same.

special method, but to all methods of the diffusion type (including evaporation).

Suppose a symmetrical fractionation procedure to be used for the division of an initially homogeneous sample into a set of fractions, all of size Q_0 , spaced at equal ΔM intervals on both sides of the initial composition (atomic weight) M_0 . The simplest procedure would consist of a series of individual or *unit* operations, in each of which a fraction of size $2Q_0$, and composition M, is divided into two fractions of size Q_0 and composition $M = EB \ln 2$. It can be shown by a study of the fractionation procedure, that when the first n-1 pairs of fractions have already been produced, a total of n^2 additional unit operations will be required to produce the n^{th} pair of fractions without permanently using up or increasing in size any of the previously produced fractions. The corresponding time expended in producing the n^{th} pair is evidently $t_n = n^2(Q_0/D)$, where D = dQ/dt, the rate of diffusion (or, in general, of production) of the light fraction.

Since
$$\Delta M = \pm nEB \ln 2$$
, (1)

$$t_n = (\Delta M)^2 Q_0 / DE^2 B^2 (\ln 2)^2,$$
 (2)

The time required to produce a pair of extreme fractions (or as can be shown, one of these) is thus proportional to the *square* of the difference between its composition and that of the original raw material, and *inversely* to the *squares* of the efficiency and of the separation coefficient. It can be shown that the same proportionalities hold for any type of fractionation procedure.

Since in the production of extreme fractions, intermediate fractions of sufficient size for efficient operation must be maintained (except as noted below) the time of production of any extreme fraction should be taken to include the total time of production of all intermediate fractions. Evidently,

$$t = t_1 + t_2 + \dots + t_n = (1^2 + 2^2 + 3^2 + \dots + n^2)(Q_0/D) = n(n+1)$$

$$(2n+1)(Q_0/6D)$$
(3)

This equation can be used to calculate the operating time required to obtain any given fraction of composition ΔM , if the corresponding value of n is calculated from Equation 1. The actual working time required will be about three times this. For n=1, t_n has the value n^3Q_0/D ; for n=5, 0.44 n^3Q_0/D ; for n=10, 0.38 n^3Q_0/D ; for $n=\infty$, $n^3Q_0/3D$. Approximately, then, t is proportional to n^3 , except for the smallest values of n. Then, approximately, from Equation 1 and the relation just deduced, t=K $(\Delta M)^3$ Q_0/DE^3B^3 (4).

Equation 4 contains a great deal of information. The other factors being constant, in each case, it shows (1) the rapidly increasing difficulty of increasing ΔM , even by systematic fractionation, which is the most rapid way of applying any method of the diffusion type; (2) the great

effect of the value of B (which depends on the element or compound used) on the possibility of obtaining a large separation ΔM in a moderate time; ²² (3) the importance of using a method and apparatus which can deal with small intermediate fractions (Q_0) , yet operate at high speed (D). ²³ Equation 4 also yields a criterion for the relative importance of speed, minimum operating volume (Q_0) and efficiency. Evidently for a given $\Delta M/B$, t will be a minimum if DE^3/Q_0 is a maximum. This criterion is of great value in both the design and the operation of any apparatus of the diffusion or of an analogous type. It was very useful in the development of the present apparatus.

The effect of the method of fractionation is not indicated by Equation 4, which was, in fact, developed above on the basis of a specific method consisting in a series of cuts of 2. It has already been stated, however, that, taking into account all practical factors, such a method of fractionation is probably more rapid than any other, and it is certain that no other fractionation procedure can have more than slight superiority. Equation 4 also does not take into account the possibility of using more than one type of apparatus in a single separation, that is, a rapid apparatus (one with large D) with large Q_0 in the earlier stages, and a slower, but also smaller, apparatus for the final stages. By such a method ΔM may be increased in a moderate time by a quite appreciable, although limited, amount with small quantities of material, the possible increase being proportional to B. In applying the criterion of the previous paragraph, the factors Q_0 , E and D must be considered in relation to the amount of time required for repairs and reconstruction and in emptying and refilling the apparatus, and in relation to losses by mixing unlike fractions, such as occur especially at refilling operations, in which complete removal of previous contents is impossible. It may be noted that the heavy fractions are here, and usually, somewhat easier to separate than are the light fractions, because of the more frequent emptying and refilling required by the latter,24 and for other reasons already noted. Although it is best to develop both fractions in equal amounts, either may be developed alone. In this case at least half the starting material must go into fractions which are left untouched after one or two operations.

Equation 2 or 4 may be made the basis of a criterion for the value of isotopic samples. The value of a fraction or set of fractions may perhaps best be considered as proportional to the time expended in producing it under standard, optimum, conditions of operation. On this basis, from Equation 2, the value of any individual fraction in a set of fractions may be defined as $V = (\Delta M)^2 Q$. V, thus defined, is an additive function.

²² Note that B varies with ΔM , causing a progressive decrease in the separation as it approaches completion. Also see Ref. 4.

²³ The tendency is, of course, for E and D to fall with Q_0 .

²⁴ This involves increased time and increased loss during mixing.

From a somewhat different point of view, which is particularly applicable to the *extreme* fractions, the value of an extreme fraction may be defined, ²⁵ on the basis of Equation 4, as $V' = (\Delta M)^3 Q$. Really, $V' = C \Sigma V$, the summation being taken over all fractions in a complete set up to and including the extreme fraction to which it is desired to assign a value, in the case of a symmetrical fractionation.

Results of the application of the first of the above definitions to a study of the loss of value by the collection of fractions of 30% or 50%, and by mixing separated fractions, have already been indicated. The loss of value when two samples of respective compositions $M + \Delta_1 M$, and $M + \Delta_2 M$, and quantities Q_1 and Q_2 , are mixed, is readily shown to be $-\Delta V = (\Delta_1 M - \Delta_2 M)^2 Q_1 Q_2 / (Q_2 + Q_2)$. This equation also holds for the gain of value when two separated fractions of different composition are produced from a single uniform sample.

In conclusion, the writer wishes to express his appreciation of the assistance of Mr. B. R. Mortimer in the operation of the apparatus, and of Mr. F. A. Jenkins in the purification of the mercury. The further operation and development of the apparatus will be in the hands of Mr. Mortimer and Professor W. D. Harkins.

Summary

- 1. An apparatus is described for the rapid partial separation of mercury into isotopes by a combined process of distillation and molecular diffusion, at low pressure, the latter process being the major factor in the separation. The diffusion membrane in each unit consists of a tube of filter paper 1 meter long, this material being selected primarily because of its thinness.
- 2. The operation of the apparatus is carried on as a systematic fractionation, in which 6 units are used independently. A set of connected units was considered, but rejected for several reasons.
- 3. Preliminary operation of the apparatus has given a separation of 0.102 units of atomic weight between extreme fractions of 22 cc. A separation of 0.3 units with 50 cc. fractions should be obtained in a year of steady work.
- 4. The method by which the new value 0.0063 for the separation coefficient of mercury was obtained is described in connection with the preliminary studies on the design of the apparatus.
- 5. Systematic fractionation requires the maintenance of a permanent stock of intermediate fractions, of some minimum size Q_0 , in order to extend the range of a separation. A thorough study of the course of systematic fractionation has yielded valuable results which are applicable to all methods of separation by diffusion or in an analogous manner.
- ²⁵ Aston ["Isotopes," Edward Arnold and Co., London, 1922, p. 139] has proposed the use of what is approximately $(\Delta M)Q$ as a measure of value; this has the disadvantage of not reflecting fully the difficulty of increasing ΔM .

The simple and symmetrical method of fractionation in which a cut of 2 is made in each individual operation is probably the most rapid for practical operation.

The time required for the production of any fraction, after the necessary preliminary or intermediate fractions have been produced, is given by the formula $t = C(\Delta M)^2 Q_0/DE^2B^2$, where E is the "efficiency," B the separation coefficient, D the rate of production of the light fraction, and C a constant. This serves to establish a criterion for the value (V) of any fraction, which may be defined as, $V = (\Delta M)^2 Q$. This criterion is applied to the calculation of loss of value by mixing, etc.

The time required for the production of any extreme fraction, taking into account the total time used in building up the intermediates, is given by $t = C'(\Delta M)^3 Q_0/DE^3 B^3$. Study of this equation shows the difficulty of obtaining large values of ΔM , especially if B is low. It also shows the relative importance of Q_0 , D and E, and this relation, somewhat modified by other practical considerations, was used in the design, and is also used in the operation, of the present apparatus. The optimum speed of operation is shown to be that for which $E^{3\cdot 5}D$ or E^4D is a maximum. The equation above can also be used as a basis for a criterion of value for extreme fractions, namely, $V' = (\Delta M)^3 Q$.

6. The approximate proportionality of the time required for a given separation to the *cube* of the degree of separation shows that while considerable separations can be effected by systematic fractionation, nothing approaching complete separation can be expected by methods of the diffusion type, unless in the most favorable cases and by factory-scale operation. It may be stated further that there seems to be little prospect that any other method or methods yet proposed will prove greatly superior to those of evaporation and molecular diffusion, although the centrifugal method may prove useful, especially for the elements of higher atomic weight.²⁶ For any particular element, the most favorable method depends greatly on the nature of the substance.

CHICAGO, ILLINOIS

²⁶ An ingenious method recently proposed by Hertz [Physik. Z., 23, 433 (1922)], while apparently very attractive in making possible an almost indefinitely large separation in one operation, can do so only at a rate of production that can be shown to decrease exponentially as the separation ΔM increases linearly. This, together with the relatively unfavorable ratio (Ref. 2, p. 1051) of the diffusion constants for gaseous, as compared with molecular diffusion, makes the apparent great superiority of the Hertz method extremely doubtful. The question reduces essentially to one of speed of production. The possibility of controlling the ΔM obtained in a single operation is however, certainly an advantage, as it gives a possibility of cutting down the volume of the intermediate fractions.

THE SYNTHESIS OF AMMONIA FROM ITS ELEMENTS IN THE LOW-VOLTAGE ARC1

By H. H. STORCH AND A. R. OLSON Received March 16, 1923

Heidemann² reported the synthesis of ammonia from its elements as being initiated by electrons of a velocity corresponding to more than 2 volts, and less than the ionization potential of either gas. His papers contain little or no description of apparatus, and practically no data.

Subsequently Andersen³ studied the rate of reaction at various applied voltages. His plot of the change in pressure per unit of time against the accelerating voltage

led him to the conclusion that the reaction did not commence until the ionizing potential (about 17 volts) of nitrogen was reached. Andersen's curves were of a wave type, the maxima and minima rising with increasing voltage. The distance between adjacent maxima or minima was 4–7 volts. No explanation of the shape of these curves was given beyond the vague suggestion that this might be due to some auxiliary resonance phenomenon.

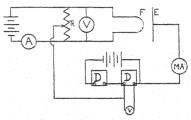

Fig. 1.—Electrical set-up

Andersen made no attempt to correct his voltages for the drop in potential along the tungsten filament used as a source of electrons. These drops were comparatively great, varying from 8 to 14 volts, and the corrections would, therefore, be of the order of magnitude of several volts.

In view of the unsatisfactory state of this problem, it seemed desirable to duplicate Andersen's apparatus, and attempt to find an explanation of the curves he obtained, using, however, much smaller potential drops across the cathode, and applying the accelerating potential at the center of the filament. The latter was done, as shown in Fig. 1, by applying the accelerating potential at the center of a resistance which was connected in parallel with the filament.

Experiments with an Apparatus Similar to that Employed by Andersen

The reaction chamber of the preliminary experiments was practically identical with that employed by Andersen.

It consisted of an 800cc. bulb into which were sealed 2 platinum plates to serve as anodes, and a tungsten filament acting as the source of electrons. Each anode was 1.5 sq. cm. in area, and the diameter and length of the filament were 0.050 and 2.5 cm., respectively. The filament was situated midway between the 2 platinum plates which were 1.5 cm. apart, thus making the distance between the cathode and anode 0.75 cm.

¹ This paper was constructed from a thesis presented by H. H. Storch to the Faculty of the Graduate School of the University of California in May, 1923, in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

² Heidemann, Chem.-Ztg., 45, 1073 (1921); 46, 97 (1922).

³ Andersen, Z. Physik, 10, 54 (1922).

The total volume of the apparatus, including the McLeod gage and connections to the mercury vacuum pump, was approximately 1500 cc. A side tube containing 1 cc. of 98% sulfuric acid was attached to the bulb.

The electrical set-up is shown in Fig. 1. The voltmeters are designated by the letter V; A is an ammeter; MA a milliammeter; R is a 2000hm resistance; F represents the filament, and E the 2 anodes. The accelerating voltage was obtained from 4 sets of small lead storage cells, each set giving 50 volts, the 4 sets being connected in parallel. These batteries were short circuited through 2 dial resistance boxes (D, D), the sum of whose resistance was kept constant at 10,000 ohms. The accelerating voltage was controlled by connecting the tube electrodes to one of the dial resistance boxes, as a shunt circuit. The heating current for the filament was supplied by 2 sets of 5 Edison cells connected in parallel.

The hydrogen was obtained by the electrolysis of 10% potassium hydroxide solution, and was freed from oxygen by passage through a tube containing platinized asbestos. The nitrogen was prepared by removing the oxygen from air with alkaline pyrogallol. The gases were led into a mixing chamber and stored there over water. Before being admitted to the reaction chamber, the gas mixture was passed through a tube containing a glowing platinum wire, and through phosphorus pentoxide. The gas mixtures so prepared were found by analysis to contain only traces of oxygen, and no combustible gases other than hydrogen could be detected by the regular method of gas analysis.

The bulb was thoroughly "baked" and evacuated until the McLeod gage indicated a pressure of less than 10^{-4} mm. of mercury. The gas mixture (20% of hydrogen to 80% of nitrogen was used in this tube) was then admitted up to the desired pressure. Only one pressure was employed throughout, namely, about 0.17 mm. of mercury. The filament was kept at the temperature necessary to give a tube current (between E and F) of 0.6 milliampere at the particular voltage to be used in the determination. After having ascertained by pressure readings at 5-minute intervals that the pressure was not changing within the limits of the experimental error of reading the gage (which was $\pm 0\,0005\,\mathrm{mm}$. of mercury at 0.17 mm. total pressure), the accelerating voltage was turned on and the drop in pressure in 5 minutes was observed. The residual gas was then pumped out, and more of the original mixture admitted, the pressure being adjusted to within a few per cent. of that in the previous determination. The tube current was kept constant at 0.6 milliampere for all determinations.

Blank tests were, of course, made, using the separate gases at pressures corresponding to the partial pressures of the gases in the mixture. The changes in the pressure in the pure gases were found to be negligible, being only 1 to 3 times the error of reading the McLeod gage.

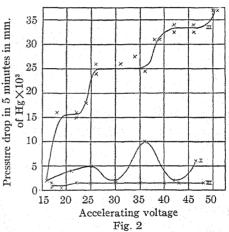

It was soon discovered that there are two phenomena which must be carefully considered in the interpretation of pressure drops in vacuum tubes containing a mixture of nitrogen and hydrogen, metallic electrodes and hot tungsten filaments. First, cold metals such as tungsten, copper, and especially nickel or platinum, will adsorb active hydrogen (produced by the hot tungsten wire) with great rapidity until the metal surfaces are in equilibrium with the partial pressure of active hydrogen present in the tube. Second, the efficiency of the absorption of ammonia by a sulfuric acid surface of small area is very low as compared with its absorption by the large surfaces of the glass walls of the vacuum tube, these surfaces being coated with an adsorbed film of sulfuric acid. Thus it was found that the sulfuric acid tube could be sealed off, and for a short

time the reaction rates observed were almost as great as with the sulfuric acid tube on.

It was further ascertained that wave curves of the type given by Andersen could be readily obtained when the glass surfaces were allowed to become saturated or nearly saturated with ammonia. This phenomenon will be referred to as the "fatigue" factor. For example, Curve I of Fig. 2 is of a wave type, and was obtained by measuring the change in pressure in 2 minutes at 17, 21, 25, 30, 36, 42 and 46 volts without evacuating the bulb after each determination. The observations were limited to 2 minutes and taken every 4 to 6 volts in order to avoid appreciable change in composition of the gas mixture. The drop in pressure for 5 minutes was calculated and plotted against the voltage.

When, however, the glass walls of the bulb were reheated, and the apparatus was thoroughly evacuated after each rate determination, the data

indicated, as shown in Curve II of Fig. 2, that the rates were approximately constant for given voltage intervals, and that abrupt increases occurred at specific voltages. Hence, the explanation of the wave type of curve obtained by Andersen is obviously that the fatigue factor distorted what would otherwise have been a "step-like" curve. In the type of apparatus employed by Andersen the fatigue factor was found to be too rapid in its action to admit of any accurate determina-

tion of the voltage intervals corresponding to the sudden increases in reaction rate. Thus the individual points of Curve II were not accurately reproducible and, as will be shown later, the fatigue effect blurred out most of the breaks that exist in the region between 20 and 50 volts. Although a smooth curve approximately quadratic would fit the observations represented in Curve II, the results of later work made it seem more reasonable to draw the curve as shown. Curve III of Fig. 2 shows the pressure changes in the separate gases at various voltages.

The following facts were also established in the preliminary experiments. Positive tests for ammonia with Nessler's reagent were obtained at as low a voltage as was necessary to start an arc in the tube. With the distance between the filament and the platinum anodes at 0.75 mm., this voltage was usually 18 volts, but it was occasionally possible, by jarring the tube slightly, to start an arc at 16 volts, and obtain a satisfactory positive test

for ammonia at this voltage. At voltages lower than 16–18 volts the pressure drops taken over periods of 2 minutes were found to be of the order of magnitude of those observed in the separate gases, and the tests for ammonia with Nessler's reagent were negative.

At the beginning of the preliminary experiments the tungsten filament was 0.050 cm. in diameter, but it gradually became thinner due to the spluttering and evaporation of tungsten. At the same time it was noted that the rate of the reaction at a given voltage increased slowly with the time. The possibility of a direct connection between these two observations led to an investigation of the effect of the diameter of the filament on the reaction rate. The results obtained are summarized in Table I. The 5 experiments were made with the same apparatus (similar to that used by Andersen, and as described above), but a different filament was employed for each experiment.

Table I

Variation of Rate of Reaction with the Diameter and Temperature of the Filament at Constant Pressure

Pressure, 0.17 mm. of Hg; tube current, 0.6 milliampere; voltage, 18 volts.

E	xpt.	Diam. of filament Cm.	Length of filament Cm.	Potential drop across filament Volts	Current through filament Amperes	Pressure drop in 5 minutes Mm. of Hg
	1	0.050	5.0	3.50	13.0	0.005
	2.	.030	6.25	3.95	4.9	.008
	3	.030	3.13	2.45	6.5	.008
	4	.0125	3.13	4.00	1.0	.010
	5	.005	2.5	5.32	0.55	.013

It will be observed that the thinner filaments gave the higher rates of reaction. That this was not due to the higher temperature of the thinner wires is proved by comparing Expts. 2 and 3. In No. 3 the filament was hotter than in No. 2, but of the same diameter, and the reaction rates are identical. The explanation of these observations is probably that the potential gradient in the arc is very steep near the cathode, and hence the electrons acquire most of their energy at a very short distance from the filament, thus causing most of the ammonia to be formed in this region. The diameter of the wire, therefore, would largely determine the chance which an ammonia molecule has to escape decomposition by the hot filament, and in this way control the rate of the reaction.

In these experiments with excess of nitrogen (4 to 1) the total drop in pressure at any given voltage (above that necessary to start the arc) was much greater than could be accounted for by the complete removal of the hydrogen introduced for the experiment. This was due to the fact that the platinum anodes provided an additional supply of hydrogen by giving up their adsorbed hydrogen during the course of the reaction. Thus it was found that when a tube was used in which a mercury surface

was the anode (see below), the total pressure drop was identical with that calculated from the composition of the gas mixture.

Experiments with a Mercury Anode and a Glass Wool Surface

The chief difficulties encountered in the type of apparatus similar to that used by Andersen were: (1) the fatigue of the absorption mechanism was rapid; (2) the quantities of hydrogen absorbed by the platinum anodes were relatively large, and hence the equilibration of the anodes before each determination was a very necessary and tedious procedure.

The apparatus shown in Fig. 3 was designed to eliminate both of these objections.

As indicated in the diagram, the mercury level (F) which served as the anode could be raised or lowered at will, thus making it possible to vary the distance between the electrodes without reconstructing the apparatus. The U-shaped filament is drawn in perspective to indicate its shape; the plane determined by the sides of the U was parallel to the mercury surface. The space A was filled with glass wool, in order to increase the adsorption surface and thus reduce the fatigue effect. The side tube E contained 1 to 2 cc. of 98% sulfuric acid. A condenser was attached below the reaction chamber in order to keep the temperature of the mercury constant. A 500cc. bulb was sealed into the line, in order to bring the total volume of the apparatus up to 1500 cc.

The clean-up of nitrogen during a 5- or 10-minute interval was found to be very small compared with the pressure drops in the gas mixture. (See similar data in Table V for a later apparatus.) The adsorption of hydrogen by the metal parts in this tube was very low, being practically within the experimental error of reading the gage. The other difficulty, namely, the fatigue effect, was, however, not entirely eliminated.

Before beginning the rate determinations the tube was thoroughly baked and evacuated as before, but it was found impossible to remove the adsorbed gas completely from the glass wool. However, after a few hours'

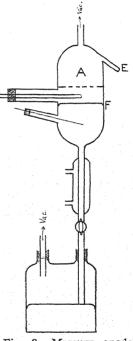

Fig. 3.—Mercury anode apparatus

baking and pumping it was found that the glass wool no longer gave off any measurable quantity of gas during the course of several hours with 0.17 mm. of mercury pressure of the gaseous mixture in the tube.

The procedure used in making the rate determinations was the same as that outlined above for the first apparatus, except that a greater tube current, namely 1 milliampere, was used. In this latter apparatus the filament was 0.0125 cm. in diameter, and 1.25 cm. long.

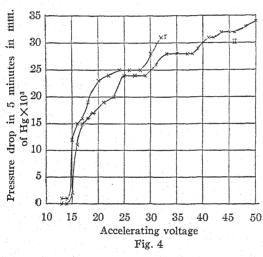

As shown in Table II, the rate of reaction at 18 volts, with the electrodes 4 mm. apart, and with no sulfuric acid present, was found to be only 1/3 as great as the rate with the sulfuric acid present. The glass wool was not in contact with the liquid sulfuric acid.

Table II Adsorption of Ammonia by the Glass Wool Surface

Electrodes 4 mm. apart. Composition of gas: H₂, 32%; N₂, 68%. Initial pressure, 0.170 mm. of Hg; 18 volts accelerating voltage; tube current, 1.0 milliampere.

	Pressure drop	Filament			
	in 5 minutes Mm. of Hg.	Voltage Volts	Current Amperes		
No H ₂ SO ₄	0.008	1.50	2.70		
With H2SO4	.024	1.47	2.65		

Since in this tube the clean-up of the separate gases was found to be negligible during a 5-minute interval, it follows from the data of Table II and the observations made with the first apparatus that the mechanism of the absorption of ammonia is 3-fold, namely, (1) adsorption by the glass surfaces; (2) reaction with the sulfuric acid adsorbed on the glass surfaces; (3) reaction with the sulfuric acid surface itself.

The results obtained with this tube are sketched in Fig. 4. Curve I represents the data obtained with a 14.3-85.7% mixture of hvdrogen and nitrogen and Curve II those with a 32-68% mixture. With the electrodes 3 mm. apart it was possible to start the arc at 15 volts, and a satisfactory positive test for ammonia was obtained at this 50 voltage. With the electrodes 7 mm. apart the arc could not be started below

18 volts, and a negative test for ammonia was obtained below 18 volts. Hence, it seems that the formation of ammonia does not occur to any appreciable extent unless an arc is present.

A comparison of Curves I and II of Fig. 4 shows that the rate of the reaction is greater for a lower hydrogen content, which is in accord with the results obtained by Andersen. Curve II clearly indicates that the rate of ammonia formation remains approximately constant for definite voltage intervals, and increases abruptly at certain voltages. The individual points of this curve were not reproducible, but the general shape of the curve could be fairly well duplicated.

The individual points of the curves in Fig. 4 were not reproducible largely because of the fatigue effect. Reheating the glass wool after each determination caused erratic results because the glass surfaces could never be freed entirely of their adsorbed gases. Hence the curves of Fig. 4

were obtained by allowing the glass wool to become fatigued, that is, by not reheating after each determination. The fatigue factor was, however, slow enough in its action to prevent distortion into the wave type of curve.

Experiments with a Copper Gauze Anode, Using a Liquid-air Bath to Remove the Ammonia Gas

To avoid the fatigue factor it was decided to construct a discharge tube that could be entirely immersed in a liquid-air bath, so as to freeze the ammonia as fast as it was formed, thus making it possible to abandon the use of glass surfaces and sulfuric acid as the absorption device.

The apparatus consisted of a small tube containing a copper gauze anode and the tungsten filament. The tube was 2.5 cm. in diameter and 10 cm. long. The anode was made of 1 mm. mesh copper gauze, was cylindrical in shape, and was 8 cm. long. The tungsten filament was 0.0125 cm. in diameter and 1.25 cm. long. The distance from the center of the filament to the anode was approximately 10 mm. The total volume of the apparatus, including the McLeod gage, and a 750cc. bulb, was approximately 1500 cc. The tube containing the electrodes was completely immersed in liquid air during the rate determinations.

The copper anode was found to adsorb comparatively little hydrogen, but it was noted that the amount taken up was considerably greater than in the previous tube containing a mercury anode. As in the case of the first tube containing platinum anodes, the total pressure drop in this last tube was considerably greater than that calculated from the composition of the gas mixture, thus confirming the explanation of this phenomenon, given in a previous paragraph.

The pressure drops observed in the separate gases are given in Table III. It will be observed that the drops at the various voltages up to 50 volts are practically identical. This proves that the increases in rate observed with the mixture of the 2 gases were not due to abrupt increases in the adsorption of hydrogen by the metal and glass surfaces of the discharge tube, nor in the clean-up of nitrogen by the hot tungsten filament.

TABLE III

BLANK TESTS WITH THE SEPARATE GASES AT VARIOUS VOLTAGES, AT CONSTANT TUBE
CURRENT

Current, 1 milliampere; distance between electrodes, 10 mm.; diameter and length of filament, 0.0125 cm. and 1.25 cm., respectively.

	1	VITROGEN		
Initial pressure Mm. of Hg	Pressure drop in 5 minutes Mm. of Hg	Accelerating voltage Volts	Volts Filan	ment——— Amperes
0.104	0.001	20	1.7	1.90
.117	1	30	1.3	1.65
.117	2	41	1.23	1.60
.115	2	52	1.10	1.57
	Ī	Hydrogen		
.065	.002	20	1.23	1.70
.062	2	30	1.15	1.65
.062	2	40	1.10	1.60
.059	2	50	1.08	1.60

It was found necessary to bombard the copper gauze anode for about an hour with a heavy electron current (1 to 3 milliamperes) in a high vacuum before starting the rate determinations. If this precaution was not observed, the apparent rates of reaction were low, and not reproducible. This bombardment should be conducted at room temperature, or preferably at $300-400^{\circ}$, for at the temperature of liquid air the time necessary for the complete removal of all foreign gases from the anode was extraordinarily long.

Table IV gives the results of two series of determinations made with the same filament. The first series shows the rates taken at 1 volt intervals from 20 volts (the arc could not be started below 19 volts in this tube) up to 32 volts, and the second series up to 48 volts. The data were found to be reproducible within the experimental error of reading the pressure gage. These results are graphed in Curve I of Fig. 5. Table V gives a third series of measurements (plotted in Curve II of Fig. 5) up to 32 volts, using a different filament. The results, except for the 20–22 volt points, run uniformly higher than those of Table IV. This is probably to be explained by the variation in the diameters of the filaments, for the filament used in obtaining the data of Table V burned out shortly after the 32-volt determination was made, and hence it was probably thinner

than the filament of Table IV. A comparison of the 2 curves of Fig. 5 shows that the voltages at which the abrupt increases in the rate of the

reaction occur, are accurately reproducible, even when different filaments are employed.

Discussion

The data given in the last two tables indicate that the rate of the reaction, after the arc is once formed, increases abruptly at the following voltages: 23, 26–27, 30–31, 33–34, 37–38, 41–42 and 46. The intervals between these voltages are about 4 volts each. This phenomenon may be characteristic of the reaction, or it may be dependent upon the particular type of apparatus employed. The latter explanation seems improbable because

the data obtained with the mercury anode apparatus also gave a "step-like" curve whose shape was reproducible. Moreover, the work on ionizing and resonance potentials shows that the voltage at which abrupt changes in the slope of current-voltage curves occur are characteristic of the gas employed.

The fact that an arc is essential for an appreciable formation of ammonia to occur makes it probable that ionized hydrogen or nitrogen, or both, are necessary before the reaction will proceed. Indeed, it is possible by various combinations of the critical potentials, observed in ionization tubes, for nitrogen and hydrogen, to account for the abrupt increases in the rates of reaction. Thus the 23-volt point may be due to increased ionization of nitrogen by electrons which have first produced resonance in nitrogen, and then gained sufficient energy to ionize nitrogen. However, these 4-volt points may be due to a critical point which is not directly observed in ionization tubes, such as the dissociation of molecular hydrogen or nitrogen.

In conclusion, therefore, we may state that the explanation of the phenomena presented in this paper must await such further research as a detailed study of the spectrum of the arc in a mixture of nitrogen and hydrogen, and the study of other reactions involving nitrogen or hydrogen.

This work was begun while one of the authors (A. R. O.) was a National Research Fellow in chemistry. We take this opportunity to express our appreciation to the National Research Council.

Summary

A study of the factors which control the rate of formation of ammonia from nitrogen and hydrogen in the low-voltage are yielded the following results.

- 1. The results of the earlier work by Andersen in which a wave type of curve was obtained for the rate of reaction as a function of the accelerating voltage are explained by the preliminary experiments described in this paper. The curve obtained by Andersen was found to be due to a superposition of the curve described in 2 (below), and a "fatigue" factor in the mechanism used for absorbing the ammonia gas.
- 2. The variation of the rate of the reaction, at constant tube current with the accelerating voltage, is such as to give abrupt increases in the rate of the reaction at specific voltages which are about 4 volts apart.
- 3. The formation of ammonia in sufficient quantity to be detected by Nessler's reagent does not occur unless an arc is present.
- 4. The magnitude of the rate at any given voltage, and at constant tube current, depends primarily on the diameter of the hot filament used as the source of electrons.
 - 5. An increased nitrogen content favors a higher rate of reaction.

THE TITRATION OF SOLUTIONS OF PERMANGANATE AND SODIUM ARSENITE

By WILLIAM T. HALL AND CARL E. CARLSON

Received March 19, 1923

The manganese content of iron, steel and other alloys is frequently determined by oxidation to permanganate followed by titration with sodium arsenite solution. It has often been assumed that the titration reaction may be expressed as follows: $2\text{MnO}_4^- + 5\text{HAsO}_3^{--} + 6\text{H}^+ \rightarrow 2\text{Mn}^{++} + 5\text{HAsO}_4^{--} + 3\text{H}_2\text{O}$. This equation assumes oxidation of the tervalent arsenic to the quinquivalent condition and reduction of the permanganate to manganous salt; each atom of maganese furnishes 5 oxidation equivalents and each atom of arsenic requires 2.

In fact, Bussy³ and Moser and Perjatel⁴ have titrated arsenite with permanganate in hydrochloric acid solution and found the above reaction correct. Vanino,⁵ Kuhling,⁶ and Klemenc⁷ have pointed out, however, that the oxidation of the arsenite toward the end of the titration is very slow. The first two have established the fact that the rate of reaction is accelerated by heating the solution nearly to boiling. Lang⁸ has recommended the addition of a little chloride or bromide to hasten the reaction.

Pean de St. Gilles⁹ carrying out the same titration under different conditions obtained a brown precipitate containing manganese probably in the quadrivalent state. Lenssen, ¹⁰ Kessler, ¹¹ and Brauner¹² titrated an arsenite solution with permanganate and found the oxidation of the arsenite complete but the permanganate only reduced to the tervalent manganic condition. This corresponds to a loss by each atom of manganese of 4 oxidation equivalents. On the other hand, Waitz¹³ found that in a sulfuric acid solution the permanganate appeared to lose 4.5 oxidation equivalents.

In the reverse titration of permanganate with arsenite solution Kessler obtained an olive-green solution and each molecule of permanganate appeared to lose 3.5 oxidation equivalents. In the analysis of steel by the Volhard method Deiss¹⁴ found permanganate is reduced to a state intermediate between $\rm Mn_2O_3$ and $\rm MnO_2$. Recently Bose¹⁵ in his

study of the reaction found the manganese reduced only to an average valence of 3.3, and Geloso¹⁶ titrated permanganate in a sulfuric acid solution with arsenite and obtained the same result. He also worked to an emerald-green end-point and determined the acidity limits within which this end-point could be obtained. He found that sulfates of zinc, nickel, aluminum, magnesium and potassium had no effect upon this end-point, but those of manganese and silver did.

In order to overcome the slow rate of reaction between permanganate and arsenite, to eliminate a colored precipitate or solution which obscures the end-point and to complete the reduction of the manganese to the manganous state, several indirect titrations have been proposed. These depend on adding an excess of permanganate and titrating the excess with some reducing agent. For a reducing agent Pean de St. Gilles used a ferrous salt, Vanino and Kano¹⁷ hydrogen peroxide, and Brauner and Klemenc oxalic acid.

This review of the literature on the titration of sodium arsenite and permanganate solutions shows that it is possible under certain conditions to make the reaction take place according to the above equation, but the conditions are certainly different from those that prevail in an ordinary steel analysis. The accelerating effect of an excess of acid might be predicted from the above equation on the basis of the mass-action principle. On the other hand, experience with the iodimetric titration of arsenic indicates that in neutral or alkaline solutions the arsenate anion is more stable than the arsenite anion, but in strongly acid solutions the tervalent arsenic cation appears to be formed easily by reduction of the arsenate anion. Apparently an excess of acid favors the reduction of the manganese to the manganous condition more than it hampers the oxidation of the arsenic, and hydrochloric acid favors the reduction of tervalent and quadrivalent manganese more than sulfuric acid does. The retardation of the reaction in the presence of considerable acid must be due to the difficulty of oxidizing the arsenite in the presence of much acid.

Experimental Part

Inasmuch as most of the previous work has been with solutions containing sulfuric or hydrochloric acid and since in steel analysis nitric acid is most commonly used, it was of interest to study the reaction under conditions more nearly approximating those of procedures in which the sodium arsenite titration has been recommended for titrating the permanganate formed from the manganese in a sample of steel. The problem was first attacked by two students in quantitative analysis who had not had previous experience with the titration and who had practically no knowledge of the literature on this titration.

Mr. A. Cohen prepared a $0.0222\,N$ solution of sodium arsenite. Several portions of this solution were titrated under conditions similar to those obtained in the analysis of steel by the bismuthate method except that all the titrations were made in the permanganate. Upon the addition of

¹⁶ Geloso, Compt. rend., 171, 1145 (1920).

¹⁷ Kano, J. Chem. Soc. Japan, 42, 699 (1921).

permanganate the colorless solutions became vellowish-green, turning to a clear green just before a distinct pink color was obtained by an excess of permanganate. After standing for an hour or more the titrated solutions became a muddy brown and some manganese dioxide was precipitated. The analyses indicated a reduction corresponding to the formation of the compound Mn₂O₃.2MnO, thus agreeing with the work of Waitz. The results varied within about 3% of the total volume of permanganate used and were not sufficiently close to justify the adoption of this titration as a standard method of procedure. Attempts to carry out the titration under the conditions which prevail in the persulfate method for determining manganese, namely, in a solution containing 1.5 N sulfuric acid and 0.03 N nitric acid, resulted in a reduction of permanganate to approximately the dioxide. Experiments were also tried to determine the effect of adding manganous sulfate solution used in the Zimmermann-Reinhardt method for titrating iron. The results were very erratic although in one case a normal reduction of the permanganate was obtained.

Mr. C. F. Schell carried out a series of experiments which are summarized in Table I. No attempt was made to duplicate the conditions prevailing

in steel analysis but the results show the need for carefully specifying the conditions of titration if the sodium arsenite reaction is to continue in favor as a means of determining the amount of permanganate in solution.

Electrometric Titrations

After these preliminary experiments by Cohen and Schell the titration was studied electrometrically. Kelley and his co-workers 18 found that permanganate formed in the analysis of steel can be titrated electrometrically with mercurous nitrate solution and the reduction corresponds to the formation of Mn_4O_7 ($Mn_2O_3.2MnO_2$) in which the average valence of the reduced manganese is 3.5.

An arsenite solution was prepared of the concentration recommended by the American Society of Testing Materials for the routine analysis of steel. It was titrated against an iodine solution which had been standardized against potassium bromate. A permanganate solution was prepared in the usual way and standardized against sodium oxalate. The ratio between the permanganate and the arsenite solution was also checked by indirect titration with hydrogen peroxide. Table II shows the results obtained in the electrometric titration when a solution of 25 cc. of permanganate and 100 cc. of nitric acid, d. 1.13, was titrated with arsenite. A tungsten electrode was substituted for the calomel, after the first few determinations, in order to eliminate any effect on the end-point due to the presence of potassium chloride.

The next set of determinations was made with 100 cc. of sulfuric acid of various concentrations, substituted for the nitric acid.

To determine whether potassium chloride had any marked effect on the end-point a series of determinations was made by adding various amounts of potassium chloride to $100~\rm cc.$ of 2.5~N sulfuric acid and $25~\rm cc.$ of 0.1133~N permanganate solution and titrating with 0.09641~N arsenite solution. The theoretical volume of arsenite required was calculated

¹⁸ Kelley, J. Ind. Eng. Chem., 10, 19 (1918).

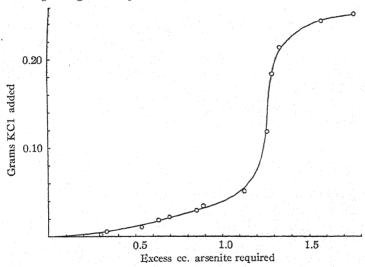

¹⁹ A Wendt titration apparatus was used for these titrations.

All of these electrometric titrations were made at room temperature.

Summary

Under the conditions that usually prevail in the analysis of steel, the electrometric titration of permanganate with sodium arsenite solution causes the manganese to be reduced from a valence of 7 to an average valence of 3.3 when the bismuthate method is used. This agrees with the results obtained by Bose and by Geloso. The reaction between the permanganate may be expressed as follows: 6 MnO₄⁻ + 11 H₂AsO₃⁻ + $15 \text{ H}^+ \longrightarrow 2 \text{ Mn}^{+++} + 4 \text{ Mn}^{+++} + 11 \text{ HAsO}_4^{--} + 13 \text{ H}_2\text{O}$. The reduced condition corresponds to the oxide Mn₃O₅ but it is improbable that such an oxide actually exists. The color of the solution indicates the presence of tervalent manganese and the fact that manganese dioxide often separates on standing shows that the quadrivalent manganese readily assumes the condition of colloidal dioxide and finally forms the gel. Probably this reaction takes place: 2 Mn++++ + 4 $Mn^{+++} + 8 H_2O \longrightarrow 2 Mn^{++} + 4 MnO_2 + 16 H^+$. The fact that halide causes a more complete reduction of the manganese is in accord with the usual behavior of halogen hydride in permanganate titrations. It prevents the formation of colloidal dioxide and keeps the manganese in a more reactive condition.

The electrometric titrations show that when arsenite is titrated with permanganate in 2.5 N sulfuric acid solution the manganese is reduced to an average valence of 2.5 just as Waitz found more than 50 years ago. $4 \, \mathrm{MnO_4^-} + 9 \, \mathrm{HAsO_3^-} + 14 \, \mathrm{H^+} \longrightarrow 2 \, \mathrm{Mn^{++}} + 2 \, \mathrm{Mn^{++}} + 9 \, \mathrm{HAsO_4^-} + 7 \, \mathrm{H_2O}$. Whenever the reaction between permanganate and arsenite is used in practice to determine either manganese or arsenic it is important to pay attention to such details as temperature, acid concentration and presence of halide or manganous salt and to standardize the solutions under exactly the same conditions that prevail in the analysis.

THE CRYSTAL STRUCTURES OF THE CUBIC FORMS OF ARSENIOUS AND ANTIMONOUS OXIDES

By RICHARD M. BOZORTH Received March 26, 1923

Introduction

Octahedral crystals of arsenious oxide were prepared by slowly cooling a solution of the substance in hydrochloric acid with the addition of a small amount of sodium chloride. A crystal of the cubic form of antimonous oxide, senarmontite, from Mt. Hamimat, Algeria, was kindly supplied by Dr. G. P. Merrill of the National Museum. A careful qualitative examination of a part of this crystal carried out in accordance with the scheme of A. A. Noyes¹ showed about 3% of arsenic, about 10% of alkaline earths and a trace of bismuth.

The Spectral Photographs of Arsenious Oxide

Photographs were taken of line spectra reflected from (100), (110) and (111) faces. The results are given in Table I. Measurements are for the rhodium $\kappa \alpha_1$ line whose wave length was found by Duane? to be 0.6121 Å.

TABLE I
REFLECTION DATA FOR ARSENIOUS OXIDE

Reflecting	Angle of	Estimated	Order of	Length of		ed structu = 0.895, v	re factors for = 0.21	or
plane	reflection	intensity	reflection	unit cube	S_{As}	S_{0x}	S	
(100)	6°21′	strong	4	11.07	-112	40	-72	
	12° 49′	medium	8	11.04	69	25	94	
(110)	4° 29′	very weak	2	11.07	8	33	41	
	9° 0′	medium	4	11.07	98	2	100	
	13° 36′	weak	6	11.04	60	0	60	
(111)	2°46′	weak	1	11.0	24	8	32	
	5°30′	very strong	2	11.06	116	0	116	1
	8° 17′	medium weak	3	11.04	64	-23	41	
	11° 2′	medium stron	g 4	11.08	- 86	19	- 67	
	13°51′	medium weak	5	11.07	- 87	32	- 55	
		absent	6		- 50	0	- 50	
	19° 35′	very weak	7	11.07	- 89	-33	-122	

A consideration of these data shows that the smallest possible unit cube is 11.06 Å. on an edge. The orders of reflection given in Table I are on this basis. Combining these measurements with the density, which was found by Baxter and Hawkins³ to be 3.865, we find that this unit

¹ Noyes, "Qualitative Chemical Analysis," 8th ed., The Macmillan Co., New York, 1920.

² Duane, Nat. Research Council Bull., 1, No. 6 (1920).

³ Baxter and Hawkins, This Journal, 38, 269 (1916).

must contain 32 arsenic atoms and 48 oxygen atoms. A larger unit would contain 256 arsenic atoms and 384 oxygen atoms, and in this case neither the arsenic atoms nor the oxygen atoms could all be equivalent. Since no X-ray reflections were found which necessitated this larger unit, the smaller one was considered the true one.

The density calculated from the spectral measurements is 3.861, in good agreement with the observed value.

The Spectral Photographs of Antimonous Oxide

The results of the reflections of the molybdenum $\kappa \alpha_1$ line, of wave length² 0.7078 Å., from a (111) face of the crystal, are given in Table II.

	Table II	
REFLECTION	Data for Antimonous Oxide	

Angle of	Estimated	Calculated structure factors for $u = 0.885, v = 0.23$				
reflection	intensity	reflection	unit-cube	$S_{\mathbf{Sb}}$	S_{Ox}	S
3° 9'	very weak	1	11.15	22	4	26
6° 19′	strong	2	11.14	203	0	203
9° 29′	very weak	3	11.15	57	-12	45
12° 43′	medium	4	11.14	-189	42	-147
15° 59′	weak	5	11.13	- 90	20	- 70
19° 17′	medium weak	6	11.14	-167	0	-167

The unit cube of antimonous oxide is thus found to be 11.14 Å. on an edge. With 32 antimony atoms and 48 oxygen atoms in the unit, the density calculated from these measurements is 5.11. Direct determinations of the density vary from 5.1 to 5.8.

The Arrangement of the Atoms

Laue photographs of the two substances showed holohedral cubic symmetry, so the arrangement must be that of one of the space groups isomorphous with the point groups T_d , O, and O_h . No spots were produced by first-order reflections from planes having one or two even indices, such as (521) and (421). Also, no spots were produced by first, second, or third order reflections from planes having one index zero and only one index odd, such as (320) and (100). Assuming all the arsenic or antimony atoms, and likewise all the oxygen atoms, to be equivalent, the only possible arrangement which will satisfy the above conditions and permit first-order reflections from planes having all odd indices is the following, derivable from the space-group O_h^a :

The Laue Photograph of Arsenious Oxide

The data from a Laue photograph of arsenious oxide, taken with the beam inclined about 2° to a trigonal axis, are given in the first 4 columns of Table III. The attempt has been made to make this table complete by including all forms below a certain complexity (d/n = 0.78 Å.) which could possibly have reflected X-rays onto the photographic plate as pure first-order or pure second-order reflections. First-order reflections from planes having an even index are not tabulated, for none was observed, and with the arrangement given above the structure factor S is identically zero for them. A few reflections involving wave lengths near and below 0.30 Å. were also omitted, since the data are not useful. In the table, d denotes the interplanar distance expressed in Ångstrom units and n the order of reflection. The wave lengths of the X-rays are expressed in Ångstrom units.

Assuming that the reflecting powers of the atoms are proportional to their atomic numbers, the structure factor was calculated in the usual way for each of the planes listed in Table III for a considerable region near u=0.9 and v=0.2. The calculated structure factors agree best with the data when u is 0.895 and v is 0.21. The value of u cannot be changed more than 0.005 without destroying the agreement between calculated structure factors and observed intensities. Because of the comparatively small reflecting power of oxygen, however, the value of v may be changed as much as 0.02 without seriously affecting the agree-

ment. Values of u and v differing markedly from 0.9 and 0.2, respectively, were found by trial to be inconsistent with the data.

The structure factor can be separated into two parts, S_{As} due to the arsenic atoms alone, and S_{Ox} due to the oxygen atoms alone, so that $S = S_{As}$ +

 S_{Ox} . This separation is made in the tables, in order that it may be seen how the final value of S would change if the reflecting powers of the atoms were not considered to be proportional to their atomic numbers. The intensity of reflection of any plane is assumed to be some function of d/n, multiplied by S^2 .

The Laue Photograph of Antimonous Oxide

The Laue data for antimonous oxide are given in Table IV. It is seen that the intensity data are satisfied when u=0.885 and v=0.23. The same limitations apply to the values of the parameters that held in the case of arsenious oxide. With either substance the particular values $u=\frac{7}{8}$ and $v=\frac{1}{4}$ will not satisfy the data. Since antimony shows a critical absorption at 0.405 Å., reflections of wave lengths near or below this value have not in general been included, for they are extremely weak.

Conclusions Concerning the Crystal Structure

The structure is represented diagrammatically by Fig. 1. It consists of As_4O_6 or Sb_4O_6 groups arranged in the same way as the carbon atoms in the diamond, 6 each group corresponding to one carbon atom. It will be seen that the atoms in each As_4O_6 or Sb_4O_6 group are related among themselves in a way different from that in which they are related to the atoms of other groups, and that the groups themselves are separated by distances

THE DIAMOND ARRANGEMENT

To represent As4O6 and Sb4O6,

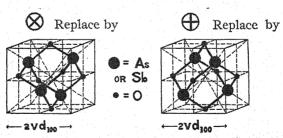

Fig. 1.—The arrangement of the atoms in As_4O_6 , and Sb_4O_6 . For As_4O_6 , $d_{100}=11.06$, u=0.895 and v=0.21; for Sb_4O_6 , $d_{100}=11.14$, u=0.885 and v=0.23

considerably greater than the distances between the atoms in any group. For example, the shortest distance between an arsenic and an oxygen atom within the same group is 2.01 Å., while the shortest distance between an arsenic atom and the nearest oxygen atom in a neighboring group is 2.78 Å. The corresponding distances in antimonous oxide are 2.22 Å. and 2.61 Å., respectively. Hence, in the solid as well as in the gaseous state, molecules of As_4O_6 and Sb_4O_6 may be considered to exist.

⁶ W. H. and W. L. Bragg, Proc. Roy. Soc., London, 89A, 277 (1913).

This determination of the arsenic to oxygen distance is, so far as the writer is aware, the only basis for an experimental value of the arsenic radius. Taking the oxygen radius as $0.65 \, \text{Å}$, the arsenic radius is $1.36 \, \text{Å}$. The radius of antimony is found in the same way to be $1.57 \, \text{Å}$.

The arrangement of the atoms within the molecule is the same as that of the carbon and nitrogen atoms in hexamethylenetetramine, $C_6N_4H_{12}$, as determined by Dickinson and Raymond.⁷ The considerations concerning the tetrahedral angles that hold for the latter compound apply also to arsenious and antimonous oxides.

Summary

The crystal structures of arsenious and antimonous oxides have been determined by means of Laue photographs and spectral photographs. These crystals may be regarded as composed of $\mathrm{As_4O_6}$ and $\mathrm{Sb_4O_6}$ molecules having a diamond arrangement, each molecule corresponding to 1 carbon atom. See Fig. 1. The arrangements are derived from the space group $\mathrm{O_h^7}$. The sizes of the unit cubes containing 8 molecules of $\mathrm{As_4O_6}$ or $\mathrm{Sb_4O_6}$ are 11.06 Å. for arsenious oxide and 11.14 Å. for antimonous oxide. The shortest distance between arsenic and oxygen atoms is 2.01 Å., and between antimony and oxygen atoms is 2.22 Å.

[CONTRIBUTION FROM THE MUSPRATT LABORATORY OF PHYSICAL AND ELECTROCHEMISTRY, UNIVERSITY OF LIVERPOOL]

THE EFFECT OF SUCROSE ON THE ACTIVITIES OF CERTAIN IONS

By J. W. CORRAN Received March 26, 1923

Experiments with Potassium Chloride

With the object of investigating the mechanism of chemical change, a method has been adopted in this Laboratory in the case of reactions in aqueous solutions which consists in making use of an artifice, namely, the replacement of various amounts of the water by sucrose, such replacement being attended by measurable alterations in viscosity on the one hand, and in the activities of the participating individuals, (molecules and ions), on the other. On the basis of this simultaneous alteration, information can be obtained regarding the nature of the process taking place in presence of the sucrose. In the first instance, it is necessary to obtain, by direct experiment, a value for only the actual change in activity produced by the sucrose, in order to apply the method. At the same time, the question naturally arises as to the mechanism of the alteration in activity itself, as in the case of an ion, and in a previous communica-

⁷ Dickinson and Raymond, This Journal, 45, 22 (1923).

tion¹ the attempt was made to account for the alteration in the activity of the chloride ion in terms of the available water present. In the paper referred to, the activities of the chloride ion, in the presence of various amounts of sucrose, were computed from measurements of the electromotive force of cells with transport, using silver-silver chloride electrodes. The expression for the e.m.f.'s of such cells is

$$E = 2n_{\rm K} \frac{RT}{F} \log \frac{{\rm Cl_{I}}}{{\rm Cl_{II}}}$$

where $\mathrm{Cl_I}$ and $\mathrm{Cl_{II}}$ are the activities of the chloride ion in the solutions and n_K represents the transport number of the potassium ion. It was assumed that in solutions of potassium chloride, the activities of the two ions were equal, even in the presence of sucrose (an extension of the Mac-Innes² postulate which states that in aqueous solutions of potassium chloride the activities of the potassium and chloride ions are equal). Further, it was assumed that the transport number of the potassium ion retained the same value in solutions containing sucrose as in aqueous solutions. It was shown that the general nature of the results obtained justified these two assumptions.

The most important inference drawn from the results obtained by means of the cell with transport was that the potassium and chloride ions are soluble in the water of hydration of sucrose, the activities of the ions being calculable with a fair degree of accuracy on this basis, activity being regarded at the same time as a concentration expressed in terms of available solvent. When the concentration of sucrose was large, however, the observed activities tended to become slightly less than those calculated on the assumption that increase in activity was due to the decrease in the total amount of water present in the solution, owing to the sucrose. These differences may have been due to experimental error. There was also a possibility that the transport number of the potassium ion had slightly, but sensibly, changed and, hence, had influenced the values of the activities calculated from the observed e.m.f.'s. This being the position it was deemed advisable to verify the results already obtained by means of the corresponding cell without transport, namely, Ag | AgCl | KCl | $K_{\rm x}$ Hg |

KCl and sucrose AgCl Ag. The e.m.f. of this type of cell is given by the

expression, $E = \frac{2RT}{F} \cdot \log \frac{\text{Cl}_{\text{I}}}{\text{Cl}_{\text{II}}}$, on the assumption that the activities of the potassium and chloride ions are equal. Any pronounced changes in the transport number of the potassium ion should be demonstrated by a comparison of the results obtained by means of the two types of cell.

² MacInnes, ibid., 41, 1086 (1919).

¹ Corran and Lewis, This Journal, 44, 1673 (1922).

Experimental Part

The electrical instruments and silver-silver chloride electrodes were as described in a previous paper. A type of flowing amalgam electrode, identical with that used by MacInnes and Parker, was employed. The precautions adopted by these authors were followed, and their statements were completely verified by the present investigation. The potassium amalgam was also prepared according to their recommendations and, provided that air was excluded, it was found to be very satisfactory. The amalgam was kept under pure, dry hydrogen.

All measurements of the cell were carried out at 25° . The concentrations of potassium chloride used were 0.5~N and 0.1~N, respectively, (moles per liter of solution) and the sucrose was introduced into the decinormal solution of potassium chloride.

The expression from which the activities were calculated was the following, $E=2\times0.059\times\log\frac{0.324}{a_{\text{Clo.1}}}$, where 0.324 is the activity of the chloride ion in 0.5 N potassium chloride and $a_{\text{Clo.1}}$ is that in the decinormal solution in the presence of sucrose. Table I contains the values of the observed e.m.f.'s and also the activities calculated from these values by means of the above expression. The values marked with an asterisk were interpolated by a graphical method.

In Table II are shown the activities of the chloride ion in decinormal solutions of potassium chloride in the presence of sucrose, calculated from the e.m.f.'s of the cells with and without transport, respectively. In the last column are given the "theoretical" activities, 4 a_2 , of this ion, calculated in terms of total water, on the basis that the activity is a corrected concentration and that sucrose, beyond the fact that it displaces a certain amount of water, is otherwise inert.

- 3 MacInnes and Parker, This Journal, 37, 1445 (1915).
- ⁴ In order to determine the values of the "theoretical" activities in terms of total water, the compositions of the solutions by weight were found and the concentrations of potassium chloride were expressed as moles per 1000 g. of total water (see the first 3 columns of Table II). The activity coefficients corresponding to these concentrations were obtained from the data of Noyes and MacInnes [This Journal, 42, 239 (1920)]. The product of these concentrations and the corresponding activity coefficients gave the "theoretical" activities shown in Table II.

It was shown previously¹ that the activities obtained by means of a consideration of the cell with transport showed an increase parallel with those of a_2 ("theoretical" activities) calculated in terms of total water, except in the case of solutions containing 60 and 70% of sucrose. In these cases, the observed activities were found to be slightly less than those calculated. This slight divergence does not appear when activities are calculated from the e.m.f.'s of cells without transport. Hence the conclusion that the potassium and chloride ions are soluble in the water of hydration of sucrose is fully substantiated by the results obtained by means of the cell without transport.

The Transport Number (n_K) of the Potassium Ion in the Presence of Sucrose

In Table III are given the ratios of the e.m.f.'s of the two types of cell or, in other words, the values for the transport number of the potassium ion in solutions of potassium chloride, in the presence of sucrose. On account of the fact that the value for $E_{\rm obs.}$, for 70% sucrose (cell with transport), namely, 0.0240, is the mean of several values which exhibited among themselves a variation of 1 mv., the value of the transport number is also an average value, between the limits 0.514 and 0.530, which is a considerable variation for a transport number. This example demonstrates the effect of a comparatively small error in the observed e.m.f. on the value of the transport number obtained. However, the results tend to show that the transport number of the potassium ion does increase slightly in 60 and 70% solutions, but remains practically constant up to 50% sucrose. That is, the assumption made in the previous paper, regarding the constancy of the transport number of the potassium ion, is approximately justified.

It is a somewhat striking conclusion that, up to 50% sucrose solutions, the transport number of the potassium ion, and also of the chloride ion, should hardly alter, even though the viscosity increases 7-fold.

Table III
Transport Numbers of Potassium Ion

Sucrose	Viscosity of solution	$E_{ m obs}.$ (cell with transport)	$E_{ m obs}$. (cell without transport)	Transport no. of potassium
0	1.00	0.0368	0.0740	0.497

Discussion of Results

Harned⁵ has published results which serve to verify the conclusion arrived at during the present investigation regarding the solubility of the chloride ion in the water of hydration of sucrose. He considered cells of the following types: (1) $H_2 \mid \text{MeCl}(c)$ in $\text{HCl}(0.1) \mid \text{Hg}_2\text{Cl}_2 \mid \text{Hg}$; (2) $H_2 \mid \text{MeCl}(c)$ in $\text{HCl}(0.1) \mid \text{HCl}(0.1) \mid \text{Hc}_2$, where Me represented potassium, sodium or lithium. The concentration of hydrochloric acid in each case was 0.1 M, while that of the alkali chloride was denoted by c. Hence the total chloride concentration was (c + 0.1).

The free energy changes in these 2 cells are given by the following expressions.

$$\begin{split} \text{Cell 1} & \quad -(\Delta F)_1 = F(E_0(1) - E(1)) \\ & = RT \log \frac{a_{\text{H}_8} \cdot a_{\text{Cl}_{(e+0\cdot 1)}}}{a_{\text{H}_0\cdot 1} \cdot a_{\text{Cl}_{0\cdot 1}}} \\ \text{Cell 2} & \quad -(\Delta F)_2 = FE_2 = RT \log \frac{a_{\text{H}_8}}{a_{\text{H}_6,1}} \end{aligned}$$

where $-(\Delta F)$ denotes decrease in free energy, E_0 the e.m.f. of the cell when c is zero, and E that when there is salt present; $a_{\rm H_s}$ denotes the activity of the hydrogen ion in the presence of salt. The value of the e.m.f. of Cell 2 was determined indirectly, in order that liquid-liquid potential differences should not be involved. If we subtract the value of Cell 2 from that of Cell 1, the following expression is obtained.

$$E_{\rm 0}(1) - E(1) - E(2) = \frac{RT}{F} \log \frac{a_{\rm Cl_{\rm 0.0+0.1}}}{a_{\rm Cl_{\rm 0.1}}}$$

In Table IV is given a summary of the results of Harned for the values of $\frac{RT}{F}$ log $\frac{a_{\text{Cl}}_{(e+0\cdot 1)}}{a_{\text{Cl}_{0\cdot 1}}}$, in the cases of potassium, sodium and lithium chlorides,

respectively. The value of the logarithmic expression for the same value of c is practically the same in the cases of all 3 salts. If the chloride ion were insoluble in the water of hydration of the accompanying cation, one would

⁵ Harned, This Journal, 42, 1808 (1920).

expect that the value of the expression would be greatest in the case of lithium chloride solutions and least in those of potassium chloride, since, according to Washburn, 6 the lithium ion is much more heavily hydrated than the sodium ion, which in turn possesses a greater degree of hydration

Table IV Harned's Results

$$\frac{RT}{F} \log \frac{a_{\text{Clo-1}}}{a_{\text{Clo-1}}} \begin{cases} \text{KCl...} & 0.2000 & 0.5000 & 1.000 & 2.000 & 3.000 \\ 0.0244 & 0.0404 & 0.0554 & 0.0724 & 0.0834 \\ \text{NaCl...} & .0241 & .0401 & .0548 & .0712 & .0821 \\ \text{LiCl...} & .0244 & .0400 & .0555 & .0718 & ... \end{cases}$$

than the potassium ion. In 2.00~M solutions of these salts the different "effective" concentrations of the chloride ion which would be thus caused, if this ion were insoluble in the water of the hydration of the cations, would certainly affect the value of $a_{\text{Cl}\,(c+0.1)}$ in such a way that it would be much greater in the solution of lithium chloride than in that of potassium chloride. But this is not so, as the table shows that the logarithmic expression is very slightly greater in the case of potassium chloride, probably due to slight experimental error. Hence, one can only conclude that the chloride ion is soluble in the water of hydration of the accompanying cations, a conclusion which is the analog of that arrived at in the present investigation, for the case of sucrose.

Experiments with Barium Chloride

The principle of the method employed for the measurement of the activities of the barium ion in the presence of sucrose is essentially the same as that employed in the case of the potassium and chloride ions. The cell without transport was used, namely, Ag | AgCl | BaCl₂ | Ba_xHg | Ba-

Cl₂ and sucrose AgCl Ag. The e.m.f. of this cell, in which solutions of a uni-bivalent electrolyte are used, is given by the expression

$$E = \frac{3RT}{2F} \log_{\bullet} \sqrt[3]{\frac{\text{Ba}_{\text{I}}.\text{Cl}_{\text{I}}^2}{\text{Ba}_{\text{II}}.\text{Cl}_{\text{II}}^2}}$$

where $Ba_{\rm I}$ and $Cl_{\rm I}$ are the activities of the barium and chloride ions, respectively, in the first solution and $Ba_{\rm II}$ and $Cl_{\rm II}$ are those in the second solution. The value of $\sqrt[3]{Ba.Cl^2}$ is the mean activity of the ions or, in other words, the activity of the barium chloride. It is evident that, knowing the mean activity in the first solution, a measurement of e.m.f. enables one to calculate the value in the second solution.

In order to obtain the individual barium-ion activities from a knowledge of the mean activities, it can no longer be assumed, as in the case of univalent chlorides, that in solutions of the same equivalent concentration the activities of the chloride ion in a uni-univalent and a uni-bivalent

⁶ Washburn, This Journal, 31, 322 (1909).

chloride, respectively, are the same. Such an assumption would be in contradiction to the results of Lewis and Randall⁷ and Brönsted.⁸ that the activity coefficient of an ion is a function of the total ion concentration or, in the words of Lewis and Randall, of the "ionic strength" of the solution. However, it is possible to calculate indirectly, on the basis of previous conclusions, the relative increase in the barium-ion activity caused by the presence of sucrose. It is known that the chloride-ion activity. in the presence of sucrose, is inversely proportional to the total amount of water in a given volume of solution. Applying this result to the case of barium chloride solutions, it is evident that the relative activities of the chloride ion can be calculated from a knowledge of the compositions by weight of the solutions. In addition, measurements of the e.m.f.'s of the above cell will furnish a means for the calculation of the relative activities of barium chloride, that is, the mean activities of the ions in the presence of various amounts of sucrose. From the values obtained for barium chloride and chloride ion, respectively, it is an easy matter to calculate the relative activities of the barium ion alone; they are the cubes of the relative activities of the barium chloride divided by the squares of those of the chloride ion itself. From the values thus obtained for the barium ion, information regarding its solubility or insolubility in the water of hydration of sucrose can be obtained in a manner similar to that adopted in the case of solutions of potassium chloride.

In order to assign correct values to the activity of the barium ion in the presence of sucrose, the values of the activity coefficients of barium chloride and chloride ion in 0.1 M barium chloride solution in the absence of sucrose, as given by Lewis and Randall⁷ and Harned and Brumbaugh,⁹ respectively, have been employed and the required activity of barium ion has been calculated from them. Using the value so obtained as that of the barium ion when no sucrose was present, the barium-ion activity in the presence of sucrose can be calculated from a knowledge of the relative activities.

Experimental Part

The amalgam was prepared by the electrolysis of a saturated solution of barium hydroxide, using a cathode of pure mercury and a platinum anode. On passing a current of 1.5 amp. (current density about 50 milliamp. per sq. cm.) for about 2 hours while the mercury was constantly stirred, a liquid amalgam was formed containing about 0.1% of barium. This amalgam was separated from the solution and washed several times with small amounts of distilled water. It was then dried in a vacuum, with the help of gentle heat, and finally kept under pure, dry hydrogen.

- 7 Lewis and Randall, This Journal, 43, 1112 (1921).
- ⁸ Brönsted, *ibid.*, **42**, 761 (1920).
- ⁹ Harned and Brumbaugh, *ibid.*, 44, 2729 (1922).

The amalgam, which closely resembled potassium amalgam, acquired a dark film on the surface and decomposed slowly in water, and rapidly in acid solution

The measurements were carried out at 25°, in a manner similar to that used in the case of solutions of potassium chloride, the flowing amalgam electrode being again employed, owing to the reaction between barium and water to form barium hydroxide. The concentrations of barium chloride employed were 0.5 and 0.1 moles per liter of solution, respectively, and into the latter solution were introduced various amounts of sucrose.

It was assumed that, in the expression for the e.m.f. of the cell, namely,

$$E = 0.0885 \log \sqrt[3]{\frac{Ba_{0.5} \cdot Cl^{2}_{0.5}}{Ba_{0.1} \cdot Cl^{2}_{0.1}}}$$

the activity of the barium chloride in $0.1\,M$ solution when no sucrose was present was unity. Thus the values obtained when sucrose was present gave the relative increase in the activity of barium chloride caused by the sucrose. In Table V are shown the results of the e.m.f. measurements, together with the calculated relative activities (or the relative increase in activity), in the cases of 0, 40 and 60% solutions of sucrose.

Sucrose	$E_{ m obs}$	(volts)	Average	Relative mean activity		
%	0.1% amalgam	0.01% amalgam	e.m.f.	√ ³ /Ba.Cl ²		
0	0.0523	0.0526	0.0524	1.00		
40	.0427	. 0426	.0426	1.28		
60	.0348	.0343	.0346	1.59		

Expressing the concentration of barium chloride as moles of salt per 1000 g. of water, the relative concentrations can be calculated, as in the case of potassium chloride, assuming that the concentration of salt when no sucrose is present is unity. These relative "corrected" concentrations $(c_{\text{corr.}})$, in terms of total water, are shown in Col. 3 of Table VI. In the fourth column are shown the observed relative activities.

Table VI Barium-ion Activities

Sucrose per liter of solution G.	Total water per liter of solution G.	corr. (in terms of total water)	Relative mean activities (obs.)	Barium-ion activities a _{Ba}
0	995.6	1.00	1.00	0.029
400	746.0	1.34	1.28	.037
600	615.0	1.62	1.59	.046

The values of $c_{\rm corr.}$ are slightly higher than those of the relative activities, but it must be remembered that, as the concentration increases, the activity coefficient decreases slightly. If we allow for this decrease in the

activity coefficient, the values in Cols. 3 and 4 will agree more closely. Since there are no accurate experimental data expressing the activity coefficient of barium chloride as a function of concentration, no attempt has been made to allow exactly for the slight decrease in activity coefficient.

It is evident from the results shown in the above table, that the increase in the mean activity of the ions of barium chloride, caused by the presence of sucrose, can be accounted for by simply allowing for the decrease in the total amount of water. In other words, since the chloride ion has been shown to be soluble in the water of hydration of sucrose, the same conclusion is arrived at in connection with barium ion. Therefore, the values shown in Col. 4 represent not only the relative mean activities of the barium and chloride ions, but also the relative activities of the individual barium and chloride ions, respectively. Hence, by assigning the value 0.029 to the activity of the barium ion in 0.1 M aqueous solution, the values shown in the last column of Table VI for the actual barium-ion activities, are obtained.

Discussion of Results

Regarding the activity of an ion as the product of the concentration and the activity coefficient, the significance of the foregoing treatment lies in the fact that it throws considerable light on the mode of expressing concentration. It is clear that the availability or non-availability as solvent of the water of hydration of ions or non-electrolytes is of primary importance. In the cases examined during the present investigation, the chloride, potassium and barium ions are apparently soluble in the water of hydration of sucrose. In addition, it has been shown, from a survey of Harned's results,5 that the chloride ion is soluble in the water of hydration of accompanying cations. On the other hand, Moran and Lewis¹⁰ have shown that the hydrogen ion is apparently insoluble in the water of hydration of sucrose, since the increase in its activity caused by sucrose is not accounted for, even by allowing for the water of hydration. addition, the fact that lithium chloride causes a greater increase in the hydrogen-ion activity of hydrochloric acid than does potassium chloride or sodium chloride, indicates that the hydrogen ion is insoluble in the water of hydration of salts. In view of this, the hypothesis of MacInnes, as extended by Harned, 5 namely, that in solutions of uni-univalent electrolytes of the same concentration and having an ion in common, the activity of the common ion has the same value in every case, is not strictly true. It cannot be true, for example, in the case of strong monobasic acids at the same concentration, for if it were, in view of what has been said, it would follow that the anions must be hydrated to equal extents, a conclusion that is untenable. However, it must be stated that, in view of

¹⁰ Moran and Lewis, J. Chem. Soc., 121, 1613 (1922).

the facts and conclusions mentioned, one is led to the conviction that the hydrogen ion stands alone in the sense that it is insoluble in water of hydration, either of an ion or of an undissociated molecule. If this conviction be true, then Harned's extension of the MacInnes postulate should hold for all ions, except the hydrogen ion. The reason for its lack of generality is suggested to be the solubility or insolubility of an ion in the water of hydration of a secondary solute (either an ion or a non-electrolyte).

The author wishes to express his thanks to Professor W. C. M. Lewis, under whose direction the above work has been carried out, and also to the Department of Scientific and Industrial Research of the British Government for a grant which has enabled the research to be performed.

Summary

- 1. By means of measurements of the e.m.f.'s of potassium chloride concentration cells without transport, containing sucrose, the conclusion arrived at in a previous paper that the potassium and chloride ions are soluble in water of hydration of sucrose has been verified.
- 2. It has been shown that whereas the transport number of the potassium ion in sucrose solutions remains constant up to 50% sucrose concentration, it appears to increase slightly in 60 and 70% solutions.
- 3. From a survey of Harned's results, it has been shown that the chloride ion is soluble in the water of hydration of accompanying cations. This conclusion is, therefore, analogous to that arrived at in connection with sucrose.
- 4. Measurements of the mean activities of barium chloride, in the presence of sucrose, by means of the cell without transport, have shown that the barium ion, as well as the potassium and chloride ions, is soluble in the water of hydration of sucrose.
- 5. Since the solubility or insolubility of an ion in water of hydration is of primary importance in determining its true concentration, in terms of available water, Harned's extension to any ion of the MacInnes postulate regarding the independent activity of the chloride ion in solutions of univalent chlorides of the same concentration, is only valid for those ions which are soluble in the water of hydration of secondary solutes (either ions or non-electrolytes).

THE UPPER RANGE OF THE QUARTZ-FIBER MANOMETER

By Albert Sprague Coolidge Received April 9, 1923

As recently pointed out by Carver, the ordinary forms of micromanometer are not suited for use with organic vapors, either because they demand that the gases whose pressures are being measured shall obey the perfect gas laws, which these vapors do not, or else because they involve the use of hot wires, etc., which might decompose them. Carver solves the problem with the aid of a very elaborate optical-lever mercury manometer. However, it would seem that a much simpler and equally satisfactory solution is offered by the quartz-fiber manometer of Haber and Kerschbaum.²

This instrument, as originally described, consists of a moderately thin quartz fiber sealed at the top into a glass bulb. By gently tapping the bulb, the fiber is set swinging, and the amplitude of its vibration can be determined at any instant with the help of a suitable telescope with micrometer eye piece. This amplitude will decrease with time, at a rate depending upon various factors, but constant under given conditions.

Let $\frac{-dA}{Adt} = C$, the damping constant, where A is the amplitude. Then, by a simple integration, it follows that

$$C = 1/T \ln A_1/A_2 \tag{1}$$

where T is the time (measured by a stopwatch) which elapses while the amplitude decreases from A_1 to A_2 .

Three cases now arise. If the tube is completely vacuous, no damping will occur except that due to the inelasticity of the quartz itself; let this be represented by C=a, where a depends only on the dimensions of the fiber and its temperature. If, however, gas is present, but at such low pressure that the mean molecular free path is large compared to the diameter of the fiber, additional damping will occur, proportionally to the pressure and to the square root of the molecular weight, so that

$$C = a + bp\sqrt{M} \tag{2}$$

where b likewise depends only on the dimensions and temperature of the instrument. Finally, with increasing pressure, the mean free path becomes comparable to or smaller than the diameter of the fiber and Equation 2 ceases to hold; instead, C increases more and more slowly with increasing pressure, and soon reaches a limiting value unchanged by further increase in pressure. This limit is proportional to the viscosity of the gas in the tube and is, therefore, different for different gases. In fact, this differ-

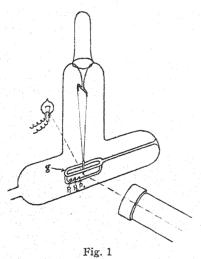

¹ Carver, This Journal, 45, 59 (1923).

² Haber and Kerschbaum, Z. Elektrochem., 20, 296 (1914).

ence in the behavior of gases having different viscosities applies over the whole range just considered.

Obviously the instrument is most useful in its "lower" range, where its behavior follows a simple law, the same for all gases. However, this range extends only up to about 0.01 or 0.02 mm., and leaves a large gap to be filled before the range of the simple mercury manometer is reached. This gap roughly corresponds with the "upper" range of the quartz-fiber gage, that is, the range within which the damping still changes with the pressure, but in a different way with different gases, and can, therefore, be used to measure the pressure only after calibration with another type of gage, with the particular gas in question.

In order to investigate the usefulness of the upper range, two such gages were constructed as shown in Fig. 1. The simple fiber is replaced by a

system of 2 fibers supported at their tops about 1 cm. apart, and having their lower ends joined by a small glass tip. The whole being made out of Pyrex, no difficulty was found in attaching the quartz to the glass, the ends of the fiber being first sealed into small glass armatures, which were in turn attached to the supporting stem. The fibers are about 9 cm. in length and 0.004 cm. in diameter. The tip of Gage B is heavier than that of Gage A. The glass guard ring g serves to limit the travel of the tip and prevents the fiber from ever coming into contact with the walls; it has proved invaluable in preventing breakage. The little glass points $p_1p_2p_3$ in the

figure are used in reading the gage. The cross hairs of the micrometer telescope are set vertically in contact with the images of two of these points $(p_1 \text{ and } p_3 \text{ for a high pressure}; p_1 \text{ and } p_2 \text{ for a low pressure, in order to save time})$, the system set in vibration by suitable shaking, and the time noted during which the extreme position of the tip relapses from coincidence with the cross hair set on p_1 to coincidence with that set on p_3 or p_2 . This time, together with twice the distances of the points from the position of the tip when at rest, is then substituted in Equation 1 to give C. The distances mentioned are found once for all with the aid of the micrometer, and will not change so long as the gage remains mounted in the same position, so that the telescope may be removed and reset as often as desired without introducing additional measurements or computations. During a reading, the top part of the gage is covered with a cap of snow, in order

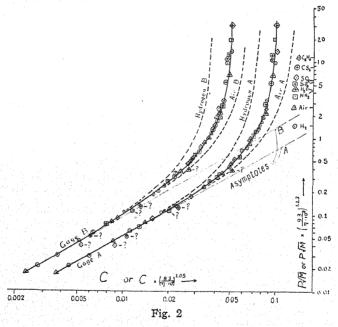

to prevent temperature variations of the constants. It was found that cooling from room temperature to zero reduced the constant a by more than half.

Two advantages accrue from this bifilar construction. First, the system can vibrate only as a whole, and in only one plane, namely, that normal to the line joining the points of support, to which the axis of the telescope should be parallel. In the simple fiber gage, especially with fibers less than 0.01 cm. in diameter, much trouble is experienced from elliptical and harmonic vibrations. Second, the mass of the glass tip serves to decrease the frequency and therewith the rate of damping of the vibrations, so that accurate measurements of the damping time can be made at pressures so high that the simple fiber would be brought to rest in one or two seconds.

The quartz-fiber gages were tested by comparison with McLeod gages, using a variety of gases and vapors. Gold foil was introduced to keep mercury vapor out of the quartz gages. No account was taken of the difference in pressure which must have been caused, at the lowest pressures. by the temperature differences in the system (273° K. at the quartz, about 290° at the McLeod; at very low pressures, where $\Delta p/p = \frac{1}{2} \Delta t/t$ this would amount to about 4%). In interpreting the results it must be kept in mind that the readings on the McLeod gage are not reliable except in the case of the permanent gases. With easily condensible gases and vapors the readings are too low, not because of failure to obey the gas laws during the last stages of compression, but because of adsorption on the walls during the early stages, the adsorbed gas failing to be carried up by the rising mercury. The fraction adsorbed will be the greater, the lower the pressure and the less volatile the vapor in the gage. In an effort to reduce the resulting error by recovering and estimating the adsorbed gas, a McLeod gage was constructed having a main chamber of 500 cc. capacity, and a "capillary" of 15 mm. diameter in which the volume and pressure of the trapped gas could be read after compression (100 times) by a micrometer microscope to 0.05 cc. and 0.01 mm., respectively. the reading was taken, the gas was expelled through an electromagneticallyoperated mercury-sealed glass valve at the top of the capillary, after which the mercury was lowered until it just continued to close the intake-port. Into the vacuum so produced the greater part of the adsorbed gas escaped and was estimated by once more raising the mercury and reading pressure and volume, the amount so found being added to the main portion in calculating the pressure. Even with this correction, it was found that no confidence could be placed in the readings below, say, 0.05 mm. in the case of benzene vapor. On the other hand, the behavior of the quartz gage with this vapor cannot be predicted from Equation 2 much above 0.005 mm., since the mean free path of the benzene molecules is exceptionally short. In the intermediate range an interpretation of the readings with

the quartz gage in terms of pressure can be found, if at all, only indirectly, by analogy from the behavior of permanent gases in the same range.

This behavior is shown by the dashed lines in Fig. 2. The letters A and B refer to the quartz gages A and B, respectively. For the sake of simplicity the observed points are not put down on these curves; furthermore, the hydrogen and air curves for each gage are drawn somewhat closer together than they should be, in order to avoid overlapping. The abscissas are values of C, the damping constant, in reciprocal seconds, while the ordinates represent $p\sqrt{M}$ in millimeters of mercury. A logarithmic scale is used so that a great range may be covered. It will be seen that in the lower range, below about $p\sqrt{M}=0.1$, the curves for both gases coincide, but that above this value they separate, air giving greater damping than hydrogen, in keeping with its higher viscosity. However, the curves

for the two gases have the same shape, and can be brought into coincidence by displacement along their common asymptote. If this relation holds for all gases, and if the required displacement for each gas can be determined by other means, we have evidently a method of interpreting the gage readings with any gas, which does not rely upon the McLeod gage except for a single calibration curve with a permanent gas. A clew as to the amount of displacement required is given by the consideration that the upper limiting values of C should be proportional to the viscosities of the gases. If, therefore, $C \times \eta^{-1}$ or $C \times k\eta^{-1}$ be plotted instead of

C (where η is the viscosity of the gas in question, and k is any constant, the same for all gases) against $p\sqrt{M}$, the upper limits of the curves for all gases will coincide. In order that the lower portions of the curves may coincide, a vertical displacement also is necessary; inspection of the logarithmic graph shows that this should bear to the horizontal displacement the ratio which measures the slope of the asymptote, namely, 1.17. It turns out, however, that the displacement necessary to bring the air and hydrogen curves together is 5% greater than that calculated from the viscosities given in Landolt Börnstein "Tabellen" by the same reasoning. We shall therefore take, as our displaced variables, (arbitrarily setting $k = (93 \times 10^{-6})^{1.05}$), $C \times \left(\frac{93}{\eta \times 10^6}\right)^{1.05}$ for abscissa, and $p\sqrt{M} \times \left(\frac{93}{\eta \times 10^6}\right)^{1.23}$

These variables are plotted in Fig. 2. It is evident that the points for hydrogen and for air actually lie on the same curve within the errors of measurement. (The probable error seems to be about 1% except in the highest range, where it increases because of the smallness of the time intervals measured.) The entire hydrogen curve can, therefore, be derived from the air curve (or *vice versa*) with the aid of knowledge of the viscosity of the two gases, or by a single measurement at a relatively high pressure, in order to determine the displacement required. This latter method, of course, is tantamount to determining the relative viscosity of hydrogen. It is reasonable to hope that in the same way curves for other gases and vapors can be derived, without reliance on the McLeod gage except for one orientating measurement at a relatively high pressure; in the orientating measurements slight errors in the McLeod gage would be unimportant, as C is here almost independent of $p\sqrt{M}$.

This hope appears to be justified. In Fig. 2 are collected observations on 6 additional gases and vapors, having a wide range of viscosities, molecular weights, and volatilities. The viscosities (η_c), calculated from the necessary displacements of the points, are listed in Table I, together with those (η_1) given in Landolt, and the molecular weights.

TABLE I

COMPTON AND MOTHER IN WINTERING ON CACHE

	V 12CO2LLI	S AND MO	LECULAR WEIGI	AIS OF GASES

NH ₃	93	95.7 17	Air	[175]	175.0	29

In Fig. 2, the symbols used to distinguish the different gases are shown at the right, at positions on the scale of ordinates corresponding to actual pressures of 1 mm. All points lie on the same curves except the 10 points marked "?," which lie too low; but this is exactly what we should

expect, because the McLeod gage reads too low at low pressures, especially with slightly volatile vapors such as those of benzene and water. It will be noticed that these vapors begin to deviate at higher pressures than the others which are more volatile. We may, therefore, safely conclude that the solid curves represent the true relations between pressure and quartz-gage readings over the entire range, and can be used to read pressures for any gas whose viscosity and molecular weight are known, from the lowest detectable pressure up to the point where the slope becomes too steep for accurate reading. This extends the useful range from about 0.1 on the axis of ordinates (the limit of the lower range) to about 1 on the same axis, thus carrying us well into the range of the McLeod gage.

An approximate explanation of this relationship can be evolved as follows. An ideal gas, with infinite molecular free path, would presumably follow the asymptote over the entire range of pressures. Actual gases will begin to deviate from the asymptote at pressures at which their free paths become smaller than some definite value. Taking $L=3\eta/\rho\omega$, where L is the mean free path, ρ , the density of the gas $=\frac{Mp}{RT}$, and ω , mean molecular velocity $=\sqrt{\frac{8RT}{\pi M}}$, we have $L=\sqrt{\frac{\pi RT}{8}}\times\frac{\eta}{p\sqrt{M}}$.

It follows that different gases will begin to deviate from the asymptote at the same values of $p\sqrt{M}/\eta$. We may also suppose that at still higher

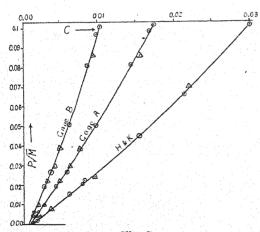

Fig. 3

pressures, different gases will deviate by the same amount when their mean free paths and, therefore, the values of $p\sqrt{M}/\eta$, are equal, so that their curves will remain coincident when $p\sqrt{M}/\eta$ is plotted against C/η . The presence of exponents different from unity is not explained.

Although the gages here described were constructed primarily for use in the upper range, they can also be used in the lower range, but

are not quite so sensitive as those of Haber and Kerschbaum. Fig. 3 shows the curves for air and hydrogen in Cartesian coördinates, together with one of Haber and Kerschbaum's. The freedom from harmonic vibrations secured by bifilar construction is particularly valuable here, as undesired modes of vibration, once set up, persist for a long time; the gage cannot be

read until they have died out. It will be noticed that the relation between C and $\rho\sqrt{M}$ is not strictly linear, even in this range.

The fact that the quartz-fiber manometer reads in terms of $p\sqrt{M}$ rather than p alone of course limits its applicability to those cases in which the gas to be measured has a known molecular weight, or is a mixture in known proportions of gases of known molecular weights. On the other hand, if M is unknown it can be determined by comparing the quartz-gage readings with those of some other form of delicate manometer, such as Carver's, which reads p directly. Evidently, this would furnish a method for identifying an unknown gas, analyzing a mixture of known gases of different molecular weights, and investigating the possibility of dissociation, at very low pressures. The method could be extended to higher pressures, in the first two cases, by reversing the principle of the McLeod gage; that is, by expanding the unknown gas in a sufficiently large ratio to bring it within the optimum range of the quartz-fiber gage.

Summary

A form of bifilar quartz-fiber manometer is described, from which troublesome harmonic vibrations are eliminated.

A method is described by which the instrument may be read up to pressures of 0.1 to 1 mm., depending on the gas used. The method involves calibration over the whole range with a permanent gas and a McLeod gage and, in addition, either a single measurement with the gas used and a McLeod gage at relatively high pressure, or a knowledge of the viscosity of the gas. So extended, the range of the instrument overlaps that of the McLeod gage, even with easily condensable vapors.

It is suggested that the gage may be used to determine molecular weights of gases at very low pressures.

ERRORS IN THE DETERMINATION OF HYDROGEN SULFIDE

By Fred H. Heath and Frank A. Lee Received April 11, 1923

Considerable interest is attached to a knowledge of the quantity of hydrogen sulfide present in natural waters. Such data are of value to the chemist, biologist and the public health officer. Hydrogen sulfide in natural waters is thought to be derived from both organic and inorganic sources and the quantity of it present in any water is likely to undergo rapid and rather great changes. Hydrogen sulfide in solution is rapidly oxidized and careful tests on solutions of the gas in distilled water show that 50% of the hydrogen sulfide may be lost in this way while a solution is kept overnight in a closed container at room temperature. Con-

sequently, the necessity for working with freshly obtained samples of natural waters is evident.

The investigations summarized in this article are the result of experimental work carried on for two summers at the North Dakota Biological Station at Devil's Lake, N. D. Further experiments were conducted at the University of Washington.

Natural waters of the lake region of North Dakota are typical saline waters of such a kind as will cause serious errors in the iodimetric determination of hydrogen sulfide. These lake waters are quite saline and are rich in alkali sulfates and carbonates. They contain considerable magnesium bicarbonate and some calcium bicarbonate. Total solids vary from 12000 to 25000 parts per million. In some instances the sulfate content of the water was more than half of the content of total solids. There appeared to be a slow bacterial reduction of sulfate to sulfide which caused a gradual precipitation of iron as iron sulfide. In many instances samples of mud from the lake bottom evolved considerable hydrogen sulfide upon treatment with hydrochloric acid. Analyses of such mud frequently showed a content of 10% to 12% of iron.

Waters of this lake region contain moderate amounts of ammonia and nitrates. Nitrites are generally absent during summer months.

Methods Now Used for Determination of Hydrogen Sulfide in Water.—In one colorimetric method¹ a lead salt precipitates brown lead sulfide or gives a brown color, the depth of which is dependent upon the amount of sulfide present. The color thus obtained is matched against that of lead sulfide derived from a known quantity of lead salt, and in this way the amount of hydrogen sulfide is measured. Waters rich in chlorides, sulfates or carbonates are not well adapted to the use of this method, since the chloride, sulfate and carbonate of lead are insoluble salts and would precipitate.

The iodimetric method for the determination of hydrogen sulfide is based upon the chemical changes which are illustrated by the following equations: $H_2S + I_2 = 2HI + S$; and $I_2 + 2 \text{ Na}_2S_2O_3 = \text{Na}_2S_4O_6 + 2 \text{ NaI}$.

To a measured quantity of the water is added a known excess of a standard solution of iodine. After a short time the excess of iodine is determined by titration with a standard solution of sodium thiosulfate. The hydriodic acid remains in the solution, and at the high dilution existing the free sulfur is in the colloidal form and does not precipitate. The iodine used is taken as a measure of the amount of hydrogen sulfide present. This process assumes that there is no substance present, other than hydrogen sulfide, which is capable of reacting with iodine. Such a condition does not exist except in very pure waters.

Effect of Organic Matter

Organic matter in general, either animal or vegetable, reacts with iodine and would therefore have a tendency to show a content of hydrogen sulfide somewhat greater than the true value.

Effect of Alkalinity

It is well known that the halogens react readily with hydroxides and carbonates. In iodimetry the presence of alkaline hydroxides or carbon¹ Winkler, Z. anal. Chem., 52, 641 (1913).

ates must be avoided, because of the reaction between these substances and iodine. Bicarbonates do no harm since they do not react with iodine.

In natural waters we often find carbonate and bicarbonate alkalinity. The former would cause absorption of iodine and consequently the amount of hydrogen sulfide as determined would be higher than the true value. The magnitude of this effect as tested upon natural waters of an average alkalinity is shown in Table I. The alkalinity of the water sample was determined by titration of a separate sample of water.

TABLE I

EFFECT OF CARBONATE ALKALINITY OF WATERS ON IODIMETRIC DETERMINATION OF HYDROGEN SULFIDE

Parts per million of hydrogen	sulfide	as :	measu	ired by	iodine	absorbed		
Before neutralization	2.0	3.	5	4.9	6.1	6.7	7.3	5
After neutralization	none	0.	2	0.06	0.2	none	0.6	റ

These samples were from different sources and their alkalinity varied somewhat, but each sample was carefully neutralized before making the tests recorded in the second line. The errors due to carbonate alkalinity are evident.

Effect of Nitrates

In order to test the effect of nitrates a solution of hydrogen sulfide was prepared in purified distilled water, and the concentration determined by the iodimetric method, using $0.01\ N$ solutions of iodine and sodium thiosulfate. To guard against changes in concentration of the hydrogen sulfide solution, because of oxidation, all tests were made immediately after the standardization of the solution. Measured portions of a dilute standard solution of potassium nitrate were then added to known volumes of the solution of hydrogen sulfide, followed by an iodimetric determination of the latter substance in the usual way. Results are given in Table II.

Table II

Effect of Nitrate upon the Iodimetric Determination of Hydrogen Sulfide

Quantity of nitrogen added as KNO ₃ G.	Volume of the solution Cc.		million of en sulfide Found by titration	Quantity of nitrogen added as KNO ₂ G.	Volume of the solution Cc.		er million of en sulfide Found by titration
0.004	150	76.0	71.0	0.004	200	5.87	3.0
.004	150	76.0	70.7	.008	200	5.87	1.9
.012	150	76.0	67.0	.002	200	0.70	0.56
.004	200	5.87	2.8	.006	200	0.70	0.50

From these results it is evident that the presence of nitrates causes the titration process to give values for hydrogen sulfide which are distinctly too low. Similar tests show that sodium nitrate acts like potassium nitrate. The explanation of this effect must be either that there is a loss of hydrogen sulfide or that iodine is liberated by chemical reaction in the course of the determination. It was found that nitrate in concentrations similar to those which occur in natural waters, does not oxidize the hydriodic acid formed, at least within any reasonable time, and further search for the cause of the low results was fruitless.

Effect of Nitrites

In order to test the action of nitrites a procedure was followed similar to that used in testing the effect of nitrates. A solution of hydrogen sulfide in pure water was prepared and standardized by the iodimetric method. To portions of this solution of the gas were added known quantities of freshly prepared standard solutions of nitrite, after which the iodimetric procedure was followed as usual. Results of such tests are given in Table III.

.030	250	6.20	7.68			1	

The presence of nitrites evidently causes high results in the iodimetric determination of hydrogen sulfide. In other words there is less free iodine in the solution to be titrated by sodium thiosulfate than should be there for the content of hydrogen sulfide known to be present. In order to interpret these results it will be necessary to account for some chemical changes which use up excess of iodine, due perhaps to a product formed by the action of hydrogen sulfide on a nitrite.

The chemical changes shown by the following equations appear as possibilities in connection with the explanation of the results of experiment.

Equation 1 shows liberation of iodine and this does occur in concd. solutions of iodide and nitrite upon acidification. It represents the determination of iodides in presence of other halides. However, this action is contrary to the fact that small amounts of nitrite in very dilute solutions cause too high results in the determination of hydrogen sulfide.

Equation 2 expresses the oxidation of nitrite to nitrate by iodine in dilute solution. Colorimetric tests for nitrate mixed with small amounts of iodine and nitrite in very dilute solutions do not seem to show any appreciable formation of nitrate.

Equation 3 calls for the formation of the compound nitrosyl iodide, NOI. Since nitrosyl bromide is a very unstable substance, even at low temperatures, it is very unlikely that nitrosyl iodide could be formed.

The chemical process illustrated by Equation 4 has been patented² for use in connection with the Le Blanc soda process. That this is the reaction which probably takes place has been shown by passing hydrogen sulfide into a very dilute solution of sodium nitrite, acidifying with sulfuric acid, boiling off the hydrogen sulfide and testing for ammonia by the Nessler method. Positive results were obtained. All of the solutions and reagents used were tested, and found to be ammonia free. Both sodium and ammonium hydroxides will use up iodine. Ammonium hydroxide and iodine may also form nitrogen iodide.

Effect of Soluble Iodide

It was thought best to attempt the iodimetric determination of hydrogen sulfide in the absence of any alkali metal iodide, so as to eliminate any possible interference by potassium iodide. For this purpose a standard dilute solution of iodine dissolved in water was titrated; the endpoint was less distinct than usual, due to the absence of iodide. As in the previous instances, it was found that nitrites cause high results, while nitrates cause low results.

In further tests it was found that sodium chloride, calcium chloride, magnesium chloride and urea had no effect upon the accuracy of the determination.

Summary

In view of the very evident errors caused by the presence of small quantities of salts the authors recommend that use of the iodimetric process for the determination of hydrogen sulfide in natural water be discontinued. In order to eliminate errors due to the action of nitrites, nitrates and alkali salts we suggest that natural waters be tested for hydrogen sulfide by the colorimetric method of W. Mecklenburg and F. Rosenkränzer in which methylene blue is formed.³ The need of a qualitative as well as a quantitative method is further shown by the fact that some of the samples from Devil's Lake gave no test by this latter method, but positive results were obtained by the iodimetric method.

EMULSIONS OF MINERAL OIL WITH SOAP AND WATER: THE INTERFACIAL FILM

By EDWARD L. GRIFFIN

Received April 14, 1923

Emulsions in which mineral oil is dispersed in water by means of soap are largely used as insecticides. Both kerosene and higher fractions of petroleum are used. Certain difficulties in the manufacture and use of these emulsions make important an understanding of the actual state of the constituents in an emulsion.

Much work on emulsions of this type has already been done, but the exact manner in which the soap functions is still in dispute. Several theories have been advanced to explain its action, the most important being as follows.

- 1. Emulsification depends principally upon obtaining the proper surface tension and viscosity. 1,2,3
- 2. Emulsions consist of droplets of oil surrounded by a film of discrete, insoluble particles which are more easily moistened by water than by oil.⁴
- 3. Emulsions are made by the dispersion of oil, not in a water solution of soap or other emulsifier, but rather in a hydrated colloid. Enough of the colloid must be present to bind all the water.⁵
- 4. Emulsions consist of droplets of oil which are surrounded by more or less plastic films, 6,7,8,9
- 5. Emulsions consist of droplets of oil in water, with an interface composed of molecules of a third substance, the molecules being so orientated that the group which has an affinity for water is dissolved in the water, while that which has an affinity for the oil is dissolved in the oil.^{10,11}

Very little work had been done to prove this last theory. In fact Harkins, Davies and Clark said that "what is presented in this paper on the problem of the formation of colloids and emulsions is only preliminary in nature but much may be expected from the application of the principles in regard to the setting of molecules in surfaces to this problem."

Theoretical Consideration

If a kerosene emulsion consists of droplets of kerosene, each surrounded by a film of soap 1 molecule thick, the whole surrounded by a soap solution containing the unabsorbed soap, it might seem possible to determine the soap extracted from the water solution in the formation of the emulsion.¹² The quantity of soap removed from aqueous solution would be directly proportional to the area of interface formed and entirely independent of the concentration of soap originally present, provided, of course, that sufficient soap is present to form the film.

It is also possible to measure the area of the droplets formed. From a comparison of the amount of soap removed by each cubic centimeter of kerosene with the area of interface formed by the same amount, the average area covered by each molecule of soap can be calculated.

In a molecule the size of that of stearic or oleic acid the replacement of a hydrogen atom by sodium would hardly be expected to greatly increase the average area occupied by a molecule and in this case the results would be expected to agree rather closely with those obtained by Langmuir for the average area occupied by each molecule of the various fatty acids when placed on water in a film 1 molecule thick (46, 22, and 21×10^{-18} sq. cm. for oleic, stearic, and palmitic acids, respectively). The possibility that the soap might be heavily hydrated is not precluded. In this case the area occupied by each molecule of soap might be much greater than that occupied by a molecule of the corresponding fatty acid.

When kerosene is emulsified in fairly dilute sodium oleate solution by shaking and then allowed to stand, the oil droplets cream out at the top, leaving a clear or nearly clear aqueous soap solution at the bottom. If this soap solution is analyzed before and after emulsification of the kerosene, the difference in the quantity of soap carried will be that taken up by the kerosene.

The area of interface may be calculated as follows. An oil emulsion contains droplets of various sizes. Let us assume that these droplets are assigned to various classes whose radii, expressed in centimeters, are r_1 , r_2 , r_3 , r_4 , respectively. Let us measure a large number of drops, denoting those with radius r_1 by x_1 , those with radius r_2 by x_2 , those with radius r_3 by x_3 , and so on. The area of interface associated with each cubic centimeter of kerosene is the sum of the areas of these droplets divided by the sum of their volumes or

$$\frac{3(x_1r_1^2 + x_2r_2^2 + x_3r_3^2 + \dots)}{x_1r_1^3 + x_2r_2^3 + x_3r_3^3 + \dots}$$

¹² Briggs, Ref. 7, made titrations which showed that soap was removed but says that absolute measurements were not obtained. His results are to be considered only as comparative.

The area of interface associated with 1 cc. of kerosene, divided by the number of molecules of soap removed, gives the area of interface formed for each molecule of soap removed. Millikan's value, 13 for the number of molecules in a mole (6.06 \times 10 23) was used.

Experimental Part

Materials Used

U. S. P. stearic and oleic acids were used. The stearic acid had been purified by alcohol. While both of these acids usually contain small amounts of impurities, the errors in the other measurements are such that it was believed that the results would not be affected.

A sample of impure commercial palmitic acid, having a yellow color, and somewhat soft, was first employed. Later, a sample of pure palmitic acid with a melting point of 62° and an iodine number zero, was obtained from Dr. George E. Jamieson of the Bureau of Chemistry.

Emulsions

Soap solutions were made as follows. The calculated amount of fatty acids was weighed into a flask. About 500 cc. of water was added, and heat was applied when necessary to melt the acid; the mixture was then shaken while the calculated amount of normal alkali necessary to form a neutral soap was added, the mixture heated and shaken until all dissolved. This was then cooled to room temperature, made up to 1 liter, and mixed by shaking. An approximately 0.2 or 0.1 M solution was usually prepared as a stock solution, weaker solutions being made from it by dilution as needed.

Except where otherwise stated, emulsions were made by the following procedure. The required volume (usually 100 cc.) of soap solution was measured into a flask and an equal volume of kerosene was added. Then the whole mixture was drawn up into a large pipet by vacuum and rapidly expelled by compressed air, repeating the process about 10 times. The emulsified product was next poured into a cylinder and the cylinder was stoppered and allowed to stand. One or two days later when the emulsion had come to equilibrium, the contents of the cylinder were run from end to end several times to guard against local differences of concentration, then allowed to stand, usually for about 2 weeks, until the oil drops had arisen to the top as a cream, leaving a clear or nearly clear aqueous lower layer sufficient for analysis.

Another portion of the same soap solution was preserved under the same conditions for comparative analysis.

Fatty Acid Determination.—Twenty-five or 50 cc. of the solution to be analyzed was pipetted into a 120cc. Squibb funnel. Enough N sulfuric

¹³ Millikan, Phil. Mag., [6] 34, 1 (1917).

acid was then added to break down the soap and leave a slight excess of acidity, followed by 40 cc. of u. s. p. ether. The contents of the funnel were well shaken and allowed to separate into layers, and the lower layer was drawn into Funnel 2. About 40 cc. of ether was added to this and the material was well shaken and allowed to separate. The lower layer was drawn into Funnel 3, where it was again washed with ether and then discarded. The ether layers in the 3 funnels were next washed with water, until the last washing contained no more than traces of acid, after which they were combined in a beaker. Nearly all of the ether was evaporated on the steam-bath. About 50 cc. of neutral alcohol was poured into the beaker containing the fatty acids and the acids were titrated with $0.1\,N$ sodium or potassium hydroxide solution, using phenolphthalein as an indicator.

Analyses were made of the clear layer from the emulsion and of the soap solution from which the emulsion was made. The quantity of fatty acid found was calculated to moles per liter. The difference between the moles of acid found per liter in the original solution and that found in the lower layer from the emulsion represents the number of moles removed by each liter of the kerosene inasmuch as the kerosene and the soap solution were used in equal volumes. The value thus obtained, divided by 1,000, gives the number of moles removed by 1 cc. of kerosene.

Measuring the Droplets.—The contents of the cylinder containing the emulsion were carefully run from end to end several times in order to mix it without changing the size of the droplets. A small quantity of the emulsion was then poured into distilled water in an Erlenmeyer flask and the flask was rotated until an even mixture was obtained. A small quantity of this diluted emulsion was placed on a microscope cover glass by means of a platinum loop, and mounted on a ground-glass slide just as a hanging drop of bacterial culture is mounted to study the motility of an organism. The droplets were immediately examined under the microscope, using a 4 mm. objective and a No. 10 evepiece containing a micrometer disc. The slide was set at random and the sizes of all the droplets whose centers appeared on the scale were recorded to the nearest half scale-division up to 3, above that to the nearest division. Each scale division was equal to 0.00038 cm. The tube was moved up and down so as to find all the droplets in the area. The slide was moved from place to place until about 200 droplets had been measured and the number in each class obtained.

Sodium and Oleic Acid Removed by Emulsification

Emulsions were made from sodium oleate solutions of various concentrations and kerosene. When a soap solution containing 0.002 mole or less of sodium oleate per liter was used, the emulsion formed was not permanent. Permanent emulsions were formed with soap concentrations

ranging from 0.003 to 0.124 mole per liter. Oleic acid was removed from the aqueous layer in the process of emulsification, the loss varying from 0.0022 to 0.0086 mole per liter. The area of interface formed was from 3,700 to 11,400 sq. cm. for each cubic centimeter of kerosene. The area of interface formed for each molecule of oleic acid lost was from 21 \times 10⁻¹⁶ to 39 \times 10⁻¹⁶ sq. cm.

These values, although somewhat lower, are of the same order of magnitude as those obtained by Langmuir for the average area of 1 molecule of oleic acid in a surface film (46×10^{-16} sq. cm.). If they differed from those for surface films it was expected that they would be higher for the reason that the sodium atom is larger than the hydrogen atom and also because hydration of the soap may be expected. It was considered possible that part of the oleic acid removed had gone into solution in the kerosene and not into the interface. If this were the case, more oleic acid than sodium would be extracted from the soap solution in making an emulsion and an excess of sodium would remain in the aqueous layer. It was decided, therefore, to conduct experiments in which both the sodium and the oleic acid removed by emulsification were determined.

Sodium Determination.—Sodium was determined as follows. A 25-or 50cc. aliquot portion of the solution was evaporated to dryness in a platinum dish and ignited at a low temperature. An excess of N sulfuric acid was added and the whole was evaporated to dryness and ashed completely. The silica was dehydrated by evaporation with hydrochloric acid, and drying for 1 hour at 110° . It was then treated with hydrochloric acid, filtered, and washed, and the filtrate was evaporated to dryness in a weighed platinum dish. Water, 0.5 cc. of N sulfuric acid, and ammonia in excess were added, and this mixture was evaporated to dryness, ignited, and weighed as sodium sulfate. The results obtained are shown in Table I.

Table I

Sodium and Oleic Acid Removed from Solution on Emulsification

Concn. of sodium oleate in soap soin. Moles per liter	Materia from ac Sodium Moles pe	Oleic acid	Area of interface × 10 ⁻³ per cc. of kerosene Sq. cm.	of molec interfac	ction area ules in the e × 10 ¹⁶ Calc. from oleic acid
0.05	0.0038	0.0046	11.0	48	39
.025	.0037	.0049	10.3	46	35
.0125	.0037	.0058	10.9	49	31

In every case the loss of oleic acid exceeded the loss of sodium. Assuming that all of the sodium that disappeared from solution went into the interface in the form of a unimolecular layer of sodium oleate and that the excess oleic acid that disappeared went into solution in the kerosene, the areas calculated for the average cross section of a molecule of sodium oleate in the film agree very well with those obtained by Langmuir for a molecule of oleic acid in a surface film.

It was thought that reduction of the hydrolysis of the soap by the addition of sodium hydroxide might make the concentration of the undissociated fatty acid in the soap solution so small that the quantity taken into solution by the kerosene would be negligible. An emulsion containing 0.1 mole of sodium oleate and 0.01 mole of sodium hydroxide per liter was therefore made. Equivalent quantities of sodium and oleic acid (0.0028 mole per liter) were removed from the solution. The interfacial area formed per cubic centimeter of kerosene was 7.45×10^3 sq. cm. and the area for each molecule of sodium oleate removed from the solution was 44×10^{-16} sq. cm.

The fact that the quantities of sodium and oleic acid absorbed were equivalent agrees with, but does not prove our theory. Since certain fatty acids form acid salts with the alkali metals, it was considered possible, in the case of the neutral sodium oleate emulsions with kerosene, that an acid salt might go into the interface, as suggested by Pickering. This would account for the discrepancy in the quantities of sodium and of oleic acid absorbed. A direct method of extracting sodium oleate solution with kerosene was therefore sought.

No method presented itself of breaking an emulsion after it had been formed, without changing conditions in the mixture to such an extent that the results would be valueless. An extraction was, therefore, made in a rotating machine in the following manner, care being taken that no emulsion was formed. One hundred cc. of the soap solution was pipetted into a 300cc. round bottle; the formation of bubbles was carefully avoided. One hundred cc. of kerosene was carefully placed on top of the soap solution by means of a pipet, and in such a way that a smooth surface between the kerosene and the soap solution was maintained. The bottle was stoppered and carefully fastened on the rotating machine so that its long axis was parallel to the axis of rotation. The machine used had a diameter of rotation of about 15 inches and made 30 revolutions per minute; when it was properly run no emulsion resulted. After the required period of rotation the bottle was removed, and an aliquot portion of the clear kerosene was taken. An equal volume of neutral alcohol was added to the kerosene and the mixture was titrated with 0.1 N alkali, using phenolphthalein as an indicator. The mixture was shaken after each addition of alkali. A value of 0.10 cc. of 0.1 N alkali for 50 cc. of kerosene was subtracted in all cases as representing the value of a blank experiment.

To determine the time necessary to run the machine to insure complete extraction, 4 bottles, each containing sodium oleate solution of the same strength and kerosene, were placed on the machine which was set in motion. One bottle was removed at the end of each successive half-hour period up to 2 hours; the solutions then required 0.60, 0.65, 0.60 and 0.65 cc. of $0.1\,N$

¹⁴ Pickering, J. Chem. Soc., 91, 2001 (1907).

sodium hydroxide, respectively; that is, at the end of a half hour the maximum amount of acid had been extracted by the kerosene. In the extractions noted in this paper 1 hour was the time ordinarily used, thus securing a sufficient margin of safety.

A portion of kerosene which had been used to extract sodium oleate solution by the method described and another portion obtained by breaking down an emulsion with heat were ignited. No weighable amount of ash remained, indicating that sodium oleate as such is not dissolved by kerosene.

Experiments were conducted to determine the quantity of sodium and oleic acid removed from the solution on emulsification and also that which was dissolved in the kerosene. The difference between the quantity of oleic acid dissolved in the kerosene and the total acid removed on emulsification was the part which went into the interface. The experimental results are shown in Table II.

Emulsions with Stearic Acid Soap

Sodium stearate is so insoluble in water that it is impossible to study emulsions made from it and kerosene by the method used for the sodium oleate emulsions. After a $0.05\,M$ solution of potassium stearate made by the method described had stood at room temperature, soap separated. All of the experiments, therefore, were run at a higher temperature, 55° being chosen, but the final dilution for measuring the droplets was made at room temperature. If there is a unimolecular layer of soap around the oil droplets, the cross-sectional area, since it is measured at room temperature, will not be changed by the higher temperature of creaming out.

Under these conditions large quantities of glass were dissolved, as shown by the silica in the ash from the soap solution and by the etching of the cylinders. The potash determinations, therefore, were unreliable and were not used.

The stearic acid in the interface was determined by the methods used for oleic acid in the emulsions from sodium oleate. The kerosene was extracted at about 55°. The results thus obtained are shown in Table III.

Emulsions with Palmitic Acid Soap

Emulsions made from a commercial sample of palmitic acid in the manner already described were held at a temperature of 40° while they settled. The cross-sectional area of the molecules in the interface determined in these experiments varied from 32×10^{-16} to 44×10^{-16} sq. cm.

These results did not check well with the cross-sectional areas obtained for palmitic acid by Langmuir (21×10^{-16} sq. cm.). In fact, they agreed better with the values for unsaturated fatty acids. The iodine number of the palmitic acid was very high, indicating the presence of a large amount of unsaturated acids. These results, therefore, cannot be considered of any value in determining the cross-sectional area of molecules of palmitic acid in an interface.

Accordingly, a sample of c. P. palmitic acid having an iodine number of zero was obtained from the Oil, Fat and Wax Laboratory of the United States Bureau of Chemistry. The results obtained by using this acid at 55° are shown in Table IV.

Conclusions

The experiments here reported show that when kerosene is emulsified with a neutral soap solution the soap is partially hydrolyzed and some of the fatty acid is dissolved in the kerosene. This hydrolysis may be prevented, or at least reduced to a negligible amount, by the addition of free alkali. No sodium or potassium is dissolved in the kerosene.

In the formation of an emulsion a certain quantity of soap is removed from the soap solution and does not go into the kerosene. It must, therefore, go into the interface between the kerosene and the remaining soap solution. The quantity of soap absorbed is (within the experimental error) proportional to the area of interface formed and is not dependent upon the concentration of soap originally in the solution.

The droplets of oil in a good emulsion must be small. This work shows that when a quantity of soap insufficient to form the interface for these droplets is present, the resulting emulsion is not stable. All of the emulsions made with very small amounts of soap "broke" on standing.

On the theory that these considerations indicated that the interface consists of a monomolecular layer of soap, the area of interface formed by each molecule of soap present (or the average cross-section of the soap molecules) was calculated. The results bore out the theoretical belief that the areas thus measured should be the same as, or somewhat greater than, those measured by Langmuir for the corresponding fatty acids in surface films. The average values for the soaps as determined by this method are 48, 27 and 30 \times 10^{-16} for sodium oleate, potassium stearate and potassium palmitate, respectively, and those for the corresponding fatty acids as determined by Langmuir are 46, 22 and 21×10^{-16} , respectively.

These results agree with the values expected and show that the film formed at the interface must be 1 molecule thick. The only other possible explanation would be the formation of a film of heavily hydrated soap of constant thickness at the interface. As these films came from solutions of widely varying concentration and as the hydration of soap in precipitates depends on the concentration of the solution from which it is precipitated, the second theory becomes untenable.

It may, therefore, be concluded that a unimolecular film must be formed at the interface when kerosene is emulsified with solutions of soap.

Summary

- 1. In an emulsion of mineral oil with soap and water, part of the soap is hydrolyzed, the fatty acids being dissolved by the oil droplets and the alkali remaining in aqueous solution.
- 2. Fatty acids may be kept from dissolving in the oil by the addition of excess alkali.
 - 3. Part of the soap forms unimolecular films around the oil droplets.

The average areas occupied by each molecule of sodium oleate, potassium stearate and potassium palmitate, were found to be 48, 27 and 30 x 10^{-16} sq. cm., respectively. These areas agree rather closely with those found for the corresponding fatty acids in unimolecular films on the surface of water.

- 4. In case there is insufficient soap to form a unimolecular film the emulsion is not stable.
 - 5. The excess soap remains in water solution.

WASHINGTON, D. C.

[Contribution from the Color Laboratory, Bureau of Chemistry, United States Department of Agriculture, No. 74]

ADSORBED MOISTURE AND WATER OF CRYSTALLIZATION IN CERTAIN COMMON DYES

By H. Wales and O. A. Nelson Received April 24, 1923

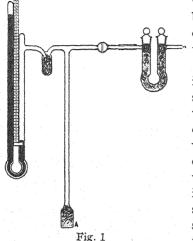

A discrepancy between the observed and calculated results for different samples of pure methylene blue when the molecular weight as given in the United States Pharmacopeia (C₁₆H₁₈N₃SCl.3H₂O) was used, always occurred during the work done on this dye in the Color Laboratory. As the authority for assuming the presence of 3 mols. of water of crystallization in this compound failed to give reliable experimental data, it was considered desirable to determine, if possible, whether or not the moisture in this dye, as well as in a few others, was present as adsorbed moisture or as water of crystallization.

From the literature, reference to which will be made as each dye is considered, it appears that no investigator has attempted to show by experiment how the moisture in his sample was held. The customary method was to heat the dye at a definite temperature for a definite period of time and calculate the amount of water present from the analytical determinations of elements. The water thus found was then considered in terms of mols. of water of crystallization when, from the data given, it might as readily be adsorbed water. Since adsorbed water is often held more tightly than the so-called water of hydration or crystallization, it seems obvious that the results obtained by such a method cannot be conclusive.

The primary object of this work was not so much to determine the quantity of water present in the dyes studied as to ascertain whether the water was present as adsorbed moisture or as water of crystallization.

Theoretically, if the vapor pressure of a hydrate be plotted against the weight of water present at constant temperature, the pressure remains constant until the last of the hydrate corresponding to this pressure has been removed. At this point the pressure drops to that of a lower hydrate,

if one is present, or to that of the anhydrous substance. Practically, however, these breaks are not always sharp. Beutell and Blaschke¹ found that in all cases where there was more than one hydrate, the dehydration on the surface of the particles proceeded further than in the interior, "where cohesion hindered the evolution of water vapor." The inside of the particles, therefore, consists of hydrates higher than those at the surface. This prevents a sharp transition from one hydrate to the next, and causes a rounding of the breaks in the curve which becomes more pronounced

with increase in the pressure difference between two hydrates. (Compare the curves for oxalic acid, crystal violet and tartrazin.)

If, however, the water in a compound is present as adsorbed water, the curve showing the relation of vapor pressure to water content will not have the breaks characteristic of the hydrate curves, but will be perfectly smooth and have a slope depending on the tenacity with which the water is being held. These two types are illustrated by the curves for hydrates, such as cupric sulfate pentahydrate or sodium carbonate decahydrate,² and by that of vapor pressure against water con-

tent curve of a substance containing adsorbed water.³ A vapor pressure-water content curve for oxalic acid (COOH)₂.2H₂O at 50° was determined to test the apparatus and also to obtain a curve for a known hydrate. The results are tabulated in Table I and shown diagrammatically in Fig. 2, Curve A.

Method.—Since the vapor pressure-water content curves of hydrates and substances containing adsorbed water are so distinctly different, the method used in determining which dyes are hydrates and which contained adsorbed water was that of determining the vapor pressure after removing a small increment of water, at constant temperature. The apparatus used was essentially the same as that described by Nelson and Hulett,⁴ a portion of which is shown diagrammatically in Fig. 1. About 1.5 g. of dye was weighed into Bulb A and a wad of fine glass wool was packed in, to prevent the dye from being carried over mechanically when the pressure in the system was lowered. The bulb was then sealed to the manometer

as indicated in the illustration. The moisture was absorbed in phosphoric anhydride and the system was evacuated by means of a Toepler mercury

Methylene Blue (C₁₆H₁₈N₃SCl).—Previous work on the water content of methylene blue is very contradictory. Koch⁵ prepared 2 samples of methylene blue under identical conditions and found that one contained the equivalent of 4 molecules of water and the other the equivalent of 1.5 molecules. Both samples gave up the water completely at 110°. Bernthsen⁶ found that the salt dried in a desiccator lost an equivalent of 2 mols. of water at 100°, 2.5 at 130° and 3 at 150°. He claims to have heated to constant weight in each case. The American and French Pharmacopeias

⁵ Koch, Ber., 12, 592 (1879).

⁶ Bernthsen, Ann., 230, 139 (1885).

accept Bernthsen's figures and give the formula as $C_{16}H_{18}N_3SC1.3H_2O$. The German Pharmacopeia makes no mention of moisture in this compound.

Four samples of methylene blue made by different manufacturers were analyzed in the Color Laboratory and contained 11.44%, 11.58%, 12.42%

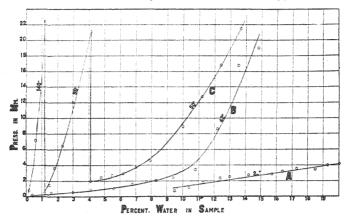

Fig. 3.—A, methylene blue at 28°; B, methylene blue at 42°; C, erythrosin at 50°, 90° and 140°

and 17.06% of water (calc. for 3 mols. of water: 14.46%). In every case the salts could be completely dehydrated by drying them at 110° for 1 day, thereby confirming Koch's results.

The vapor pressure-water content curves of the sample containing 17.06% were determined at 28° and 42°, with the results shown in Table II and Fig. 3, Curves A and B. The curves show no indication of breaks,

thus indicating that the moisture in this dye is not present as water of crystallization. In the following tables the percentage of water has been recomputed to a pure color basis, for convenience in determining the degree of hydration.

The Zinc Chloride Salt of Methylene Blue.—The formula for the zinc chloride double salt of methylene blue is usually given as $(C_{16}H_{18}N_2SCl)_2$.— $ZnCl_2$. H_2O . Apparently the only authority for this is Bernthsen³ who found 2.13% of moisture (calculated for $1H_2O$: 2.27%). No mention was made of the temperature at which the moisture was evolved. Three samples of the zinc chloride salt of methylene blue analyzed in the Color Laboratory yielded 4.0%, 3.4% and 3.1% of moisture. Heating in an oven for 1 day at 110° was sufficient to remove all but very minute traces of water.

The vapor pressure-water content curve was determined on the sample containing 4.0% of water. The results again indicated the absence of water of hydration. It should be noted that the total percentage of water obtained by the authors' method agreed well with that obtained by heating in an over.

Crystal Violet, C₂₃H₃₀N₃Cl.—Crystal violet or hexamethyl-p-rosaniline hydrochloride is stated to contain 8 molecules of water of crystallization.⁹ Green¹⁰ gives the same figure, and Schultz¹¹ gives 9 molecules.

A sample of commercial crystal violet was found on analysis to contain 4% or about 1 molecule of water. After recrystallization from water and drying for 24 hours at room temperature in a desiccator, this sample yielded 29.5% of water. The vapor pressure-water content curve for this sample (Fig. 2, Curve B), determined at 26° , showed breaks corresponding to hydrates containing 9, 6, 4, 3 and 2 molecules of water. The presence

⁷ By pure color basis is meant the parts of water per 100 parts of anhydrous dye. A dye containing 20% of water, therefore, would contain 25% on a pure color basis.

4.0	3.4	3.8	50				

While the vapor pressure-water content curve of a mixture may indicate the absence of hydrates, this evidence alone cannot be considered conclusive. That either rosaniline or p-rosaniline contains 4 molecules of water of crystallization does not seem likely, however, from other observations made in this Laboratory. For example, the highest percentage of water obtained in any sample prepared or purified was 7.2, against 17.9 required for 4 molecules (the calculations are based on an equimolecular mixture of rosaniline and p-rosaniline). If one of the components of the mixture contained 4 molecules of water of crystallization and the other was anhydrous, the amount of water present in an equimolecular mixture of the two should be approximately 8.5%. If this were the case, however, the vapor pressure-water content curve should show the breaks characteristic for hydrates. This it failed to do.

Erythrosin.—Erythrosin, or disodium tetra-iodo-fluoresceinate, has received much attention in the analytical work on food colors, because of the constant discrepancy in its analysis. Determinations of iodine in dried samples of this dye give results about 1% low, while those made on the pure acid agree very well with the theoretical value. Gomberg and Tabern¹³ found an average of 56.99% of iodine in the sodium salt (calc. for C₂₀H₆I₄O₅Na₂: 57.70), and of 60.67% (calc. for C₂₀H₅O₅I₄: 60.75) in the free acid. Their results for iodine content in samples of technical erythrosin were approximately 0.6% low. These investigators account for this discrepancy by assuming the presence of a small amount of water, equivalent to approximately 1 molecule, held very tenaciously. Similar conclusions have been reached by W. C. Holmes¹⁴ of the Color Laboratory in connection with a gravimetric method for determining erythrosin.

A vapor pressure-water content curve was obtained on a sample of re-

¹⁸ Gomberg and Tabern, J. Ind. Eng. Chem., 14, 1117 (1922).

¹⁴ Holmes, Estimation of Erythrosin, Color Trade J.

crystallized erythrosin containing 13% of water. No trace of hydrate formation was observed. (Table VI, Fig. 3, Curve C.) However, the sample which had been subjected to prolonged evacuation under pressure of less than 0.2 mm., and at a temperature of 160° , gave on analysis 56.58% of iodine, which agrees well with the value 56.55% required for a sample containing the equivalent of 1 molecule of water. Therefore, all work indicates that there must be an equivalent of 1 molecule of water in the sodium salt of erythrosin and that this water is bound much more firmly than ordinary water of crystallization.

Computed from water actually removed.

No definite evidence as to how this water is held is available at this time. Gomberg and Tabern¹³ suggest that the quinoid tautomer of the dye combines with water to give Formula I. This formula does not seem to explain the characteristics of this compound. There is no reason to expect a difference in structure between the sodium salt and the free acid which can easily be obtained in the anhydrous form. Pending further work on this subject, it is suggested that this seeming irregularity might be explained on the basis of an addition compound formed by the union of 1 molecule of the monosodium salt with 1 molecule of sodium hydroxide, such as shown in Formula II.

$$\begin{array}{c|c} I \\ ONa \\ \hline COONa \\ \hline I \\ \hline OH \\ \hline \end{array} \qquad \begin{array}{c} I \\ OH.NaOH \\ \hline COONa \\ \hline \end{array} \qquad \begin{array}{c} I \\ OH.NaOH \\ \hline \end{array}$$

Tartrazin, C₁₆H₉N₄S₂O₉Na₃: This is of especial interest as it is one of the 11 permitted food dyes. Anschütz¹⁵ records that tribarium tartrazin ¹⁵ Anschütz, Ann., 294, 288 (1897).

 $((C_{16}H_9N_4S_2O_9)_2Ba_3)$ contains 6 molecules of water. All investigators report that the di- and trisodium forms are anhydrous, although users of this dye know that the sodium salt very rapidly takes up approximately 17% of moisture on exposure to the air.

A pure sample of trisodium tartrazin was recrystallized from water and partially dried in the air. A moisture determination on this product showed approximately 33% of water. Vapor pressure-water content

curves on this sample were obtained at 26° , and repeated at 30° because of certain irregularities observed at the lower temperature. Curves C

and D, Fig. 2, show that breaks in the curve obtained at 26° occur at points corresponding to hydrates of 14, 11, 10, 6 and 3 molecules of water. As the presence of the hydrates containing 10 and 11 molecules of water seemed a little doubtful, owing to the slight change in pressure (1 mm.) between them and the next higher hydrate, and in order to obtain more information regarding the location of the curve between the hexa- and octahydrate, this experiment was repeated at 30°. The curve obtained at the higher temperature indicates the presence of hydrates containing 14, 10, 6 and 3 molecules of water. The rounding-off effect due to the presence of higher hydrates in the interior of the particles, as suggested by Beutell and Blaschke, is clearly demonstrated between the decaand hexahydrates which differ in pressure by 13 mm.

As already mentioned, tartrazin after exposure to air contains about 17% of water. This corresponds to the hexahydrate, which has a vapor pressure approximately that of the aqueous tension of the air.

Summary

Vapor pressure-water content curves have been obtained for methylene blue, crystal violet, erythrosin, magenta and tartrazin, for the purpose of determining whether the water present in these dyes is adsorbed or held as water of crystallization. Crystal violet and tartrazin alone show hydrate formation. Further proof was also obtained that the equivalent of 1 molecule of water in crythrosin is present as part of the molecule and a new theory of the structure of this dye is offered.

WASHINGTON, D. C.

[Contribution from the Chemical Laboratory of the University of Illinois]
THE USE OF BROMATE IN VOLUMETRIC ANALYSIS. III. THE
DETERMINATION OF BROMATE IN THE PRESENCE OF FERRIC
IRON

By G. FREDERICK SMITH Received April 27, 1923

In the former papers of this series, the stability of boiling solutions of potassium bromate in the presence of mineral acids was demonstrated and the relation of this stability to further applications in the use of bromate for volumetric analysis suggested. The use of bromate in acid solution in the presence of mercuric ion was shown to alter the course of several reactions of analytical importance, increasing the oxidation value of the bromate from 5 to 6 equivalents of oxygen, thus preventing the trouble-some formation of free bromine and in other ways increasing the flexibility and value of bromate oxidimetric processes.

Determinations involving the use of bromic acid in excess generally ¹ This Journal, 45, 1115, 1417 (1923).

involve the determination of this excess in the presence of ferric iron. The most common procedure consists in adding potassium iodide to the acid solution followed by a determination with thiosulfate solution of the iodine liberated. Ferric iron, therefore, interferes through the simultaneous liberation of iodine. Methods employed for preventing this influence of ferric iron in iodimetric estimations of strong oxidizing agents, have been devised. The object of the present paper is not only to demonstrate how these known methods may be improved and adapted to the determination of bromates, but also to introduce entirely new reactions for the determination of bromate in the presence of ferric iron.

These reactions, which proceed in the presence of mercuric ion in accordance with the principles stated in the second paper of this series, employ pure sodium oxalate and standard ferrous sulfate solutions in excess as reducing agents, and the excess is determined by titration with standard permanganate in the usual manner. The reactions follow: (1) $3H_2C_2O_4 + KBrO_3 \rightarrow 6CO_2 + KBr + 3H_2O$; (2) $6FeSO_4 + KBrO_3 + 3H_2SO_4 \rightarrow 3Fe_2(SO_4)_3 + KBr + 3H_2O$.

Previous Work

Iodimetric determinations in the presence of ferric iron involve the formation of complex ferric salts which do not give ferric ions in solution and which consequently do not act on potassium iodide. Phosphoric acid thus converts ferric salts to complex salts containing the diphosphatoferric ion, $(Fe(PO_4)_2)^{---}$. Sodium pyrophosphate in excess dissolves ferric phosphate to give a colorless solution according to the same principle. Other reagents likewise form complex salts with ferric iron which do not give reactions of the ferric ion. Phosphoric acid and phosphate complexes only are of importance here.

Moser² determined copper iodimetrically in the presence of iron by the addition of an excess of sodium pyrophosphate to a solution of copper sulfate and ferric chloride with the formation of cupric and ferric pyrophosphates, of which the copper precipitate was readily soluble and the ferric precipitate difficultly soluble in the excess employed. The solution was then treated with an excess of potassium iodide, acidified with acetic acid and the iodine liberated after 10–15 minutes by the action of the copper alone, was titrated with sodium thiosulfate. This process is objectionable because of the time required for the liberation of iodine, the difficult solubility of ferric pyrophosphate in the excess of pyrophosphate, and the limitation in the amount of ferric iron that may be present without interference.

The action of phosphoric acid in preventing the liberation of iodine from potassium iodide by ferric iron was used by Barnebey³ in the iodimetric determination of iodate. The similar determination of permanganate iodimetrically was carried out by Barnebey and Hawes.⁴ In general the methods involving these processes limit the amount of iron permissible without measurable interference.

² Moser, Z. anal. Chem., 43, 597 (1904).

³ Barnebey, This Journal, 37, 1502 (1915).

⁴ Barnebey and Hawes, ibid., 39, 607 (1917).

Factors Influencing the Determination of Bromate Iodimetrically

The best procedure for the iodimetric determination of bromates should be one which works advantageously in the presence of the largest amount of iron. At the same time conditions must be chosen which require a minimum length of time in the reaction between the bromate to be determined and the iodide added. The method finally devised combined the principles of the phosphoric acid process of Barnebey and the pyrophosphate method of Moser.

With increasing amount of iron in phosphoric acid solution the ferric iron color of the solution increases regardless of increasing concentration of phosphoric acid. That this color is due to the presence of ferric ions formed by the dissociation of the diphosphato-ferric ion may be shown by the liberation of iodine from potassium iodide added to such solutions. To prevent this dissociation from giving ferric ions the phosphate ion

Fig. 1

must be added in large excess. This was done by adding easily soluble sodium pyrophosphate.

The addition of sodium pyrophosphate to a phosphoric acid solution greatly decreases the hydrogen-ion concentration. Under these conditions even strong oxidizing agents such as chromic acid fail to liberate iodine rapidly upon the addition of potassium iodide. The very high oxidizing power of bromic acid, however, overcomes this disadvantage. The time rate of oxidation of potassium iodide to free iodine by potassium dichromate with various concentrations of phosphoric acid has been determined by Barnebey.⁵

To show the comparative oxidizing power of bromic acid for potassium iodide a curve was constructed showing the equilibrium between barium bromate, potassium iodide and phosphoric acid in the presence of increasing concentrations of phosphoric acid; in the experiments, 1 minute and 3 minutes were allowed as reaction periods. The results are shown in Fig. 1.

The values were obtained as follows. The measured volume of barium bromate solution was diluted with water, the proper amount of phosphoric acid to give the acid normality shown (calculated on the basis of 3 available hydrogen atoms) was added and the whole diluted to 90 cc.; 1 to 1.5 g. of potassium iodide dissolved in 10 cc. of water was added and the mixture stirred vigorously during the allotted time for reaction, whereupon the

⁵ Barnebey, This Journal, 39, 604 (1917).

liberated iodine was titrated with approximately $0.1\ N$ sodium thiosulfate solution. When the reduction of the bromate by potassium iodide was incomplete at the time the thiosulfate was added, part of the thiosulfate was oxidized slightly. The extent of this reaction was negligibly small in all cases.

By comparison with the data of Barnebey for the corresponding dichromate reaction it will be seen that for $2\,N$ phosphoric acid the reduction of barium bromate is complete in 1 minute as compared with 3 minutes required by the dichromate reaction. Allowing 3 minutes as reaction period, complete reduction of bromate takes place in a little less than N phosphoric acid as compared with $2\,N$ acid required by the dichromate reduction. The strength of bromic acid under these conditions compared with that of chromic acid as an oxidizing agent for iodides is, therefore, roughly 3 to 1. It is thus assured that, without increase of the time in the reactions involved, the hydrogen-ion concentration of phosphoric acid may be decreased by the addition of considerable sodium pyrophosphate.

The Effect of Sodium Pyrophosphate in Phosphoric Acid Solution Upon the Formation of an Undissociated Diphosphato-Ferric Ion Complex

As has been shown in previous papers of this series, solutions of nitric and perchloric acid are best adapted to the determinations involving bromate oxidations. Solutions containing ferric perchlorate of increasing iron content were treated with phosphoric acid in different concentrations and diluted to 100 cc. Proportionate amounts of crystalline sodium pyrophosphate were then dissolved in these solutions, followed by the addition of 1-1.5 g. of crystalline potassium iodide. The potassium iodide was dissolved by vigorous stirring to prevent high local concentrations of dissolved material and the reaction medium was allowed to stand in covered beakers for 30 minutes. At the end of this time starch indicator was added and the iodine which had been liberated was titrated with 0.1 N sodium thiosulfate. A blank determination, under the same conditions without iron, was made to show the effect of atmospheric oxygen in liberating iodine from the iodide added. Under conditions which were least favorable to the rapid reduction of bromate by potassium iodide, the time required for the completion of the reaction between 25.00 cc. of 0.1 N potassium bromate and excess of potassium iodide was also determined. The results of the experiments are shown in Table I.

As will be seen, iron to the extent of 600 mg. may be effectively eliminated as an interference in iodimetric determinations of bromates. Substantially the same results were obtained using crystalline ferric nitrate instead of ferric perchlorate. When ferric sulfate solutions are employed, much more iron may be present without interference, as shown by Barnebey. The first and second experiments in Table I show that under

similar conditions without the addition of sodium pyrophosphate a prohibitive error is introduced with but half the amount of ferric iron possible with addition of pyrophosphate. In all the above experiments, the solutions remained clear throughout the whole of the time interval employed.

TARLE I

THE ACTION OF FERRIC IRON UPON POTASSIUM IODIDE IN PHOSPHORIC ACID SOLUTION
AS INFLUENCED BY SODIUM PYROPHOSPHATE

Iron was added as ferric perchlorate (containing 11% of Fe) free from ferrous iron. Time of reaction, 30 minutes. Volume of solution, 100 cc. The sodium pyrophosphate did not liberate or absorb iodine under the conditions studied. 1.0 g. of potassium iodide was added in the first five experiments and 1.5 g. in the last six.

. 6.	2.0	10.0	.20	0.00	<3

^a 1/10 of these values is the extent of their effect in practice.

The iodine liberated from potassium iodide by 25.00 cc. of $0.1\ N$ potassium bromate in $0.3\ N$ hydrochloric acid solution required 26.21 cc. of the sodium thiosulfate used in Table I. With $0.66\ M$ phosphoric acid 26.21 cc. also was required. With $2\ M$ phosphoric acid 26.15 cc. was required. With $2\ M$ phosphoric acid to which $10\ g$. of sodium pyrophosphate decahydrate per 100 cc. had been added, 25.99 cc. of the sodium thiosulfate solution was required. Therefore, the sodium thiosulfate in strong phosphoric acid solution with and without the addition of sodium pyrophosphate should be standardized, using potassium bromate under the same conditions.

The procedure for preparing a nitric or perchloric acid solution containing ferric iron for determination of its bromate content consists, therefore, in adding sodium bicarbonate to neutralize the acid and give a small precipitate, followed by phosphoric acid or phosphoric acid and sodium pyrophosphate, depending upon the amount of iron present, and finally 1–1.5 g. of potassium iodide with stirring. After 2 to 3 minutes the liberated iodine is titrated with standard thiosulfate using starch as indicator. The thiosulfate should be standardized under the same conditions.

The Determination of Bromates with an Excess of Pure Sodium Oxalate Followed by Permanganate Determination of this Excess

Since many oxidation processes involving bromates are best conducted at 100°, iodimetric determination of any excess of bromate can be made only after the solutions have been cooled to room temperature. It would, therefore, be an advantage to develop a method for bromate determination applicable to hot solutions, and Reaction 1 was accordingly studied.

An exactly $0.1\ N$ solution of sodium oxalate and approximately $0.1\ N$ solutions of potassium and barium bromate were prepared; $25.00\mathrm{cc}$. portions of the latter solutions were treated with $0.1\ N$ mercuric perchlorate solution in amount slightly more than that equivalent to the bromide ion resulting from the subsequent reduction of the bromate, and $50.00\ \mathrm{cc}$. of the $0.1\ N$ sodium oxalate solution was added followed by 5 cc. of 95% sulfuric acid, and the volume was adjusted to $100\ \mathrm{cc}$. The solution was boiled for 3 minutes in a covered beaker and, without cooling, the excess of sodium oxalate was titrated with potassium permanganate solution that had been standardized against pure sodium oxalate.

The standardization of three bromate solutions in this way was accomplished with the results listed in Table II.

TABLE II

STANDARDIZATION OF POTASSIUM AND BARIUM BROMATE SOLUTIONS WITH SODIUM OXALATE IN SULFURIC ACID SOLUTION FOLLOWED BY DETERMINATION OF THE EXCESS OF OXALATE WITH POTASSIUM PERMANGANATE

Fixed quantities: 25.00 cc. of approximately 0.1 N KBrO₃ or Ba(BrO₃)₂; 50.00 cc. of 0.1000 N Na₂C₂O₄; 5 cc. of 95% H₂SO₄. 7–10 cc. of 0.1 N Hg(ClO₄)₂ in 0.1 N HClO₄ solution. Volume of solution, 100 cc. Time of boiling, 3 minutes.

Sample	0.10040 N KMnO ₄ required Cc.	Bromate determined N	Bromate using pure As ₂ O ₂ N	Difference
1 KBrO ₃	24.97	0.09971	0.09965	+0.00006
$Ba(BrO_3)_2$	25.125	.09909	.09903	+ .00006
2 KBrO ₃	24.08	.09972	.09973	00001

These results are in each case the means of at least three closely agreeing determinations. The potassium bromate from a measured portion of Sample 2, after reduction with hydrazine, was precipitated with excess of silver nitrate and the weight of the silver bromide gave the closely agreeing value, $0.09967\ N$. The purity of the arsenious oxide used was thus proved.

The end-point in the titrations of Table II in which permanganate was used is the equal in permanency to the ordinary sodium oxalate-permanganate titration in spite of the presence of considerable mercuric bromide, but the last 3 or 4 drops of permanganate added are only slowly reduced. The point at which the pink color produced is permanent for $^3/_4$ to 1 minute is the true end-point of the reaction.

The explanation of the influence of mercury in the determinations given

- ⁶ Sodium oxalate solutions should be made up as used to avoid decomposition which occurs upon standing.
- ⁷ It was found that the pink color from 1 drop of 0.1 N permanganate in excess often persisted after 12 hours or even longer.

in the second article of this series was further tested by substituting $0.1\,N$ silver sulfate solution for mercuric perchlorate, and using a considerable excess. The concentration of the solution of Sample 2 potassium bromate was thus found to be $0.09974\,N$. The silver bromide precipitated during the reaction was without effect on the end-point. The addition of mercuric perchlorate solution to these reactions may be readily obviated through the use of mercuric bromate as standard solution. The use of mercuric bromate for this purpose will be considered in subsequent papers of this series.

Sodium oxalate serves as one of the very best standards of quantitative analysis.⁸ The standardization of bromate solutions with sodium oxalate as the only reference reagent, according to the determinations included in Table II, thus shows that bromate is probably the equal of permanganate in accuracy as a standard in volumetric analysis.

The standardization of bromate solutions by comparison with pure arsenious oxide or pure metallic antimony, following the procedure of Györy⁹ and more recently the modified Györy electrometric method of Zintl and Wattenberg¹⁰ further increases the value of bromate for volumetric processes. The high purity of metallic antimony available for this purpose has been described by Henz.¹¹ That it dissolves in hot concd. sulfuric acid to give only trivalent antimony was shown by Osterheld and Honegger.¹² Work now being carried out in another laboratory,¹³ involving the use of potassium bromate and including a critical study of its physical properties as related to stability will further increase the value of bromate as a standard.

By the use of bromate solutions standardized against sodium oxalate and potassium permanganate to liberate iodine from potassium iodide in acid solution, sodium oxalate can in general be used in place of arsenious oxide as a primary standard for iodimetric processes with no sacrifice in accuracy or convenience. Another method in which sodium oxalate is used as primary standard was devised by Rosenthaler.¹⁴

Factors governing the determination of bromate in the presence of ferric iron by the oxalate-permanganate method given above are shown in Table III.

It will be seen from Table III that solutions containing only free sulfuric acid serve for oxalate reduction of bromate in hot solution in the presence of mercuric perchlorate. Phosphoric acid, if added to decolorize

determination, addition of sulfuric acid following neutralization, in place of phosphoric acid and sodium pyrophosphate. The effect of more than 3 minutes' boiling was not tested when using phosphoric or perchloric acid instead of sulfuric acid.

The Determination of Bromate in the Presence of Mercuric Salt Using Ferrous Sulfate Followed by Titration of the Excess with Permanganate Solution

A second substitute for the iodimetric determination of bromates, using standard ferrous sulfate and potassium permanganate solutions, following the second reaction given above, would prove highly desirable if accurate because, as in the oxalate and iodimetric methods already described, the standard solutions used are the common stock reagents of any analytical laboratory. The determinations of bromates by this reaction would be most convenient if they could be made applicable in the presence of nitric, perchloric and phosphoric acid solutions, since bromate oxidation processes are best carried out in the presence of the two former acids, and phosphoric acid could be used to decolorize the ferric iron, giving a sharper permanganate end-point.

Standard solutions of potassium permanganate and ferrous sulfate were prepared in the usual manner by comparison with each other and with pure sodium oxalate. Potassium bromate was standardized with pure arsenic trioxide. Measured amounts of potassium bromate solution were treated with an excess of the equivalent amount of mercuric perchlorate solution and a considerable excess of standard ferrous sulfate solution was added. In the presence of $0.5\ N$ nitrie, perchloric and sulfuric acids complete reduction of the bromate was obtained in 2 to 3 minutes at room temperature. Molar phosphoric acid gave the same time of reduction. The results are listed in Table IV.

TABLE IV

Phosphoric acid sufficient to decolorize the iron present was added at the end-point in all these experiments if not already present.

From Table IV it is seen that the experimental and theoretical results obtained agree excellently in the case of phosphoric and perchloric acid solutions but are uniformly in error for nitric and sulfuric acid solutions. The end-point is best and most permanent in phosphoric acid solution but is very satisfactory as well in perchloric acid solution. As with a permanganate-oxalate end-point in the presence of mercuric salt, the last few drops of permanganate added are but slowly reduced and the pink tinge should persist for $^3/_4$ to 1 minute while the solution is stirred. The explanation of the error with nitric and sulfuric acid solutions is not apparent and is unusual in its constancy. The study of the electrometric end-point as applied to the reaction will be considered later in connection with work on volumetric processes involving bromate solutions, but the slowness of the reaction at the end-point would probably interfere with this method.

The preparation of bromate solutions in nitric acid containing ferric iron for determination of their bromate content according to the procedure of Table IV is the same as that for the iodimetric determination and the oxalate procedure already given.

The results here reported were obtained with mutually calibrated flasks, burets and pipets and are believed to be accurate to ± 0.02 cc.

Summary

The determination of bromates in the presence of ferric iron was studied, three methods proposed and their applicability demonstrated experimentally.

- 1. Iodimetric Method. Phosphoric acid solutions containing sodium pyrophosphate in which the dissociation of the resulting iron complex to give ferric ions is less than in the presence of either reagent alone, were analyzed for their content of bromate by the addition of potassium iodide in excess and titration of the liberated iodine with sodium thiosulfate. The time rate of reduction of bromate by potassium iodide with various concentrations of phosphoric acid was determined. The necessary variation in the concentration of phosphoric acid and sodium pyrophosphate with increasing amounts of ferric iron was determined.
- 2. Oxalate-Permanganate Method. The bromate was reduced by excess sodium oxalate in boiling sulfuric acid solution in the presence of mercuric perchlorate and the excess oxalate determined by titration with potassium permanganate. It was shown that this reaction furnishes the basis of an improved method for iodimetric standardization using sodium oxalate as primary standard.
- 3. Ferrous Sulfate-Permanganate Method. This involved the same procedures as in the Oxalate-Permanganate Method except that ferrous sulfate was substituted for sodium oxalate and titration was effected cold instead of in a hot solution.

OXONIUM COMPOUNDS IN THE VAPOR STATE. METHYL ETHER—HYDROGEN CHLORIDE

By O. Maass and D. M. Morrison Received May 2, 1923

Organic compounds containing oxygen have been shown to form complexes with the halogen hydrides; these are known as oxonium compounds. For reasons which are discussed below, further work dealing with their stability is of interest. In the investigation which is the subject of this paper, methyl ether and hydrogen chloride were mixed in the gaseous state with the object of determining whether or not association of these molecules occurred.

A thorough investigation of oxonium compounds has been made by D. McIntosh¹ and some of his co-workers. In one of his papers² on the sub-

¹ McIntosh, This Journal, 27, 26, 1013 (1905); 33, 71 (1911).

² Ibid., 34, 1273 (1912).

ject, properties of these compounds were reviewed with the object of comparing the oxonium complexes with the so-called molecular compounds such as water or alcohol of crystallization. The conclusion arrived at was that these oxonium compounds were very stable. They are simple, that is, generally 1 molecule of organic liquid unites with 1 molecule of acid. The melting points of the compounds are far above the melting points of the constituents; also, the behavior on electrolysis and the magnitude of the heats of formation serve to distinguish the oxonium compound from the ordinary solvent of crystallization.

The existence of these compounds is definitely established in the solid state; as they melt, dissociation into the original molecules takes place. Conductivity experiments indicated that this was not at all complete, but the validity of this derived interpretation is not absolutely certain. If it could be definitely shown that a measurable amount of association exists in the liquid or gaseous state, the character of the oxonium compound would at once be established as comparable to that of ammonium chloride.

This is of particular interest since in the past the structure of the oxonium compound has been given by assigning a valence of 4 and in some cases 6 to the oxygen atom; this is not in agreement with the present theory of the structure of the atom and consequent ideas of valence.

Methyl ether and hydrogen chloride form an oxonium compound melting at -96° ; the liquid boils lower than -12° . It is, therefore, possible to mix these two as gases above this temperature. The methyl ether and hydrogen chloride were prepared and purified as previously described and the boiling points were shown to be in exact agreement with those previously found.

The experimental procedure consisted in mixing a definite volume of hydrogen chloride with an equal volume of methyl ether in a container having exactly twice this volume. The pressures of the unmixed hydrogen chloride and methyl ether were the same; hence, after the gases were mixed any decrease in pressure would indicate association or increase in molecular attraction; which of these two would be the cause of the change, if any took place, would then be established in the manner described further on.

The accompanying diagram (Fig. 1) will serve to illustrate the manner in which the required amounts of methyl ether and hydrogen chloride were mixed.

The hydrogen chloride was condensed in the bulb M; the pressure tap L made it possible to keep it liquid at the temperature of a mixture of solid carbon dioxide and ether. The construction of this tap is shown in the diagram. The stopper, of large

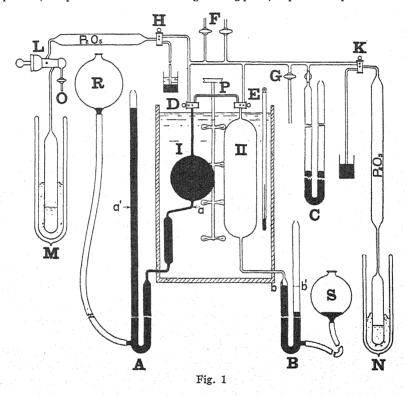

³ This Journal, 35, 535 (1913).

⁴ Ref. 2, p. 1279.

⁵ This Journal, 44, 1709 (1922).

diameter, is surrounded at the bottom by a space which may be evacuated and then closed off by means of the tap O, thus being held in place by the pressure of the atmosphere. The area exposed to atmospheric pressure in this way is large as compared to that exposed to the vapor pressure of the hydrogen chloride and taking into account the angle at which this latter pressure is applied, some 30 atmospheres' pressure in the bulb may be withstood, yet the stopper turns easily. The tap L is connected through a pentoxide tube and the 2-way tap H to the main apparatus. The volumes up to the tap H could be swept out as indicated in the diagram.

The methyl ether was condensed in Bulb N which is similarly connected to the main apparatus, except that on account of its high boiling point, no pressure tap was necessary.

Two reservoirs, I and II, were contained in a bath, the temperature of which could be kept constant. Each reservoir was connected to a manometer (A and B, respectively) in which the mercury could be raised or lowered. These reservoirs were connected through 2-way taps, D and E, to the glass-tube system which could be evacuated through Taps F and filled with air through Tap G. The volumes of I and II were chosen such that II measured from Point b was exactly twice that of I measured from Point a. This was tested by completely evacuating I and II, filling I with air at atmospheric pressure, and sending this into II, through the capillary tube P by raising Reservoir R until the mercury filled I up to Tap D. This was repeated, while the temperature was kept constant, and it was found that the mercury in both arms of manometer B was level when it reached the height b. Obviously with this procedure no corrections need be applied to the gas laws.

is approached and the aberrations from the gas laws of this mixture will mask any effect due to association of the molecules.

It might be argued that all the diminutions in pressure when the gases are mixed might be due to a similar cause; whether or not this is the case can be tested in the following manner. The concentration of the hydrogen chloride in the mixture is n(1-X)/2v, that of the methyl ether n(1-X)/2v, and that of the oxonium compound nX/2v; hence, if the above equilibrium between oxonium compound, methyl ether and hydrogen chloride really exists.

$$\frac{n \ (1-X)^2}{2nX} = K \tag{2}$$

where K is a constant

Substituting $\frac{Pv}{RT}$ for n

$$\frac{P(1-X)^2}{X} = 2 RTK = k (3)$$

where k is a constant at a definite temperature.

Hence X and consequently p (Eq. 1) can be calculated for various value of P and this value checked by experiment.

Table II

EXPERIMENTAL DATA AND CALCULATED AND OBSERVED VALVES OF P

Temp.	Press. HCl P ₁ mm.	Press. $(CH_3)_2O$ P_2 mm.	X Calc.	Press. of mixt. Calc. p mm.	Press. of mixt. Found	Differ- ence
18.8	756.0	756.0	0.1124		713.53	
	573.4	573.4	.0896	547.8	547.5	+0.3
	382.9	382.9	.0634	368.8	369.2	-0.4
9.2	758.0	758.0	.1472		702.2	
	557.0	557.0	.1162	524.7	524.4	+0.3
	378.7	378.7	.0848	362.65	362.7	-0.05
	218.4	218.4	.0524	212.7	212.5	+0.2
	767.8	385.5		546.1	545.2	+0.9
	382.1	758.5		540.2	539.8	+0.4

The first experiments carried out at 18.8° show agreement within experimental error between calculated values and those found. The calculation was based on the value of k at 18.8° and atmospheric pressure. See Table I.

Furthermore, the test of varying the relative proportions of the gases to be mixed was applied. In this case p can be calculated as follows.

Let P_1 equal the pressure of unmixed hydrogen chloride of which there are N_1 gram molecules in volume v_i let P_2 be the pressure of unmixed methyl ether of which there are N_2 gram molecules in volume v.

Then, if N_3 gram molecules of oxonium compound are formed.

$$\frac{\frac{(N_1 - N_3)}{(2v)} \frac{(N_2 - N_3)}{(2v)}}{\frac{N_2}{2v}} = K \tag{4}$$

where K is identical with K in Equation 2.

$$N_1 = \frac{P_1 v}{RT} \qquad N_2 = \frac{P_2 v}{RT}$$

$$(N_1 + N_2 - N_3) = \frac{2 p v}{RT}$$

$$\therefore N_3 = \frac{P_1 v}{RT} + \frac{P_2 v}{RT} - \frac{2 p v}{RT}$$

and substituting for N_1 N_2 N_3 in Equation 4,

$$\frac{(2p - P_2)(2p - P_1)}{(P_1 + P_2 - 2p)} = 2RTK = k$$
 (5)

The next series of experiments was carried out at 9.2°. The pressure change on mixing the gases (56.0 mm.) is greater than at the higher temperature and, therefore, the experimental error is correspondingly smaller. The very good agreement between calculated and observed values shows that the assumption of the equilibrium in which there is a 1:1 compound is without doubt correct⁶ and the result is not due to the mass effect of changed molecular attraction in the gas mixture.

As was mentioned above, at temperatures below -4° , the condensation temperature (boiling point) of the mixture being near, the molecular attractions play a part as well as association in causing a diminution in pressure when the gases are mixed. At -7.65° the above calculation should, therefore, not be valid because the association X is really smaller than that calculated from the diminution of pressure, and hence the diminution calculated on this basis for a lower pressure of unmixed gases will be smaller than that observed. An experiment was carried out at this temperature in which the original pressures of hydrogen chloride and methyl ether were 383.2 mm. of mercury. The pressure observed on mixing was 363.0 mm., whereas that calculated on a basis neglecting molecular attraction was 331.5.

The conclusion which may be drawn from all of these experiments is that methyl ether and hydrogen chloride form an oxonium compound, $(CH_3)_2O.HCl$, existing in the vapor state to a measurable extent even at temperatures 150° above its melting point. The compound is quite analogous to ammonium chloride which also is partly dissociated into its component molecules when it is vaporized.⁷

In the latter case, 2 polar molecules form the resultant compound. Methyl ether is not polar, that is, in the sense that the center of gravity of the positive and negative electricity is identical when the molecule is built up out of atoms to which the Langmuir or Thomson electron structure is given. Although this is in agreement with its dielectric constant, the

⁶ At 9.2° and 758.0 mm. pressure the decrease in pressure on mixing is 55.8 mm. Hence, at half the initial pressure, 378.7 mm., one might have expected half the above decrease in pressure 27.9 mm., but the decrease in pressure found was 16.0 mm. which is in perfect agreement with the calculated change (See Table II).

⁷ Smith and Lombard, This Journal, 37, 38 (1915).

stability of the oxonium compound is rather surprising. However, from the space model it can be imagined that the approach of the hydrogen end of the very polar hydrogen chloride molecule to the oxygen of the methyl ether might induce pronounced polarity in the latter. This would mean a displacement of the methyl groups and the attachment of a hydrogen nucleus to the oxygen atom quite in agreement with the electrolytic dissociation of the oxonium compound when in solution. Furthermore, the oxonium compound itself would be polar, which would account for the higher complexes² [(CH₃)₂O.3HCl] which have been isolated at low temperatures.

It will be interesting to investigate other oxonium compounds in this manner. The compound formed between ether and chlorine is particularly interesting, since in this case neither of the component molecules is itself polar in the above sense. This compound, therefore, should not be detectable in the gaseous state.

In this connection it may be pointed out that the chlorine complexes when melted are non-conductors, that is, no electrolytic dissociation occurs.

The heat of formation of methyl ether-hydrogen chloride can be calculated from the above experimental data, but this will be left until other oxonium compounds have been examined.

Acknowledgment is hereby made of a scholarship granted during the time of this research by the Honorary Advisory Council for Scientific and Industrial Research of Canada.

Summary

Equal volumes of methyl ether and hydrogen chloride were mixed in the gaseous state at atmospheric pressure and the resultant pressures recorded over the temperature range 30° to -10°. From these data the amount associated to form the oxonium compound, (CH₃)₂OHCl, was calculated, and the resultant pressures on mixing these gases, at pressures other than atmospheric and in unequal proportions, were deduced. These latter were checked by observation, thus proving the original assumption to be correct, namely, that a 1:1 compound exists in the vapor state, the dissociation of which increases with rising temperature.

The similarity between methyl ether-hydrogen chloride and ammonium chloride has been pointed out and the formation of the former attributed to induced polarity in the methyl ether molecule caused by the polar hydrogen chloride molecule.

THE SYSTEM, LEAD-ANTIMONY

By R. S. DEAN Received May 3, 1923

Introduction

The equilibrium in the system, lead-antimony, because of the commercial importance of this series of alloys, has been the subject of a very considerable number of investigations. The conclusion reached in most of them and generally accepted in all the recent handbooks and texts¹ is that neither solid solutions nor compounds are formed at least in the alloys rich in lead.

The earliest investigation of the system seems to have been made by Roland-Gosselin2 who found by thermal investigations that the system was a simple eutectiferous one with the eutectic containing about 12.5% antimony and melting at 228°. This eutectic temperature was checked roughly by Ewen.3 Stead,4 however, in a thermal and microscopic examination of the system found a eutectic temperature of 247°, but his microscopic examinations confirmed the earlier conclusion that the system was simple eutectiferous. Campbell⁵ with very little further data accepts Roland-Gosseliu's results. In 1907 Gontermann⁶ reviewed the conflicting data and made a very careful thermal investigation of the system. In general his results checked those of Stead. It is to be noted, however, that with allows above 13% Gontermann obtained two arrests for the eutectic point. He explained this as a matter of crystal size, which explanation, however, has been questioned by Guertler who leaves the facts unexplained. Gontermann further found no detectable arrest in the cooling curve for 1% antimony alloy, but since his microscopic examination of the specimens showed dendrites he discarded the possibility of the formation of solid solution. The later investigations of Loebe⁷ and of Leroux8 have agreed quite closely with those of Gontermann.

A number of investigations of the physical properties of the lead-antimony alloys have been made from which conclusions have been drawn regarding the equilibrium. The potential of the lead-antimony series has been studied by Puschin⁹ who found that all alloys had the same potential as lead which he interpreted to mean that neither solid solutions nor compounds were formed. The electrical conductivity of the series has been

investigated by Mathiessen¹⁰ who found a break in the curve at the composition corresponding to the formula PbSb. His figures near the lead end are too far apart to allow any conclusions to be drawn concerning the formation of solid solutions. The conductivity of liquid lead-antimony alloys has been investigated by P. Muller¹¹ and no evidence is found of a compound existing in the liquid state. The specific heat of the lead-antimony alloys has been determined by R. Durrer¹² who found that at constant temperature the specific heat was a linear function of the concentration, indicating no compound or solid solution formation. The hardness of lead-antimony alloys has been investigated by Saposhinkow and Kanewsky¹³ who concluded that neither compounds nor solid solutions were formed.

In a recent investigation Ludwick 14 finds that the hardness of annealed alloys varies smoothly with the antimony concentration up to 8%, the highest concentration investigated. However, when the 2% alloy is annealed it increases sharply in hardness, but no great change is produced in the others by this treatment. Ludwick does not offer any explanation of this but it would appear to indicate the formation of a solid solution up to about 2% of antimony. The most recent investigation of these alloys is that of Gurevich and Hromatko 15 who find the maximum tensile strength in an alloy containing 10% of antimony.

Our interest in the lead-antimony system was from the standpoint of the manufacture of cable sheath and we were, therefore, particularly concerned with alloys containing up to 2% of antimony. It is obvious that in an extrusion process the temperature of working must not be above the melting point of any of the constituents of the alloy but on the other hand it is advantageous to use as high a temperature as possible, as the plasticity of metals approximately doubles for every 10° rise of temperature. Accordingly, the maximum extrusion temperature for lead-antimony cable sheath depends on the equilibrium near the lead end of the system. The present investigation was, therefore, made with a view to determining the equilibrium in the low-antimony alloys; however, in the course of the investigation it was found desirable to extend it less completely to alloys containing about 13% of antimony.

Investigation

The Solidus Curve of Lead-Antimony Alloys.—The method adopted for the study of the low-antimony alloys was based on the differential heating curve. A small cylinder of pure lead was used as the neutral body which was connected with a similar cylinder of the alloy under test by a copper-constantan thermocouple. The differential e.m.f. was measured on a high sensitivity galvanometer so arranged that its sensitivity was about 70 mm. of scale per microvolt. The actual temperature for the furnace was determined by means of a copper-constantan thermocouple and a

small potentiometer and was accurate to 0.5° . This apparatus, although laborious to operate, probably gave as accurate results as could have been obtained with a recording instrument. The rate of heating was such that a temperature of 300° was reached in about 2 hours. Some of the results of these experiments are shown in Fig. 1, corrected for the calibration of the thermocouple made at the melting points of pure tin and lead. The unannealed alloys show a eutectic arrest at 258° even when only 0.5% of antimony is present, but a few hours' annealing causes the disappearance of this arrest in alloys containing up to 2%. The 2% alloy becomes free from thermal evidence of the presence of the eutectic only after 200 hours' heating at 235° , and in the 3% alloy the eutectic still persists after this time. The evidence from these heating curves would then indicate that

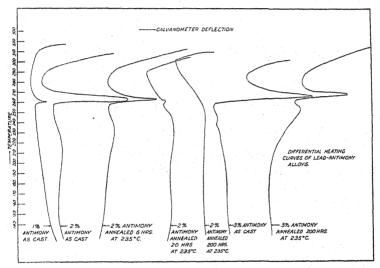

Fig. 1

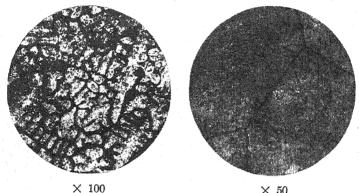

as much as 2 to 3% of antimony dissolves in lead when sufficient time is given. This slowness of attaining equilibrium is also characteristic of the lead-tin alloys as has been found by Rosenhain and Tucker.¹⁶

Microscopic Examination.—Microscopic examination confirms the findings of the thermal analysis in every respect. The eutectic which is present in the unannealed alloys disappears on annealing the alloys containing 2% of antimony or less. Fig. 2 shows micrographs of the 2% alloy before and after annealing. The etching is with silver nitrate and nitric acid. These microphotographs themselves would seem almost sufficient evidence for the formation of solid solutions in this system.

The Liquidus Curve of the Lead-Antimony Alloys and the Possibility of Compound Formation.—In order to have further data on the

¹⁶ Rosenhain and Tucker, Trans. Rov. Soc., 209, 89 (1908).

freezing-point curve of lead-antimony alloys to supplement those of Gontermann, for the purpose of drawing the complete equilibrium diagram, several determinations were made. The apparatus consisted of an electric crucible furnace in which was placed a crucible of alloy, the temperature of which was determined by means of a mercury thermometer calibrated in freezing lead and tin, and compared with the thermocouple used in

× 100 × 50

1.3			305		
1.8			300		
2	313	245	292		
3.0	305	245	258		
4.0	301	247			
10.4	255	247			
11.0			258		
12			258		
12.5		247			
13	252	245	253		
16	272	245			

There is a difference of several degrees between the positions of the solidus as determined by the cooling and heating curves, respectively.

The eutectic temperature from the cooling curves agrees well with that of Gontermann, namely, 245-246°, but the eutectic temperature on heating is

10° higher. In order to be certain of the reality of this hysteresis, both a heating and a cooling curve were obtained by use of the differential apparatus and a 3\% antimony alloy. The resulting curves are shown in Fig. 3 and leave no doubt as to the existence of the hysteresis. Our work has not been carried far enough to offer a complete explanation of this phenomenon. The equilibrium diagram shown in Fig. 4 shows our tentative interpretation of the results. The diagram assumes the formation of a compound Pb₄Sb containing 12.6% of antimony which forms an eutectic with its solid solution in lead at 10% antimony. The data are not sufficient to fix these points accurately, however. This compound, forms very slowly and when the mixture is cooled is not formed from the liquid but from the solid eutectic between antimony and solid solution. As a result of the reluctance of this compound to form,

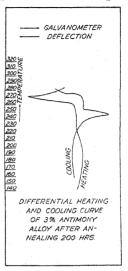

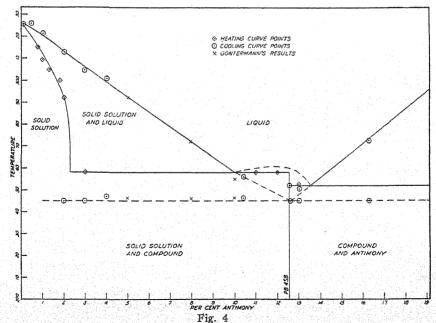

Fig. 3

the system as it cools behaves as if it were an antimony-solid-solution eutectic, and hence freezes at 247°. When this is heated the compound forms and the melting point is the eutectic point between compound and

solid solution at 258°. Mazzotto's explanation¹7 of a similar hysteresis in the lead-tin eutectic is that the eutectic supercools with relation to the separation of tin. A similar supercooling with relation to antimony does not seem to be the explanation of our results, since the freezing point is not raised by seeding.

My thanks are due to Mr. G. S. Rutherford in charge of the Chemical Division for his interest and cooperation in this work.

Summary

Investigation by means of differential heating curves and microscopic examination has shown that antimony is soluble in solid lead up to between 2% and 3% of antimony at the eutectic temperature.

The alloys containing up to 13% show a higher eutectic temperature on heating than on cooling. A suggestion for the interpretation of this is made and a tentative equilibrium diagram drawn.

This investigation is being carried further to determine the solubility curve for antimony in lead at temperatures below the eutectic and to obtain further data on the possible existence of a compound in the system.

CHICAGO, ILLINOIS

[Contribution from the Chemical Laboratory of Harvard University, and the Fixed Nitrogen Research Laboratory]

ANALYSIS OF HYDROGEN FOR TRACES OF NITROGEN¹

By R. L. Dodge Received May 7, 1923

The usual method for the determination of hydrogen in a mixture of gases by combustion over copper oxide has been modified and applied to the determination of traces of nitrogen in hydrogen. The details of the modified procedure are described in this paper. This procedure was employed in the analysis of hydrogen used for some special tests on ammonia catalysts. It is also useful for the analysis of hydrogen which is to be liquefied, since traces of nitrogen interfere materially with the liquefaction.²

Briefly, the method consists in burning large amounts (12–20 liters) of hydrogen over heated copper oxide in an evacuated system, circulating the residual gases over copper oxide to insure complete removal of the hydrogen, collecting the residual unburned gases (designated as nitrogen), and measuring them by the usual gas volumetric method. The volume

- ¹⁷ Mazzotto, Intern. Z. Metallog., 2, 269 (1911).
- ¹ The expenses of this investigation were in large part defrayed by the United States Fixed Nitrogen Research Laboratory,
- ² Dr. C. W. Kanolt of the Bureau of Standards, Washington, D. C., in connection with his study of the liquefaction of hydrogen, developed, subsequent to this work and independently of it, a similar procedure.

of hydrogen burned is calculated from the volume of water formed by the combustion.

Apparatus.—The apparatus is shown diagrammatically in Fig. 1.

The combustion tube A is of Pyrex glass, approximately 34 cm. long and 25 mm. in internal diameter, and contains about 350 g. of copper oxide.³ The heating is accomplished by means of the external resistance heater B. A Pyrex glass buret C, immersed in ice water, serves to collect the water formed by the combustion. Connection to the rest of the apparatus, which is of soft glass, is made through the ground glass joint (x, y). The bulb D (about 300 cc.) and stopcocks (d, e) make possible the circulation of the residual gases through the copper oxide to insure complete combustion of the hydrogen. The stopcock (c) controls the rate of admission of the hydrogen to the combustion system. The Töpler pump F serves to evacuate the combustion system. The McLeod gage J indicates the degree of evacuation. The gases removed by the Töpler pump are collected and measured in the water-jacketed buret G. H is a phosphorus pentoxide tube for the absorption of the traces of water uncondensed in the buret C.

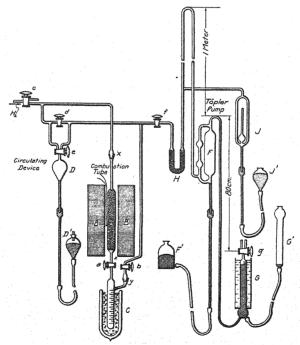

Fig. 1

'Procedure.—The hydrogen to be analyzed is dried and admitted through the Cock c to the combustion system, which has previously been evacuated to a pressure of 0.01 mm. of mercury.⁴ During the combustion,

³ A great excess of copper oxide is necessary, since reoxidation after an analysis is slow. The reoxidation is accomplished by heating the material to about 400° in a current of oxygen.

4 When both the initial and final evacuations are carried to the same point, errors due to incomplete evacuation are negligible.

Cocks d and f are closed. The rate of admission of the hydrogen is limited by the temperature of the combustion in the copper oxide tube, which should not exceed 400°, as above this temperature metallic copper forms a slag with Pyrex glass. Care must be taken to maintain a pressure in the hydrogen supply line greater than atmospheric to avoid inadvertent contamination of the hydrogen with air.

After a sufficient amount of hydrogen has been burned, as indicated by the water collected in the buret C, Cock c is closed and the gases remaining unburned in the combustion system are circulated through the copper oxide tube and buret by manipulation of the leveling bulb D' and the 3-way cock (e). Warming the combustion tube at z during the circulation insures transfer of all condensed water to the buret.

When continued circulation causes no further diminution in volume of the residual gas (indicated by using the bulb D as a rough McLeod gage) Cocks a and b are shut and d and f opened. The residual gas is then pumped into the water-jacketed buret G, where its volume is measured.

An error of 0.05 cc. in the volume of nitrogen causes an error of about 0.0005% in the percentage of nitrogen. An error of 0.01 cc. in the water formed causes an error of about one part in 200 in the actual percentage of nitrogen or, with a nitrogen content of 0.5%, an error of 0.002%.

The nitrogen lost by solution in the water formed during the combustion is, for an apparatus of this size, less than 0.04% of the total nitrogen.

The nitrogen left in the free space of the water buret is less than 1% of the nitrogen collected. This is within the limit of accuracy of the method for hydrogen containing less than 0.5% nitrogen. In using the method for hydrogen containing more than this amount of nitrogen, it is advisable to open the water buret to the combustion system for an instant after the first removal of the nitrogen and to collect this additional nitrogen by a second evacuation.

Results.—The method was standardized by analysis of "pure" hydrogen. This gas was generated in a modified form of Edwards' hydrogen generator⁵ from c. p. air-free sulfuric acid and c. p. mossy zinc. The generator was equipped with mercury-sealed stoppers and was evacuated before the acid was admitted. A 50% excess of zinc was used. The results of the analysis are given in Table I.

The analyses of "pure" hydrogen indicate that any errors due to liberation of incombustible gas by reduction of copper oxide or by solution of the zinc and the acid of the generator are less than 6 0.005%.

⁵ Edwards, J. Ind. Eng. Chem., 11, 961 (1919).

⁶ Auxiliary experiments show that the gas liberated by the copper oxide on solution in acid is less than 0.5 cc. for every 90 g. of CuO, this being the limit of accuracy of the determination. It is probable that the actual value is considerably below this. See Richards, *Proc. Am. Acad.*, 26, 276 (1890).

^a That is incombustible gas, unadsorbed by cuprous ammonium chloride or potassium hydroxide; it may contain argon and other inert gases.

^b The hydrogen supply line was under less than atmospheric pressure for a short time allowing possible contamination of the hydrogen with air.

"Special" hydrogen was taken from a commercial tank which had been filled as nearly as possible directly from electrolytic cells, special precautions being taken to remove all air from compressors, lines and tank before filling. It is probable that 0.04% represents the minimum percentage of inert constituents in commercial electrolytic hydrogen.

"Ordinary" hydrogen was taken from a commercial tank chosen at random.

In conclusion the author wishes to express his appreciation for the valuable assistance of Professor Arthur B. Lamb, under whose supervision this work was conducted.

Summary

A modification of the usual method for the determination of hydrogen by combustion over copper oxide has been devised and applied to the analysis of hydrogen for traces of nitrogen.

Large quantities of hydrogen (12–20 liters) were burned by circulation over heated copper oxide in a previously evacuated system and the hydrogen determined by measuring the water formed. The residual nitrogen was pumped off and measured.

The method is accurate to 0.005%.

THE DESIGN AND USE OF CONDUCTANCE CELLS FOR NON-AQUEOUS SOLUTIONS

By J. Livingston R. Morgan and Olive M. Lammert Received May 11, 1923

Introduction

In the course of an investigation involving the precise measurement with non-platinized electrodes of the electrical conductance of solutions in non-aqueous solvents, it has been found necessary to take certain precautions in the selection and use of the conductance cell. Since the difficulties necessitating such precautions are those which would be encountered by others attempting to determine the conductance of non-aqueous solutions within the range from 2×10^{-3} to 2×10^{-7} reciprocal ohms, with an accuracy of 0.1% or less, the experimental method followed is given in some detail.

Washburn¹ from the theory of the Wheatstone bridge, has derived equations relating for aqueous solutions the minimum allowable area of the cross section between the electrodes and the distance between them; Taylor and Acree² have taken up in some detail the difference in the results obtained using non-platinized electrodes with varying frequency and voltage, and have given an experimental criterion for good cells; Schlesinger and Reed³ have also emphasized this point; Haworth⁴ investigating the variation of the resistance with frequency, using a different type of Wheatstone bridge, has confirmed Taylor and Acree's results, as have also Kraus and Parker.⁵

It is the object of this paper to correlate the work of these previous investigators with the results of this research in the hope that the cell design and technique developed will give comparable results from all different investigators working with non-platinized electrodes.

Bridge Assembly.—The bridge assembly was made up of standard commercial instruments of the usual type now recommended for precision work; the source of current was a Vreeland oscillator operating at a frequency of either 500 or 1000; the roller-type of Wheatstone bridge was used, and 2 dial resistance boxes, the smaller 1, 10 and 100 dials, bifilar wound with an aggregate resistance of a thousand ohms, and the larger a 1000- and 10,000-dial box of the Curtis⁶ type; 2 variable air condensers were employed with a maximum capacity of 0.005 mfd. and 0.00125 mfd.,

respectively. The telephone was a Baldwin head piece, Type F, with an impedance of 2000 ohms.

Both bridge and resistances were calibrated in the Ernest Kempton Adams Precision Laboratory using direct current and a D'Arsonval galvanometer; the resistances by direct comparison with resistances calibrated at the Reichsanstalt loaned by the Columbia University Department of Physics; the bridge by the Kohlrausch method.⁷

A water-bath regulated at $25^{\circ} \pm 0.002^{\circ}$ by the method of D. J. and J. J. Beaver* was used for most of the work. An oil-bath regulated in the same way was used for the higher resistances when necessary.

The usual grounding and shielding between different parts of the apparatus and of the leads was used. Furthermore, the Vreeland oscillator, which was in the same room but at some distance from the assembly, was shielded and the shield grounded in such a way that no stray currents could be heard in the telephone. The bridge was placed close to the baths with the leads of such length in either arm of the set-up that no lead correction was necessary, the leads being connected to the cells in the way recommended by Washburn.

Comparison Solutions.—The first difficulty encountered in this work was the lack of a suitable solution for comparing the cell constants, one with the other. In any work requiring more than one conductance cell, liquids for the purpose of comparing the relative constants of the cells are as necessary and important as the standard solution employed to find the absolute constant of any one of them. The customary method of simply diluting with water the liquid used for calibrating the cell was found to be unsatisfactory, for the solutions would have to be so dilute $(0.0002\,M)$ as to make it difficult to keep them free from contamination in handling as well as in measuring in glass cells.

The most convenient and satisfactory comparison solutions we have found are those obtained by diluting the calibrating solution of potassium chloride with 95% alcohol. Such a solution was forced into the cell by a pressure of purified air. The air, furnished by a water pump and purified by passage successively through solutions of sulfuric acid, potassium hydroxide, through water, and through soda lime, was then bubbled through some of the alcoholic solution of like concentration to give it the same pressure of vapor there as in the air above the solution. By filling the cell, in this way conductances of the same solution could be duplicated exactly throughout the entire range.

Variation of Resistance with Frequency.—Taylor and Acree have found with bare platinum electrodes (1) that the difference in the resistance

⁷ Kohlrausch and Holburn, "Leitvermögen der Elektrolyte," Leipzig, B. G. Teubner, 1898, p. 47.

⁸ Beaver and Beaver, J. Ind. Eng. Chem., 15, 359 (1923).

of a solution at frequencies of 1000 and 600 decreases as the diameter of the electrode increases, (2) that for a given electrode this difference decreases as the resistance of the solution increases from 11.492 to 534.4 ohms, (3) that the resistance of a cell decreases as the frequency is increased from 60 to 2000 cycles. To obtain then the "true electrical resistance" of the solution the authors suggested one of the following methods: (1) an extrapolation of the resistances to infinite frequency, which involves the measurement of each resistance at several frequencies; (2) the use of their extrapolation formula in terms of resistance, frequency and inductance, which necessitates the use of standard inductances or capacities; (3) an increase in the size of the electrode to at least 25 mm., preferably to 50 mm., at the same time with a construction of the cell and a method of using such that the resistance of the solutions measured in that cell is above a certain minimum.

The first two methods call for inconvenient experimental procedures and calculations; the third method possesses the advantage that any necessary alterations in the design of the cell or any restrictions, which must be placed on the resistance of the solutions measured in the cell, can be made once and for all at the beginning of the research. The subsequent determinations involve no more labor than when platinized electrodes can be used. Furthermore, if by simply fixing the minimum resistance to be measured in a given cell, small electrodes can be used, the

economy of both platinum and solution possible would certainly justify any attempt to use such a method.

Therefore, since of all the cells on the market the Washburn Types A and B were the most carefully designed and capable of giving the range of conductance we needed with the minimum volume requirement and exposure of the solution to the air in transferring, an investigation was undertaken to determine for each cell a minimum resistance, above which the difference in the result due to frequency would be negligible. Taylor and Acree made no measurements above 534.4 ohms at 1000 cycles, but estimated that in general above 10,000 ohms the resistance measured at 1000 cycles would not differ from the true resistance by more than 0.01%. In Table I are values, each an average of a number of readings, for the resistance in ohms at 1000 and 500 cycles and the differences between these values, in percentage of the value of 1000 cycles. Cells 2, 4, and 6 are of Type B, Nos. 2 and 4 with a range at 10^{-4} to 10^{-6} reciprocal ohms, No. 6 with a range of 10^{-3} to 10^{-5} reciprocal ohms. Cell 3 is of Type A with a range of 10^{-6} to 10^{-7} reciprocal ohms.

While these data show that for Cells 2, 4 and 6 the differences in resistances at the two frequencies are comparable to the values obtained by Taylor and Acree, in the range covered by these investigators, for their 13 mm. bright electrodes, these differences do not decrease continuously in the manner predicted, but pass through a minimum between 5000 and 10,000 ohrus. That this phenomenon is not peculiar to any one cell or solution but to the size of the electrode is shown by the fact that when three different types of solutions are used in all 3 cells having the same size electrodes, the results are similar. That it is due to some cause inherent in the cell and not in the assembly is shown by the results obtained with Cell 3. In this case, with the larger electrodes, the differences are smaller throughout the entire range and do not increase above 10,000 ohms. The slight irregularities in these differences can readily be attributed to the difficulty in taking the readings at 500 cycles during the day, since the telephone was not tuned particularly to this frequency.

Apparently then, for cells having bare platinum electrodes, there is, for a maximum allowable error, no mimimum resistance above which a given cell may be used, but an optimum range of resistances throughout which the differences in resistance with differences in frequency may or may not, depending on the size of the electrode, be small enough to come within this limit of error. As the size of the electrode increases (at least up to 50 mm.) these differences in the resistances throughout this optimum range become smaller, and the range throughout which the cell may be used becomes larger. In other word, to choose the cell so that the resistance of a solution in it is large does not give the same results experimentally as to increase the size of the electrode and reconstruct the cell.

At very high resistances, 90,000 ohms or over, with Cell 3 in the waterbath, there was observed on some days a decrease in resistance at 500 cycles. When measured in an oil-bath this decrease disappeared and the usual slight increase was noted. At lower resistances, however, no differences in resistance of a cell in a water-bath or an oil-bath could be observed. Evidently this phenomenon is due to the capacity effects prevalent when a high resistance is measured in a water-bath. Since this effect was not always the same in the same laboratory and could conceivably be quite different in different laboratories, depending upon the grounding facilities, etc., Washburn's suggestion¹ that in the design of a conductivity cell a maximum resistance of 10⁴ ohms should be imposed when possible seems especially pertinent.

Throughout the work the capacities were measured and found to be greater at 500 than at 1000 cycles, but as the difference in the resistance at the two cycles increased the difference in the capacity decreased. Inasmuch as the condensers were of the type used to balance out capacity in the cell and were not standardized, the actual values are qualitative and are therefore not given.

Cell Design.—Since the only conditions imposed upon the use of Washburn's simplified Equation 4 in place of Equation 3 are that the

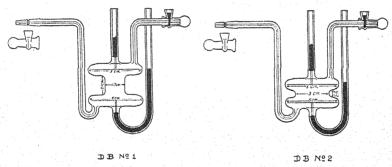

Fig. 1

specific conductance L^- shall not be less than 10^{-7} reciprocal ohms, the maximum resistance R not greater than 10^5 ohms, the frequencies not greater than 1000 cycles and the dielectric constant of the liquid not greater than 80, there was no reason why, for the non-aqueous solutions to be measured, the Type B cells could not be used, except for the fact that, due to the small size of the electrodes, the resistance at 1000 cycles is not the true resistance of the solutions. From Taylor and Acree's values and from the results with Cell 3 with electrodes 38 mm. in diameter, which showed that although there was a decided decrease in the difference at two frequencies this difference was not entirely eliminated, it was assumed that this error would probably be negligible were the diameter of the elec-

trodes increased to 50 mm. Accordingly, since the size of the electrodes was fixed, calculations were made by Washburn's Equations 24 and 25 to determine the dimensions of the construction between the electrodes.

The cells and their essential dimensions are shown in Fig. 1. The circular, sand-blasted electrodes were made of platinum 0.15 mm. thick with a rod 1.0–1.5 mm. in diameter securely welded to the center of the disc. The cells were of Jena glass. Since the solvents used were hygroscopic and volatile, the arms of the cells carried the mercury seals shown in the figure. Cell DB No. 1 has a cell constant approximately 1.39 and can be used for 0.02 N potassium chloride solution with a resistance of approximately 500 ohms. With 400–500 ohms minimum resistance there can be no errors due to the measurement at any one frequency, and only air condensers are needed. Cell DB No. 2 overlaps the range of Washburn's Type A cell and Cell DB No. 1, although the resistance does not fall below 500 or rise much above 10⁴ ohms. Unless extreme precision is desired, Washburn's Type A cell can be used with roughened or sand-blasted electrodes, although an increase in the diameter to 50 mm. would be an improvement.

Solutions having resistances ranging from 300 to 60,000 ohms were measured in both of the new cells. Since there was no difference in the resistance with the change in frequency to 500 cycles the resistance measured at 1000 cycles was assumed to be the true resistance of the solution.

The Methods of Cleansing and Drying Cells.-Little attention has been given by previous investigators to one factor which, in this Laboratory, has been found to be of the greatest importance, namely, the history and treatment of the electrodes previous to their use. Taylor and Acree² found that unless their cells were "scrupulously clean" the resistance of a filled cell varied with a change in voltage. This fact they used as a criterion of cleanliness, but suggested no method for either cleaning or drying. Possibly, since they used water solutions, they did not dry their cells before filling but rinsed them with successive portions of the solution to be measured. Such a procedure is almost impossible with hygroscopic solvents, however, and at best is wasteful of the liquids which are usually expensive and purified with difficulty. Kraus and Bishop¹⁰ also reported some trouble in checking their values for amyl alcohol when they used a cell that was dried after being steamed, but they gave no practical method for obviating the difficulty. In our own experience, when the cells were cleaned with chromic acid mixture, steamed, or rinsed with hot conductivity water, and then dried with warm, purified air either directly or after rinsing with redistilled alcohol, the values for the resistance of a given solution varied so capriciously and the variations were of such magnitude that quite

⁹ These cells were made by Mr. H. O. Morgan of Eimer and Amend.

¹⁰ Kraus and Bishop, This Journal, 44, 2206 (1922).

evidently the greatest source of error in the conductance method lies in the pre-treatment of non-platinized electrodes.

Since the discrepancy among results with any one solution was more apparent when the measurement was made in cells with electrodes near to one another, a series of determinations was made in which various methods of cleaning and drying Cells 3 and DB No. 2 were employed to discover if possible the cause of the error and, in any case, a method for the preparation of the cell that would give results consistent with those obtained when the cells were not dried but were rinsed with the solution. In the failure to develop such a method errors arising from the factors discussed in the foregoing sections of this paper are of little moment, as the error from this source alone frequently rises as high as 2 to 3%. The following is typical of the behavior of the 2 cells when the same solution is measured in both.

Cells cleaned with chromic acid-mixture, thoroughly rinsed with hot conductivity water and, without drying, finally rinsed with the solution to be measured, and allowed to stand for 1 hour after filling. Resistance: Cell DB No. 2, 11799 ohms; Cell 3, 801 ohms.

Cells cleaned with chromic acid, rinsed as before, and dried by passing purified air through them; the same solution was used and the cells were allowed to stand for I hour after filling. Resistance: Cell DB No. 2, 11940 ohms; Cell 3, 816 ohms.

After cleaning, etc., the cells were allowed to stand for 24 hours. Resistance: Cell DB No. 2, 12158 ohms; Cell 3, 815 ohms.

The same cells were allowed to stand for an additional 12 hours. The resistance of the cells decreased because of movement of cell or lead but finally became constant. Resistance: Cell DB No. 2, 12112 ohms; Cell 3, 815 ohms.

The cells were refilled without cleaning or drying them. Resistance: Cell DB No. 2, 11805 ohms; Cell 3, 801 ohms.

The cells were cleaned with chromic acid mixture, rinsed and dried as before and allowed to stand for 1 hour after filling. Resistance: Cell DB No. 2, 11860 ohms; Cell 3, 812 ohms.

The cells were refilled without cleaning or drying them $^{1}/_{2}$ hour after the previous measurement and allowed to stand for 1 hour after filling. Resistance: Cell DB No. 2, 11780 ohms; Cell 3, 797 ohms.

The cells were refilled 1 hour after the previous measurement, and allowed to stand for 1 hour after filling. Resistance: Cell DB No. 2, 11775 ohms; Cell 3, 799 ohms.

The same cells were again refilled, 2 hours after the previous measurement, and allowed to stand for 1 hour after filling. Resistance: Cell DB No. 2, 11774 ohms; Cell 3, 799.55 ohms.

The cells were thoroughly washed with hot conductivity water. Treatment with cleaning mixture was omitted. Resistance: Cell DB No. 2, 11843 ohms; Cell 3, 803 ohms.

These results and others, of which these are typical, show that without a doubt the treatment of the cells with cleaning mixture was responsible for a considerable part of the error. Kohlrausch¹¹ has discussed the difficulty in measuring the conductance of solutions of acids and bases

¹¹ Ref. 7, p. 10.

with bare platinum electrodes due to the apparent absorption of the solute by the electrodes from stronger solutions, and the gradual liberation of the absorbed material to water and to the more dilute solutions. were this the only effect of the cleaning mixture in the case at hand the values for the resistances following such treatment should be lower, since the solution of material from the electrodes would increase the conductance of the solution between them. Furthermore, there should be no difference among values for wet or dry cells. Invariably in our work when a dry cell was used, the resistance of the solution was higher than the value in a wet cell, well rinsed. When the dried cell was immediately refilled without further cleaning or drying, the results were at first always too low, but on further refillings gradually rose to the normal value of the undried, rinsed cell. When the solution was left standing in the cell for 24 hours or more, the reading after the first refilling assumed its normal value. Were it not for the anomalously but uniformly high value obtained on the first filling of a dry cell, these data would seem to indicate the occurrence of phenomena similar to those observed by Kohlrausch.

The general theory underlying the measurement of an electrolytic cell by the Wheatstone bridge method is that when the cell, acting as a resistance and a capacity in series and shunted by a condenser in one arm, is balanced in the other arm by a pure resistance, shunted by an air condenser until no current flows through the telephone, the drop of potential along one half of the bridge is equal to the drop of potential along the other half, and therefore the resistances are equal. It is only, then, when there is a definite relationship between the resistances, the capacity and inductance, the drop of potential, and the current in one arm of the bridge to that in the other, that silence in the telephone can be obtained. A change in any one of these factors would cause a loss of balance in the bridge. In the present situation the only possible change is in the conductance cell itself, since the bridge assembly is identical for all the measurements.

In the cell the pure resistance is made up of the resistance of the solution and the small resistance of the electrodes both of which are constant for any one cell and solution. The capacity effects in a cell are assumed to be due to polarization and are dependent upon the area of the electrodes, the resistance of the solution between them and the frequency of the current. These also remain constant under the given conditions.

The only possibility remaining which would account for an unbalancing of the bridge network, otherwise in resonance, would seem to be that the cell filled with the solution in itself acts as a source of current. In this event the process of cleansing and drying the cells must in some way have so affected the electrodes that they are no longer similar pieces of the same metal dipping into the same solution but in effect two dissimilar electrodes

giving a potential difference across the terminals of the cell. In reality, then, we seem to be measuring, instead of a resistance and a capacity, a voltaic cell, the potential difference of which depends upon the difference in effect on the two electrodes of the pre-treatment, which in turn depends upon the difference in the specimens of platinum comprising each electrode and in the time and methods of pre-treatment.

If this is, indeed, the correct explanation of the abnormal behavior of the dried cells, the problem becomes one of finding how to bring the electrodes to the same potential after they are immersed in the liquid, and at the same time keep the resistance of the solution the same, or how to clean and dry the electrodes so that the potential difference of each in contact with the liquid is the same in the first place.

Accordingly, to determine whether it was possible to bring the electrodes to equilibrium after they had been treated with chromic acid and dried, the cell was filled and the electrodes short-circuited overnight, but no change in the measured resistance was observed. Without breaking the connection between the electrodes, the cell was cleaned with cleaning mixture, rinsed, steamed for several hours, rinsed with hot conductivity water and allowed to stand filled with water for several days. The cell was then rinsed with redistilled alcohol and dried. With the electrodes still connected the cell was filled with some of the same solution and allowed to come to temperature equilibrium in the bath. The short circuit was then removed, the lead wires put in place and the following readings taken. Resistance: Cell DB No. 2, 11785 ohms; Cell 3, 801 ohms.

The cells were then allowed to stand with the electrodes on open circuit, when the resistance began to rise. Resistance: Cell DB No. 2, 11795 ohms; Cell 3, 803 ohms.

The connecting wire was then again replaced and the filled cells allowed to remain in the bath overnight. The next morning the readings were the same. The cells were then refilled without drying or rinsing. Resistance: Cell DB No. 2, 11760 ohms; Cell 3, 799 ohms.

Of a number of such determinations made by cleaning and drying the electrodes, connected or unconnected, only those gave results approaching the normal value that were made after the electrodes had been connected throughout the entire process of cleansing, drying, filling, and attainment of temperature equilibrium. As this method seemed a possible solution to our problem, a systematic series of determinations was made on another solution to see what variations in the method were possible and how often the cell could be used by simply rinsing with alcohol and drying between refillings. In the interests of economy of space the results are summarized in the following statement.

The variations in the results are greater with Cell 3 than with Cell DB No. 2, and greater with Cell DB No. 2 than with Cell DB No. 1. In fact, no difference could be observed when Cell DB No. 1 was used even when the chromic acid cleansing was followed only by the thorough rinsing with conductivity water before drying, while with Cells DB Nos. 2 and 3 variations of the same order of magnitude as in the typical data given above were observed. When the electrodes were short-circuited during

the treatment with the cleaning mixture the discrepancies were reduced to about 1/4 of those observed when the cell was cleaned with the electrodes on open circuit; similar differences were noted when the cells were steamed, large errors being obtained if the cells were dried after steaming with the electrodes on open circuit. When the cells with the electrodes on open circuit were rinsed with hot conductivity water, without previous treatment with chromic acid mixture, the results with Cell DB No. 2 were usually normal but those with Cell No. 3 showed variations of 0.2-0.5%. It was only when the electrodes were short-circuited throughout the entire process of cleansing, drying and filling that consistent values for the resistance of a given solution were obtained in all cells. Furthermore, as soon as the short circuit was broken the resistance began to rise; when the connection was replaced the reading became constant. Evidently the electrodes prepared in this way are under some sort of a strain which is relieved by their taking up some of the solute from the solution when the current is broken. On refilling the cell after such adsorption has taken place without rinsing or drying, the next result is invariably too low, just as in the first experiments given in this section after the treatment on open circuit of the electrodes with cleaning mixture. This would seem to indicate that the adsorbed material was given back to the next solution. When the circuit was left open too long in taking a series of readings consistent results for the next refilling were not given by the usual procedure of short-circuiting, rinsing with alcohol and drying. In such a case, filling the cell with hot conductivity water and allowing the electrodes on open circuit to soak overnight seemed to relieve them of the adsorbed material and the cell could then be employed as usual with success.

The number of continuous determinations possible with only a thorough rinsing with alcohol and drying between refillings seemed to be contingent on the length of time the electrodes were left unshorted during measurement. When great care was taken in this respect the cells could be used all day for several weeks, particularly when they were soaked overnight in conductivity water and kept free from atmospheric contamination. With a cell of the pipet type, which does not permit much movement of the contained liquid, our criterion for the equipotentiality of the electrodes was the constant value obtained on moving the leads or the cell sufficiently to change the position of the solution between the electrodes. With cells of the bottle type, however, there is a constant mixing of all parts of the solution possible; whether the final result is burdened with an error can be determined only by a previous rigid examination of the cell with a known solution to determine what treatment is necessary to make the cell usable.

All in all, then, the term "clean" applied to conductance cells made up with bare electrodes takes on a new meaning, involving the attainment of electrodes which will act as similar pieces of the same metal toward a solu-

tion, and the maintenance of such a state of equipotentiality throughout the time required for the measurement of the resistance of the solution. The following procedure is recommended for the "cleansing" of the cells. The electrodes, during the entire operation, are connected by a heavy copper wire dipping into the mercury cups. The cell is then filled with hot cleaning mixture and allowed to stand for a few minutes, rinsed thoroughly with distilled water and finally filled with hot conductivity water: it is then steamed by allowing the steam to pass up through the water: this permits enough steam to condense so that in time the water that has been in contact with the electrodes is automatically siphoned off. The steaming is continued for several hours, after which the cell is filled with hot conductivity water and the outlets closed. After it has been allowed to stand overnight, the cell is rinsed with alcohol, dried with a current of warm purified air, and filled at once with the solution to be measured. Only when the actual readings are being taken must the short circuit be broken; it should be replaced between check readings. Whenever the cell is not in use it should be filled with hot conductivity water and tightly closed to keep the water as free as possible from contamination. This method has been found infallible with the 3 cells used; nevertheless, there seems still to be present an element of caprice, for some determinations made on another Washburn cell of the same type as Cell 3, and purchased at the same time, gave very unreliable results. In the first place, it was difficult to check the readings even when the cell was not dried; in the second place, extreme precaution was needed to obtain any sort of consistent results with dried cells; and in the third place, only a few refillings could be made before it was necessary to subject the cell again to a most rigorous cleansing process. With the possible variations in any one piece of a metal and the still greater possible variations in pieces from different sources it is to be expected that such differences among cells will be found. To Taylor and Acree's experimental criterion12 for good cells, namely, that whatever the solutions used, the ratios of the resistances of any solution in two such cells must be the same, must then be added the stipulation that such cells can be cleaned and dried successfully with comparative ease.

Especially interesting in this connection and confirmatory of our explanation of this phenomenon is the recent work of Willard and Fenwick¹³ and of Beans and Hammett.¹⁴ Willard and Fenwick found a great variation in the values for the potentials of supposedly similar platinum electrodes in a given solution, not only with different methods of pre-treatment but with repeated applications of the same method. Beans and Hammett found that a bare platinum electrode may differ in potential from a

¹² Ref. 2, p. 2403.

¹³ Willard and Fenwick, This Journal, 44, 2516 (1922).

¹⁴ Hammett, Dissertation, Columbia University, 1922.

similar platinized foil, both immersed in a $0.1\ N$ hydrochloric acid saturated with hydrogen, by as much as $0.3\ volt$. In both of these researches the treatments which gave the greatest deviations in the values of the potentials for similar electrodes were of the same variety as those that gave for us the greatest increase in the resistance of the solution. There remains the possibility that even for the most persistently unreliable cells a method using polarizing currents, on treatment with alkaline cleansing solutions such as alcoholic potash, or of saturating the electrodes with some gas other than air can be developed; an attempt to find such a method is now being made in this Laboratory.

Variation of Resistance with Voltage.—Kraus and Parker⁵ came to the conclusion that the only reason for the change in resistance with the change in voltage observed by them as well as by Taylor and Acree could not be the contamination of the solution from the cells, as suggested by Taylor and Acree, since with the greatest care they could not entirely eliminate this effect in some of their determinations. In the present research no change in resistance with the change in the impressed voltage has been observed when the electrodes were properly cleaned. With the great difference in the potential of the electrodes possible among different cells "cleansed" in the same or different ways, it is not surprising that such discrepancies should occur. In every case the method of cleansing and the criterion for clean cells should be given before any confidence can be placed in the experimental results.

Summary

A study has been made of the errors inherent in the design and use of conductance cells containing non-platinized electrodes, when employed for non-aqueous solutions, and the following general conclusions drawn.

- 1. In order to make accurate conductance measurements of dilute non-aqueous solutions, some comparison solution other than the very dilute aqueous solutions needed should be used, since the latter cannot be kept as free from contamination as the non-aqueous solutions which are to be measured. A solution of potassium chloride diluted with alcohol is suggested as the most convenient comparison solution.
- 2. The change in resistance with a change in frequency from 500 to 1000 cycles has been measured throughout a wide range of resistances, with a number of different cells and types of solutions. The results of Taylor and Acree have been confirmed in the range covered by them; however, the difference in resistance for small electrodes does not decrease continuously with an increase in resistance but passes through a minimum between 5000 and 10,000 ohms. There is not, as Taylor and Acree state, a minimum resistance above which a cell may be used with accuracy, but an optimum range which may or may not give results sufficiently accurate, depending upon the accuracy needed and the size of the electrodes;

as the size of the electrodes increases, the range and possible accuracy within the range increase. So choosing the cells that the resistance in them is large is not equivalent experimentally to increasing the size of the electrodes.

- 3. Cells have been designed, with the aid of Washburn's equations, which do not change in resistance with a change in frequency and which with the Washburn Type A Cell cover the range from 2×10^{-3} to 2×10^{-7} reciprocal ohms.
- 4. The method of cleansing and drying the electrodes has been found to be of far greater importance than any of the other factors involved, the errors from this source alone often being as high as 2 to 3%. The usual method of cleansing and drying seemed to make the cell, filled with its solution, not a resistance and a capacity but a voltaic cell, which gives the effect of an abnormally high resistance. A method is given for cleansing the cells which has for its underlying principle the production of 2 electrodes having as nearly as possible the same contact potential when immersed in the same solution; it involves thoroughly "scrubbing" the electrodes after any treatment with an acid cleaning mixture and keeping the electrodes short-circuited during all the processes of cleaning, drying and the bringing of the cell to temperature equilibrium.
- 5. It is believed that the difference in the potential developed by different electrodes when subjected to the same treatment accounts for the change in resistance with a change in the impressed voltage, and for the fact that some observers have not been able to eliminate the change by thorough cleansing while others have. The term "clean" applied to conductance cells should be more rigidly defined, if comparable values are to be obtained by different workers.

THE OSMOTIC PRESSURES OF AQUEOUS SOLUTIONS OF PHENOL AT 30°

By Arthur Grollman and J. C. W. Frazer Received May 15, 1923

Introductory

The only reference to be found in the literature of an attempt to determine experimentally the osmotic pressure of phenol solutions is that of Naccari, whose results, being much lower than those theoretically expected and incapable of either duplication or accurate determination, were rejected by Naccari as unsatisfactory. Owing to the crudity of the method employed, which at its best could give but qualitative results, his data are of interest only from an historical standpoint.

¹ Naccari, Atti. accad. Lincei. 6, 32 (1897).

Indeed, even with the experimental refinements of the later methods as developed by Morse and Frazer, and their co-workers, only such compounds as the sugars were capable of accurate measurement. Failure to obtain results with substances of a low molecular weight were attributed to permeability of the cupric ferrocyanide membrane, or to the disintegration of the latter in the presence of such substances. Recent improvements in cell structure, which have been made in this Laboratory, have enabled the methods of direct osmotic-pressure measurements to be applied to a variety of substances hitherto considered beyond experimental determination, with an accuracy comparable to that of the best results obtained with cane sugar.

Phenol, presenting as it does rather anomalous behaviors in aqueous solution, was chosen for measurement, to determine whether the results so obtained could be correlated with its other properties. The great uncertainty existing regarding certain of its actions, such as cryoscopic behavior, hydration, etc., demanded an attack from another point of view in order to throw light on these subjects. The fact that it forms solutions with two coexisting phases was also suggestive. Moreover, all substances hitherto measured have approximated ideal solutions and obey the van't Hoff osmotic-pressure formula more or less closely. Phenol was, therefore, chosen, as it diverges widely from such behavior.

Experimental Part

The measurements were carried out throughout the solubility range at 30°, with nitrogen-filled manometers in a bath constant to 0.05°. The method was essentially that described and used by Frazer and Myrick² for sugar solutions, manometers being used, however, instead of the resistance gage there described. For low pressures, the manometric method is the most accurate though not the most convenient mode of measurement.

The solutions were analyzed with a Zeiss water-interferometer which permitted an accuracy exceeding that required by the manometric readings with a cathetometer.

The cells were perfected in a manner to be described in a later article;

upon them were deposited the usual membrane of cupric ferrocyanide. These allowed but a slight permeability of the phenol, which was finally corrected for by analysis of the solutions. Equilibrium was obtained in less than 6 hours, even with the most concentrated solutions.

Table I and Fig. 1 give the results obtained. The curve is practically linear, tending to slope slightly towards the X axis with increasing concentration. The third and sixth columns show this tendency.

From the equation for ideal solutions,

$$P = \frac{RT}{V_0} \left(x + \frac{1}{2} x^2 + \frac{1}{3} x^3 + \dots \right)$$
 (1)

where P is the osmotic pressure, V_0 , the molecular volume of solvent and x, the molar fraction of solute, we can, neglecting the association of water,³

calculate the theoretical osmotic pressures of phenol solutions. This has been done in Cols. 2 and 6 of Table II. By interpolation of the observed values in Table I, the values for exact concentrations are obtained in Cols. 3 and 7.

A comparison of the observed values in Cols. 3 and 7 and the theoretical values calculated in Cols. 2 and 6 shows, as Cols. 4 and 8 indicate, that the former are approximately $^{1}/_{2}$ the latter, thus showing the probability of association of 2 molecules of phenol in aqueous solution to form a diphenolic complex.

If α is the degree of association of phenol, we must introduce this factor in Equation 1. Assuming the association to take place exclusively according to the equation, $2C_6H_5OH \longrightarrow (C_6H_5OH)_2$, instead of C, the molar concentration, we must use $\frac{\alpha c}{2} + (1-\alpha)c$ or $c\left(1-\frac{\alpha}{2}\right)$ and x, the molar

fraction, becomes
$$\frac{c\left(1-\frac{\alpha}{2}\right)}{55.5+c\left(1-\frac{\alpha}{2}\right)}$$

Making these substitutions in Equation 1 and substituting for the osmotic pressure, P, the observed values, we are able to calculate, α , the degree of association at the various concentrations. The decrease in the relative osmotic pressures with increasing concentrations is due to an increase in the degree of association of phenol with higher concentrations. The value of α increases from 86% for 0.1 M to 99% for 0.9 M solutions.

Beckmann and Maxim4 have derived values for the association of phenol in carbon tetrachloride and bromoform in various concentrations and at temperatures varying from the freezing points of the above-mentioned solvents to their boiling points under normal pressure. The degree of association is found to be most sensitive to dilution, rising for example from the value 1.21 for a solution of 0.599 g. of phenol in 100 g. of carbon tetrachloride at 54.1° to the value 1.58 when the same amount of solvent contains 2.738 g. The results in Table II, Cols. 4 and 8, derived from the osmotic pressure studies, lead us to the same conclusion, namely, that dilution is a potent factor in decreasing the association of phenol. This decrease of association with dilution may explain the great variance in the behavior of phenol in aqueous solutions on bromination. The formation of tribromophenol and tribromophenol bromide (tetrabromocyclohexadienone) may be due to the presence of both the simple molecule and the associated form in solution. Attention may be called to alternative explanations of the above phenomena, as due to the presence of a quinoid form, or as due to the presence of hydrobromic acid.

The Association of Phenol

The above conclusion that phenol exists in solution in an associated form is supported by its behavior in other respects, both physical and

⁴ Beckmann and Maxim, Z. physik. Chem., 89, 411 (1915).

⁵ Dinwiddie and Kastle, Am. Chem. J., 46, 502 (1911).

⁶ J. Chem. Soc., 121, 2810 (1922).

chemical. Essex⁷, from a study of the compressibility of phenol, applied the principle of Tammann⁸ whereby molecular magnitudes of anisotropic phases are determined, and finds that phenol exists as two forms of $(C_6H_5OH)_2$, a third species $-C_6H_5OH$ — being enriched at higher temperatures. Turner and English⁹ found, by a study of the freezing points in benzene, that the molecular weight of phenol varies from 149.6 to 194.5; these results are in the same order of magnitude as those derived from the osmotic-pressure measurements. Walden, ¹⁰ by a study of the specific cohesion, reaches the same conclusion. The surface-tension measurements of phenol solutions, ¹¹ cryoscopic measurements, etc., all point to association of phenol.

In its chemical reactions, also, phenol shows a tendency towards reacting not as a simple molecule but rather in an associated form. Thus the following compounds have been isolated: $2C_6H_5OH.H_2O;^{12}$ $2C_6H_5OH.TeCl_4;^{13}$ a series of compounds having the structure $2C_6H_5OH.Ca(OH)_2 \times H_2O;^{14}$ ($C_6H_5OH)_2H_2SO_4;^{15}$ as well as numerous other addition products. In all of these compounds 2 molecules of phenol react, which points to the probability that phenol reacts as the dimolecular compound $-(C_6H_5OH)_2$, as indicated by the values of the osmotic pressures.

Effect of Temperature on the Degree of Association

Solution of phenol is accompanied by a large absorption of heat. The measurements of various properties, such as ebullioscopic, etc., all give results indicating a decrease in the degree of association with increasing temperature. Applying the Le Chatelier principle, it is obvious that the compound formation must be exothermic and, vice versa, the dissociation of the double molecule takes place with an absorption of heat. We must, therefore, attribute the negative heat effect resulting on dissolving phenol as due to the breaking down of the more complicated structure with the formation of a certain percentage of simple molecules. The pure substance, therefore, exists practically entirely in an associated form; experimental studies of the molten material corroborate this (as, for example, Essex's work quoted above).

Summary

- 1. The osmotic pressures of phenol solutions have been determined throughout the solubility range at 30.0°.
- 2. From the results so obtained the degree of association of phenol in aqueous solution has been calculated, and it is found that the percentage of simple molecules existing in the dimolecular form varies from 86% for 0.1~M solution to 99% for 0.9~M solution. The pure material is entirely associated.
- 3. It is suggested that the variance in the chemical compounds formed on direct bromination of aqueous phenol solutions of varying concentration is attributable to the different molecular combinations present.
- 4. The great absorption of heat attending the solution of phenol is due to the partial decomposition of higher molecular forms, the reaction $(C_6H_5OH)_2 \longrightarrow 2C_6H_5OH$, being endothermic.

IMPROVEMENTS IN THE MODE OF MEASUREMENT OF OSMOTIC PRESSURE

By Arthur Grollman and J. C. W. Frazer Received May 15, 1923

Introduction

Of the various experimental physicochemical methods, none is of greater importance than the measurement of osmotic pressure. The thermodynamic considerations of solutions are based on the concept of an osmotic pressure and all other properties of solutions are derivable from osmotic-pressure data. Of paramount importance is the fact that osmotic-pressure measurements are capable of the greatest refinement, being measurable with an extreme accuracy. Though we possess other accurate means of measurement such as of the freezing point and the vapor pressure, these are very limited, the former being confined to one temperature, the latter applicable over only a limited range of temperature. Osmotic-pressure measurements, on the other hand, can be carried out with equal precision over the range of temperature in which the solvent in question exists in the liquid form and throughout all possible concentration limits.

Despite these desirable conditions and advantages, measurements of osmotic pressures have been limited to a few substances, such as sugar and glucose. Substances of lower atomic weight, and especially electrolytes, have defied measurement and it has usually been assumed in the case of electrolytes that measurement is impossible because of the destructive effect on the semipermeable membrane and the permeability of the latter to such substances. The object of this investigation was so

to modify the present mode of measurement as to make it more widely applicable and, if possible, to apply it to the measurement of electrolytes.

The Cells and Membranes

Of primary importance in the experimental determination of osmotic pressure is the character of the clay cell used as the support of the semi-permeable membrane. Indeed, the lack of cells of proper texture was the cause of failure by early investigators. The cells used by Morse and Frazer in their work were made with every precaution to obtain a final product having a uniform porosity, a fine structure, and lacking, above all, any "air blisters." Such cells were obtained in the laboratory by carefully elutriating and washing the clays, pressing the obtained mixture, and finally turning to the required form on the lathe, after which the cell was baked and its collar glazed. The microscopic structure of such a cell (Type A) showed that it had a fine and uniform texture.

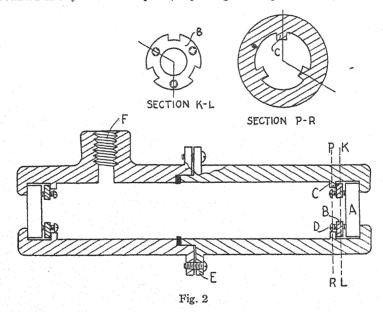

Since the function of the cell in measurements of osmotic pressure is to secure a support for the membrane to be used, it is perfectly obvious that the fineness of texture of the latter will depend entirely on the size of the pores of the cell itself. If there should happen to be a point where the cell wall is highly porous, the membrane, if deposited at all over this area, must necessarily be held but loosely, and the exertion of any pressure at this point would easily disrupt it.

The failure of early attempts to measure the osmotic pressure of solutions of electrolytes was usually attributed to the destructive effect of the electrolytes on the colloidal nature of the copper ferrocyanide membrane. To be sure, this is an important factor in such determinations, but it appeared likely that the failure of early attempts was due also, in a large measure, to the character of the cell itself. The fact that only substances of high molecular weight could be studied while other materials of molecular weights of a lower magnitude including electrolytes, passed through the semipermeable membrane suggested that cells of a finer structure might support membranes of a finer structure which, though incapable of prolonged existence in the presence of disrupting agencies would, nevertheless, prevent leakage of the solute and thus serve as true semipermeable materials for the period of time required to make a measurement.

To obtain cells with a texture finer than the one described above by the same method is scarcely possible. This cell was subjected during preparation to a pressure of about 3000 kg. per sq. cm. of surface of clay for 15 hours. Moreover, as shown later, cells of any appreciable thickness of finer texture than shown by Type A, although capable of supporting a membrane impervious to the solute would, nevertheless, fail to give accurate osmotic-pressure measurements. It was decided, there-

fore, to produce in the cells heretofore used some insoluble material which would give a support for the membrane. Microphotographs of cross sections of cells so prepared (Types B, C, D and E) showed darker areas representing the areas where the interior of the cell had been modified by the introduction of these fillings, whose extremely fine structure was indicated by the opacity to light which these sections showed under the microscope.

The Type B cell was filled with magnesium silicate by electrical diffusion. The cell to be treated was placed in an apparatus similar to that used in depositing the membrane, and a current (taken directly from the lighting circuit) passed between a roll of platinum foil placed within the cell, which served as the anode, and a foil (2 cm. wide) which surrounds the cell, dilute solutions of magnesium nitrate and sodium silicate serving as anolyte and catholyte, respectively. In this manner the required filling can be obtained in any thickness required, depending on the period of deposition. The

optimum results are obtained with an electrolysis of about 10 hours. The initial amperage, which varies with the porosity of the cell in question, ranged from 0.5 to 1 ampere under the above conditions and drops in 10 hours to 0.02–0.2 amperes. It was found that cells filled in this manner scarcely cracked on baking and gave most efficient results. After all treatments, the cells are baked in a pottery kiln for several days at $1000-1450^{\circ}$ and then, after thorough electrolysis with a 0.05% lithium sulfate solution to remove all air from the cell by endosmosis, the cell is electrolyzed with pure water until all electrolytes have been removed. It is then ready for the deposition of the membrane.

Type C cell was filled in a similar manner, except that sodium hydroxide was used instead of the silicate and the magnesium hydroxide thus formed was burned in the kiln. The filling was rather narrow and not at the very surface of the cell, but toward the interior.

Type D was filled exactly as was Type E cell but was not baked after filling. This was made evident in the photographs by the greater porosity of the baked cell due to the

contracting effect of heat on the filling. The baked cells invariably gave better results, which may be explained by the fact that too dense or too thick a filling does not allow free and easy diffusion of solvent through the cell which, in turn, results in a slow and incomplete attainment of equilibrium, despite the fact that with such cells no leakage or a negligible amount occurs.

Type E cell contained a filling of magnesium silicate produced as follows. The cell was placed in a solution of concentrated magnesium chloride which diffused and thoroughly filled the pores of the cell. After the outer surface had been washed, the cell was transferred to a solution of sodium hydroxide which on diffusion precipitated magnesium hydroxide in the cell. In order to produce a more insoluble filling, this was converted to the silicate by boiling in a 10% solution of sodium silicate. The above process was repeated several times until no more "filling" could be inserted. The "filling" was precipitated at the outer surface of the cell where it was desired, since it is here that the membrane is deposited. The main objection to this method of cell treatment is the fact that the majority of cells so treated crack on drying.

Type F cell was filled by diffusion. A cell filled with magnesium chloride and inserted in a beaker of sodium hydroxide was allowed to stand for several weeks. In this way a fine layer of magnesium hydroxide was precipitated where the solutions met, which was then converted to the silicate. One cell of this type was actually used in quantitative measurements and gave excellent results until finally it cracked from the pressure developed in use.

Deposition of Membrane.—It was found that the optimum and quickest results are obtained if, instead of bringing about the first deposition of the membrane by means of electrolysis as is commonly done, a modified form of the method described by Pfeffer¹ be used.

The cell is filled with a molar solution of cupric sulfate and placed in a beaker of water until the solute has diffused through the cell. The cell is then washed, the water is replaced with a molar solution of potassium ferrocyanide, and the arrangement allowed to stand overnight. Such a cell set up immediately with a $2\,M$ solution of sugar often gives the theoretical pressure which in the case of unfilled cells can only be obtained after from 6 months to a year of constant seasoning.

Discussion of the Cells.—The results already obtained by the use of filled cells in the case of phenol solutions² and qualitative measurements made, show that the above method of cell treatment accomplishes its purpose. Regardless of the magnitude of the molecular species under consideration, the leakage in any case is but minimal. However, it cannot be too strongly emphasized that non-leakage is not to be taken as a criterion of a successful measurement, as has been done by some investigators. The only criteria for a good measurement are the attainment of a pressure which remains constant for some time, non-leakage of solute and, above all, the ability to duplicate all results with other cells and measuring apparatus, in so far as the limit of accuracy of the method permits. Data based on measurements not fulfilling these requirements are to be considered worthless.

¹ Pfeffer, "Osmotische Untersuchungen," 1877.

² Grollman and Frazer, This Journal, 45, 1705 (1923).

Another point of superiority of the filled cells is the speed with which they attain equilibrium, which far exceeds the time required with unfilled cells. Indeed, measurements of 50 atmospheres' pressure have been attained with sugar solutions, using air manometers, within 20 minutes after setting up, and the fact that in such measurements a considerable diffusion of solvent must take place to produce the pressure, shows the potency of the force with which we are dealing.

A New Interferometer Cell for Use as a Pressure Gage

Besides the question of cells, whose improvement has been discussed above, the mode of measuring the pressure exerted is of fundamental impor-Nitrogen-filled manometers which have been used in the past have the great disadvantage that the time for equilibrium is rather long, since for its attainment, considerable solvent must pass through the cell. With electrolytes it is essential to make rapid determinations, since long contact with the solutions has a detrimental effect on the membranes. Hence, a more rapidly registering pressure gage was desired. Van Doren, Parker and Lotz³ have devised a method of measurement in which the change of refractive index with pressure as measured by the Zeiss waterinterferometer serves as a pressure gage. By the use of this instrument rapid determinations can be made. As developed by these investigators the instrument has, however, several defects. It is rather difficult to assemble, leakage at the glass windows being especially hard to avoid. Moreover, due to the manner in which the windows are held in place, the length of the pressure chamber is necessarily made small, which means a corresponding diminution in the sensitivity of the instrument, the sensitivity being directly proportional to the length of the column of liquid compressed.

The two objections mentioned above have been satisfactorily overcome by the modified instrument shown in Fig 1. This new form combines ease of assemblage and high sensitivity, the latter being twice that of the original instrument. As it is generally applicable wherever pressure measurements are to be quickly and accurately made, it will be briefly described.

It consists essentially of a brass tube, with optical glass windows inserted at its ends, which is held in place by means of a square block of brass through which are drilled 2 holes. One of these serves to hold the pressure chamber in place, while the other, which is contiguous to the first, holds the other window which, dipping into the water-bath of the interferometer, serves as the non-pressure or comparison chamber. By this arrangement only the pressure tube requires especial care in construction to avoid leakage, and it is this simplification which gives the instrument both ease in assemblage and greater accuracy. A plate screwed on the end blocks serves as a support of the chambers in the bath. Since the parts on being assembled assume the same relative position, no diffi-

³ Van Doren, Parker and Lotz, This Journal, 43, 2497 (1921).

culty is experienced by a change in the zero reading of the instrument such as would occur were the arrangement not exactly reproducible.

In order to introduce the glass windows into the ends of the pressure chambers from the inside, thus giving a tighter joint between glass and metal with increasing pressure. the pressure tube must be made in two parts. These are joined by the flange arrangement E, leakage being prevented by insertion of a washer made of steam packing where the two ends meet within the tube. Such washers do not flow under pressure as ordinary rubber does. The tube, which is otherwise of uniform bore throughout its length, has 3 points of projection, C, which serve to support the washer B. The glass windows, A, are circular, but have 3 notches corresponding to the 3 projections from the tube, in order that the windows may be slipped past these projections. After the windows are introduced as shown in the figure, a circular brass washer, B, having notches similar to those of the glass plate, is slipped beyond the projections, turned so that it is now supported by the projections, C, and the glass windows are held tightly against their supports by means of the screws, D. The windows are made air-tight by the use of a rubber solution which, after assemblage, is vulcanized by slow heating. The tube is joined by F to a mercury trap which in turn is connected to the pressure cell or to the source of the pressure to be measured.

The instrument as described above has a range of 30 atmospheres. This can be increased as described by Van Doren, Parker and Lotz³ by the use of thin glass plates inserted in the path of the beam passing through the non-pressure side.

Since the range of 30 atmospheres corresponds to 3000 divisions on the interferometer and since readings on the latter are capable of duplication within 10 divisions, the pressure readings are accurate to 0.1 of an atmosphere. The accuracy can be further increased by using a more compressible liquid than water in the instrument and interferometer bath and by the use of a longer pressure chamber and wider windows. The length of the pressure chamber of the instrument as described above was 80 mm. By arranging the mirrors and prisms of the interferometer so that there is a greater distance between the two beams, larger windows can be used in the pressure gage, which insures more accurate readings.

For a complete description of the use of the interferometer, the reader is referred to the papers⁴ by Adams, Cohen and Bruins, Löwe, and Haber and Löwe.

Owing to the difficulties inherent in most methods of pressure measurements, their limited applicability and accuracy, the use of the water interferometer should prove itself a most desirable substitute for certain methods heretofore employed.

Conclusion

It is hoped that with the modifications above described, the road is paved for the measurement of the osmotic pressure of electrolytes and other substances whose behavior in solution, as shown by the osmotic pressures

⁴ Adams, This Journal, 37, 1181 (1915). Cohen and Bruins, Z. physik. Chem., 103, 337 (1923). Löwe, Chem.-Ztg., 51, 405 (1921). Haber and Löwe, Z. angew. Chem., 23, 1393 (1910).

which they exert, may throw light on the important questions of solutions. Qualitative results obtained with lithium chloride, sodium nitrate, sodium acetate, cupric chloride, sodium chloride, ethyl alcohol and acetic acid are promising and though no successful quantitative results with concentrated solutions have as yet been obtained, experiments on the more dilute solutions are now in progress, the results with phenol having already been published.

Summary

- 1. The method of experimentally determining osmotic pressures has been improved by filling with various silicates the cells on which the membrane is precipitated.
- 2. Such cells are efficient supporters of the membrane, allow but a minimal leakage, a rapid attainment of equilibrium, and do not require long seasoning.
- 3. An interferometer cell has been devised which is capable of acting as an accurate and rapid pressure gage.

ELECTROMOTIVE-FORCE MEASUREMENTS WITH A SATURATED POTASSIUM CHLORIDE BRIDGE OR WITH CONCENTRATION CELLS WITH A LIQUID JUNCTION

By George Scatchard Received May 17, 1923

The determination of the activities of individual ion species is a very interesting and important problem of physical chemistry. The measurement of hydrogen-ion activity, often under the name of hydrogen-ion concentration or $P_{\rm H}$, is being applied to so many varied problems that a consideration of all the possible evidence as to the validity of the procedure becomes important. The applications themselves present a considerable body of evidence.

The electromotive force of a cell of the type, Pt, H_2 [HCl, AgCl Ag, can be derived rigorously from thermodynamics alone. At constant temperature and pressure it is $E_1 = E'_1 - RT/F \ln(a_{\rm H} \times a_{\rm Cl})$, where E'_1 is the corresponding electromotive force when the activities are unity, and the other symbols have their usual significance. This electromotive force is divided between the two electrodes; we will assume that it is so divided that the electromotive force at the hydrogen electrode is $E_2 = E'_2 - RT/F \ln a_{\rm H}$ and that at the silver-silver chloride electrode is $E_3 = E'_3 - RT/F \ln a_{\rm Cl}$. Although this generally accepted assumption is apparently incapable of direct proof there seems little reason to question it, for it is difficult to imagine a mechanism of the reaction in which the chloride ion

could affect the electromotive force of the hydrogen electrode except by changing the activity of the hydrogen ion. Without such an assumption any attempt to determine the activity of individual ions by electromotive-force measurements is hopeless.

The customary procedure for measuring the activity of a single ionic species is to use a single electrode in combination with a saturated potassium chloride bridge and a standard electrode, which involves the assumption that the potential drop is zero at the liquid junction: saturated potassium chloride, unknown. Then, since the electromotive forces at the standard electrode and at the junction of the electrode solution with the bridge are constant and may be included in E', the electromotive force of the whole cell is given by E_2 or E_3 . Corran and Lewis¹ have presented what they consider to be a proof of this equation for the hydrogen electrode in solutions of hydrochloric acid and sucrose in water. However, their proof contains the assumption that the electromotive force of the silver-silver chloride electrode is given by the equation, $E_4 = E'_4 RT/F \ln \sqrt{a_H \times a_{Cl}}$, which differs from E_3 . Since the value of E_3 follows necessarily from those of E_1 and E_2 , the result proved is incompatible with the assumption made to prove it, and the proof is invalid.²

The assumption that a saturated potassium chloride bridge eliminates liquid-junction potentials is usually based on the extension to solutions in general of the proof of Fales and Vosburgh⁸ for solutions of N and 0.1 N hydrochloric acid. The argument of Fales and Vosburgh depends upon the proof that the electromotive force at the liquid junction with saturated potassium chloride is the same for 0.1 N as for N acid, and that the most reasonable explanation is that both are zero. The authors recognize that this proof depends upon the assumption that "the combinations represented by Hg-HgCl x MHCl - x MHCl-H2 (1 atmos.) Pt change their pole potential differences by the same amount, but in an opposite direction, as we vary x."4 However, this assumption is not substantiated by the consistency of their results, for there are too many arbitrary variables. It is equivalent to assuming that the hydrogen and calomel electrodes each measure the mean activity of hydrogen and chloride ions, or that the ratios of the activities of the two ions are equal in these two solutions. The extension to all concentrations would require that the activities themselves be equal.

It seems more reasonable to make the assumptions of MacInnes:⁵ that (a) the activity of the chloride ion is the same in solutions of all uni-

¹ Corran and Lewis, This Journal, 44, 1673 (1922).

² H. S. Harned [*ibid.*, 42, 1808 (1920)] makes the same two contradictory assumptions, but uses them in only a few of his calculations.

³ Fales and Vosburgh, *ibid.*, 40, 1291 (1918).

⁴ Ref. 3, p. 1299.

⁵ D. A. MacInnes, ibid., 41, 1086 (1919).

valent chlorides at the same molality, and (b) equal to the activity of potassium ion in potassium chloride solutions. With these assumptions the difference between the 2 liquid-junction potentials is 6.4 mv.; both cannot be zero and there is no reason to suppose that either is.

From other results of Fales and Vosburgh it is possible to determine the electromotive force of the cell, Hg | HgCl, KCl (c_1) | KCl (sat.) | HCl (c_1), HgCl | Hg. A combination of Experiments 9, 18 and 23 gives 0.1 mv. when the solutions are 0.1 N. Expt. 1 give 8.3 mv. for 1 N solutions; corrected to equal molalities this becomes 8.9 mv. for 1.023 M solutions. By the MacInnes assumption (a), the electrode potentials cancel. The liquid-junction potentials between the solutions of potassium chloride are probably only a few tenths of a millivolt; the Nernst-Planck formula gives 0.6 and 0.4 mv. With this assumption the liquid-junction potential is small with 0.1 N solutions, but becomes large for N solutions.

A test of this assumption would be very simple by comparing the activity determined with a saturated potassium chloride bridge with that from cells without transport, but apparently the necessary measurements have never been made. The most direct comparison possible is one between the measurements of Fales and Morrell⁶ with the bridge at 35° and the values given by Lewis and Randall⁷ for cells without transport at 25°. The activities change with the temperature, but the general nature of the curves should be the same. Table I contains this comparison for the activity coefficients (activity divided by molality), and also for the activity coefficient of the hydrogen ion calculated by the MacInnes assumptions.

Table I

Comparison of Activity Coefficients in Hydrochloric Acid

Molality	$\sqrt{a_{\rm H} \times a_{\rm Cl}/m}$	$a_{ m H}/m$ Fales and Morrell	$a_{\rm H}/m$ MacInnes assumptions
0.0010	(1.00)	(1.00)	(1,00)
0.0100	0.94	0.94	0.94
0.1001	0.83	0.84	0.84
0.3017	0.78	0.84	0.83
0.6071	0.78	0.82	0.90
0.9161	0.82	0.82	1.02
1.229	(0.88)	0.87	(1.22)

The necessary change from moles per liter to molality is made by means of the density determinations of Fales and Morrell. Since their values are only relative, all coefficients are given on such a scale that the coefficient is unity for the $0.001\,M$ solution. It is apparent that the cell with saturated potassium chloride bridge measures neither the mean activity nor that of the hydrogen ion calculated by the MacInnes assumptions. For solutions $0.1\,M$, or more dilute, the agreement with the MacInnes assumptions is

⁶ Fales and Morrell, This Journal, 44, 2071 (1922).

⁷ Lewis and Randall, *ibid.*, **43**, 1112 (1921).

good, confirming our conclusions that the liquid-junction potential is very small with these solutions.

Hitchcock⁸ has used a saturated potassium chloride bridge with both hydrogen and silver-silver chloride electrodes in hydrochloric acid through the concentration range 0.001– $0.1\ M$, but his measurements were reproducible only to about 1 millivolt. His results show that the liquid-junction potential may be ignored within this range and within his experimental error.

Most applications of the saturated potassium chloride bridge involve the presence of a second solute. Some insight into the validity of assuming that the liquid-junction potential is eliminated in such cases may be obtained from the measurements of Corran and Lewis¹ on sucrose solutions if we recognize that the silver-silver chloride electrode measures the activity of the chloride ion and not the mean activity. These solutions have a particular interest in themselves on account of the importance of sucrose inversion to the study of reaction speed. The measurements on potassium chloride are made with a concentration cell with transport; those on hydrochloric acid with a saturated potassium chloride bridge.

Although a concentration cell with transport cannot be reversible on account of diffusion, it seems generally accepted that the derivation of the differential equation for its electromotive force rests only upon the two laws of thermodynamics. The thermodynamic derivation, however, involves the assumption that the only matter transported when a current is passed through is the ions, and it must be recalled that the ions whose activity is measured are the anhydrous ions. Washburn¹⁰ has definitely established that there is also a transport of water. If we follow the method of Lewis and Randall, taking this into account and changing at the end from free energies to activities, we obtain for the electromotive force of a cell with electrodes at which the anion reacts,

$$E = -\frac{RT}{F} \left[\int_{A}^{B} t_{+} \, d \ln (a_{+} \times a_{-}) + \int_{A}^{B} t_{w} \, d \ln a_{w} \right],$$

where the a's are activities, and the t's transport numbers, or the number of moles carried in the direction of the positive current when 1 faraday of electricity is passed through the solution. The subscript w refers to water, the others to the ions, and A and B to the two solutions.

An idea of the magnitude of the second term may be obtained from the measurements of MacInnes and Beattie⁹ on lithium chloride solutions

⁸ Hitchcock, J. Gen. Physiol., 5, 383 (1923). I wish to acknowledge my gratitude to Dr. Hitchcock for the use of some unpublished calculations and for calling my attention to some results of Fales and Vosburgh.

if it is assumed that $t_{\rm w}$ is constant and equal to 1.5, the value found by Washburn for 1.28 M solution. The corresponding electromotive force is 0.14 mv. for a 0.1 M, and 5.35 mv. for a 3.0 M solution. The value of 308 for $t_{\rm +}$ in 1.28 M solution agrees well with 306 and 301 found by Washburn for the true transport number. Since there is no reason to suppose that $t_{\rm w}$ is really constant, $t_{\rm +}$ by this assumption should not equal the true transport number at other concentrations, and it does not seem worth while to publish the complicated calculations. Neglecting the transport of water, MacInnes and Beattie find excellent agreement between $t_{\rm +}$ and the Hittorf transport number, but the above argument shows that no exact relationship between these two quantities is thermodynamically established.

The magnitude of the effect of the transport of water in the potassium chloride-sucrose solutions may be estimated by integrating the equation assuming that t_+ is constant, and that $t_{\rm w}$ is, first, zero or, second, constant and equal to the value 0.6 found by Washburn. The mean activities calculated by these two assumptions are given in the second and third columns of Table II, on such a scale that the activity is unity in the solution without sucrose. The neglect of $t_{\rm w}$ makes a difference of about 10% in the most concentrated solution. Since we know nothing of the effect of sucrose on either t_+ or $t_{\rm w}$, and there is no reason to suppose that either is constant, we cannot even say that the activities lie between these two values.

TABLE II
ION ACTIVITIES IN SUCROSE SOLUTIONS

G. of sucrose Mean activity KCl		$a_{\rm Cl}$	$a_{\rm H}$		
per liter	$t_{\rm w}=0$	$t_{\rm w} = 0.6$	in HCl	in HCl	N/N_0
0	(1.00)	(1.00)	(1.00)	(1.00)	(1.00)
100	1.06	1.07	1.12	1.20	1.08
200	1.14	1.16	1.26	1.44	1.19
300	1.21	1.24	1.41	1.74	1.33
400	1.31	1.36	1.59	2.09	1.49
500	1.41	1.49	1.80	2.50	1.71
600	1.52	1.64	2.07	3.00	1.97
700	1.66	1.84	2.38	3.60	2.31

The fourth and fifth columns of Table II give the activities of chloride ion and of hydrogen ion in hydrochloric acid determined with a saturated potassium chloride bridge. The chloride-ion activity increases much more rapidly than the mean activity of the ions of potassium chloride calculated upon the above assumptions, and the hydrogen-ion activity increases still more rapidly. It may be noted that, if we assume that the chloride-ion and hydrogen-ion activities are really equal, all the discrepancies between Cols. 4 and 5 must be attributed to the liquid-junction potential, which leads to a difference of 5.3 mv. between the liquid-junction potentials of sat-

urated potassium chloride with $0.1\ N$ hydrochloric acid when there is no sucrose present, and when there is $700\ g$. per liter.

The following argument indicates that it is at least reasonable to assume that the saturated potassium chloride bridge does give constant liquidjunction potentials with varying sucrose concentration. There are two important reasons for the deviation of the activities of the ions from proportionality to their mole fractions which, in dilute solutions of the univalent chlorides, seem to exceed greatly the total of other more specific effects. The first is the effect of the electrical charges upon each other, which depends upon the total ionic concentration (not mole fraction) and upon the dielectric constant of the medium. In these solutions the concentration of salt is constant and the dielectric constant probably varies but little. If we assume that it is constant, the concentration of the ions and the effect of this factor will be constant. The second factor arises from the fact that our measurements give the activities of the unhydrated ions. The fraction of ions not hydrated may be extremely small, but any change in this fraction will give a corresponding change in the activity coefficient. Since the ions probably vary both in the stability and the complexity of their hydrates this effect will be specific for the various ions. It will be a function of the activity of the water, and should not be measurable until that activity becomes appreciably less than that of pure water. It offers the simplest explanation of the unequal activities of ions and the increase of activity coefficients with concentration in concentrated solutions. behavior of the metallic chlorides indicates that this factor is very small for the chloride ion. If it is zero, the activity of the chloride ion should be proportional to its mole fraction in these solutions. Any effect of this factor would be to make the activity increase more rapidly than the mole fraction as the concentration of sucrose is increased. The last column of Table II gives N/N_0 for either ion, calculated by the equation, N/N_0 = $[55.5 + 0.2]/[C_s/(1 - a_w) + 0.2]$, where N and N₀ are the mole fractions with and without sucrose, C_s is the concentration of sucrose in moles per liter, and a_w is the activity of water in a solution containing the same proportion of sucrose and water but not salt. The use of this formula assumes that the solution is ideal with respect to water except for the hydration of sucrose, and that no appreciable fraction of the water is used to hydrate the ions at such dilutions. The values are only a little smaller than the measured values of the chloride-ion activity in hydrochloric acid, indicating a small decrease in hydration and offering some confirmation of the assumption that the liquid-junction potential is independent of the sucrose concentration.

According to these hypotheses the increase in the ratio of activity to mole fraction for the hydrogen ion is due to an increase in the fraction of unhydrated ion with decreasing activity of the water, whether this decrease is due to high concentrations of sucrose or of the acid itself. Whatever the cause is, it is obvious that the activity of the hydrogen ion is not proportional to its mole fraction or molality, and that it cannot be used legitimately to calculate the extent of hydration. The fact that the activity of hydrogen ion in acetic and in sulfuric acids increases less rapidly than in hydrochloric acid may be accounted for most simply by assuming that the dissociation of these acids decreases as the sugar concentration increases. This decrease may be explained, at least semi-quantitatively, by the increase in the mole fraction without any variation in the ionizing power of the solvent.

The confirmation of the elimination of liquid-junction potential with sucrose solutions is not too reassuring, but even this cannot be extended to the addition of another solute in general. Analysis of Planck's differential equation for liquid-junction potentials indicates that the potential depends upon both the activity and the conductivity of the ions, and probably also upon their concentration. If these solutions the concentration remains constant, the activity increases, and the conductivity decreases still more rapidly. It is possible that these effects equalize one another in this particular case, but it is not probable that they would do so in general. The extension of the use of the saturated potassium chloride bridge to solutions in general seems very dangerous.

Summary

- 1. The proof of Fales and Vosburgh that the saturated potassium chloride bridge eliminates liquid-junction potentials depends upon the assumption that in a hydrochloric acid solution the activities of the 2 ions are equal. The proof of Corran and Lewis depends upon incompatible formulas for the electromotive forces at the 2 electrodes.
- 2. An analysis of experimental results indicates that the liquid-junction potential with saturated potassium chloride is not more than 1 millivolt for solutions less than $0.1\ M$ but that it increases rapidly with the concentration for hydrochloric acid.
- 3. There is some theoretical confirmation for the assumption that the liquid-junction potential with a saturated potassium chloride bridge is independent of the sucrose concentration if the concentration of electrolyte remains constant. This substantiation cannot be extended to solutes in general.
 - ¹¹ Lewis, Merriman and Moran, This Journal, 45, 702 (1923).
 - 12 Jones and Lewis, J. Chem. Soc., 117, 1120 (1920).
- 13 I must disclaim any credit given me in Ref. 12 for originating the hypothesis that the increase in hydrogen-ion activity on the addition of another solute is due to increased ionization, which dates back at least to Loomis and Acree [Am. Chem. J., 46, 621 (1911)]. My contribution was to show that, if this effect were attributed to increased ionization, the ionization need not be more than 100% for sulfuric acid.

¹⁴ See also MacInnes and Yeh, This Journal, 43, 2563 (1921).

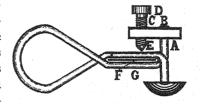

- 4. The ordinary thermodynamic formula for the electromotive force of a concentration cell with transport ignores the transport of water. If this be taken into account the transport number involved is the true and not the Hittorf number.
- 5. Emphasis is laid upon the fact that activity measurements give the activity of the unhydrated ion. An increase in the fraction of ions not hydrated gives the simplest explanation of the increase of activity coefficients in concentrated solutions.

NOTES

A Screw Modification of the Mohr Pinch Clamp.—Although the use of a Mohr buret is often made imperative in volumetric work, no satis-

factory pinch clamp has ever been devised to allow dropwise delivery of solutions from a buret of this type. The accompanying sketch shows the details of a pinch clamp designed to fill this need. It may easily be made from an ordinary Mohr clamp, and has an advan-

tage over a screw clamp in that only one hand is required for its manipulation.

Into a brass plate 3 mm. thick, 1 cm. wide, and 2 cm. long 2 holes, B and C, are drilled and then tapped. The wire A leading up from the jaws of the clamp is threaded, screwed into the plate through B, and then brazed or soldered securely in the position shown in the figure. A large-headed brass screw D is then screwed through C until its pointed end E just touches the top of plate F when the clamp is pressed just hard enough to allow liquid to pass in drops through the rubber tube between plate F and wire G. Of course, by screwing D further it is possible to secure any other desired rate of flow.

Gas Electrode.—A convenient form of hydrogen or other gas electrode and one which attains the equilibrium value very quickly, may be made as follows. A piece of round graphite rod A of any convenient size (3 mm. diameter was used) is drilled axially to within 6 mm. of the bottom. This is attached to a similar sized copper tube B, for leading in the gas, by a short length of rubber tubing C as shown in the figure. A spiral of light

copper or platinum wire D, inserted as shown, ensures electrical contact between the copper and graphite. The outside surface of the graphite is then platinized in the usual manner. When gas at $^1/_4$ to $^1/_2$ of an atmosphere is forced in, it passes very slowly and uniformly through the graphite forming small bubbles over the entire surface, thus very quickly saturating the platinum black and using a minimum quantity of gas. Such an electrode supplied with hydrogen from a cylinder came to the equilibrium value within $1^1/_2$ minutes and remained constant even though the electrode was in an open beaker of acid. This type of electrode is being used at this Laboratory for measurement of the reduction potential of acetylene and ethylene mixtures and is found to come to an equilibrium very much more quickly than a platinized platinum electrode and to

require less gas. A glass tube can of course replace the copper tube, and the light spiral wire be carried through a seal further up the tube.

Wilke² tried to use a palladium tube as a hydrogen electrode in the same way as the graphite electrode described above, but found the electromotive force was dependent on both the internal and external pressures. This effect was not observed with the graphite electrode; a higher pressure only caused the electromotive force to reach equilibrium sooner. There is an essential difference between the two electrodes; the graphite is actually porous but Wilke believes the hydrogen must diffuse through the palladium. There is reason³ to believe that it is monatomic hydrogen which passes through the electrode in the latter case and there may exist, therefore, on the outer surface of the palladium a slight excess of monatomic hydrogen over its equilibrium concentration. This would cause the electromotive force to be higher and to increase with increase of pressure. In the case of the graphite the diatomic hydrogen passes through and has at the surface a pressure of 1 atmosphere. The platinizing on the surface very materially stabilizes the elec-

tromotive force, and the opinion is ventured that if the palladium tube were platinized it would catalyze the formation of diatomic from the excess monatomic hydrogen and give correct values for the electromotive force dependent only on the external pressure.

Tetramethylammonium Tri- and Tetrachloro-iodides.—Weltzien¹ describes the preparation of the di-, tri- and tetrachloro-iodides of tetramethylammonium. No polyhalides of ammonium or the alkali metals corresponding to tetramethylammonium trichloro-iodide, N(CH₃)₄ICl₃, are known; it was, therefore, thought desirable to repeat Weltzien's work.

Analysis of the solid obtained by the method which Weltzien supposed to yield the trichloride gave results which were low and variable, so that the existence of this compound does not appear to be satisfactorily established; probably it is a mixture of the di- and tetrachloro-iodides produced by the partial decomposition of the latter substance.

Weltzien's analysis of the tetrachloro-iodide showed that his product was partly decomposed. A solid more closely approaching the composition of tetramethylammonium tetrachloro-iodide, N(CH₃)₄ICl₄, is obtained by the long continued action of dry chlorine gas on tetramethylammonium iodide at 28°. The solid was weighed in a small glass-stoppered weighing bottle, with glass inlet and outlet tubes also fitted with ground glass stoppers. A slow, continuous stream of chlorine was conveniently obtained by the electrolysis of a concd. solution of hydrochloric acid, the gas was passed through water and concd. sulfuric acid and then into the bottle containing the iodide; the latter first turned brown, then black and finally was completely converted into an orange-colored solid. The bottle was weighed from time to time with the following results:

Expt. 1. 0.5173	g. of iodide used	Expt. 2. 0.6	030 g. of iodide used
Time: days	Gain: G.	Time: days	Gain: G.
2	0.0898	38	0.3522
14	0.1874	51	0.3779
29	0.2739	77	0.3820
52 (constant)	0.3616	99 (constan	nt) 0.4244
Total gain 69.9%		70.4%	

The formation of N(CH₃)₄ICl₄ requires a gain of 70.6% in weight The substance formed in Expt. 1 was analyzed; 0.8484 g. required 140.48 cc. of 0.0694 N arsenite equivalent to 0.3457 g. of chlorine or a gain in weight of 68.8 %.

MICHELE GIUA

In the preceding note Professor Giua states that in his experimental data he has taken the point C of the diagram as representing the freezing point of a binary mixture. In his Italian and German articles to which reference has been made he labels the recorded temperatures as "beginning of crystallization." The beginning of crystallization obviously comes at the point B, and the rise in temperature from B to C is a result of crystallization which has followed supercooling. The confusion which has arisen comes, therefore, from the misnaming of temperatures which should have been called "maximum temperatures after crystallization" and not "temperatures of the beginning of crystallization."

An Intercepted Hydrolysis.—In one of a series of experiments designed to bring about the formation of phosphonium cyanide, potassium cyanide was heated with stick phosphorus and a little water, in an atmosphere of hydrogen. The free caustic potash in the solution of potassium cyanide was expected to react with the phosphorus to give phosphine, the corresponding amount of liberated hydrogen cyanide providing an opportunity for combination. The gases evolved were passed over warm phosphorus pentoxide, and a white, crystalline product was collected in a cooled receiver. On analysis, this substance proved to be a very pure sample of ammonium cyanide, containing no phosphorus whatever.

The history of the reaction must be as follows. At ordinary temperatures, in a closed vessel, we have the equilibrium, $KCN + H_2O \longrightarrow KOH + HCN$. At higher temperatures, this equilibrium is destroyed by the disappearance, through further hydrolysis, of the hydrogen cyanide, $HCN + 2H_2O = NH_4OOCH$, which is a *complete* action, the ammonium formate being destroyed by the equivalent potassium hydroxide formed: $KOH + NH_4OOCH = NH_3 + HCOOK + H_2O$. In sum, $KCN + 2H_2O = NH_3 + HCOOK$, and when potassium cyanide is boiled with water, nearly all of the gas evolved is ammonia.

When phosphorus is present the hydrolysis is interrupted to an extent defined by the reaction of the phosphorus with the potassium hydroxide

⁶ Macleod, Pfund and Kilpatrick, This Journal, 44, 2260 (1922).

present, an equivalent amount of hydrogen cyanide being liberated. With a large excess of water, we should probably have $3KCN+4P+12H_2O=3KH_2PO_2+PH_3+3HCOONH_4$, but this excess is not present, and after a small amount of ammonium formate has formed, we reach equilibrium and hydrogen cyanide is liberally evolved.

There is, thus, a main reaction, $KCN + 2H_2O = NH_3 + HCOOK$, and a subsidiary reaction, $3KCN + 4P + 6H_2O = 3KH_2PO_2 + PH_3 + 3HCN$. We refer to them in this manner because the ammonia evolved was always in excess over the hydrogen cyanide.

The experiment was repeated with other non-volatile substances, reactive with potassium hydroxide. Aluminum powder, in place of phosphorus, also produced ammonium cyanide of great purity. A greatly superior yield, however, was obtained by using a suitable proportion of sulfuric acid. Attention was called in this case to the great readiness with which ammonium cyanide is oxidized. In the first trials of the sulfuric acid method, hydrogen was neither formed in the reaction (as in the case of aluminum) nor flushed through the apparatus (as in the case of phosphorus). The product was ochreous in appearance, and was sublimed only with difficulty. The cause of this proved to be the formation of a matrix of azulmic acid, produced, we think, as follows.

 $2NH_4CN + O = 2NH_3 + C_2N_2 + H_2O. \quad NH_4CN \rightleftharpoons NH_3 + HCN \\ 2NH_3 + 2C_2N_2 = C_4H_6N_6 \ (Hydrazulmin). \quad C_4H_6N_6 + H_2O = C_4H_6N_6O + NH_3.$

It has often been remarked that while ammonia is effectively administered in cases of prussic acid poisoning, ammonium cyanide is powerfully poisonous. As, however, this substance cannot exist at the temperature of the body, its effects are probably due to the formation of cyanogen, as shown above, through a damp oxidation. Ammonium cyanide is most readily ignited, burning with a pale, fawn-colored flame. It immediately decolorizes neutral potassium permanganate solution: when the latter is added drop by drop until the decolorization is slow, a vivid yellow solution is formed, and this does not become brown nor deposit hydroxides until after standing exposed to the air for many hours.

Similarly, ammonium cyanide is reactive with sulfur. When it is dissolved in a chloroform solution of sulfur, thin leaves of ammonium thiocyanate separate on partial evaporation.

THE ACTION OF CONCENTRATED HYDROCHLORIC ACID ON DIFFERENT CELLULOSES

By E. C. Sherrard¹ and A. W. Froehlke² Received September 27, 1922

Introduction

When white spruce wood is hydrolyzed with dilute acid at atmospheric pressures, or higher, one of the reducing sugars produced is mannose. Some investigators have assumed that mannose is present in the wood as a mannan; others consider it to be present as a part of the cellulose. Sherrard and Blanco have further shown that in such a hydrolysis the quantity of sugar produced corresponds very closely with the quantity of cellulose removed. This would indicate that the mannose is present as a mannose cellulose. Recent investigation has brought to light the fact that mannose is contained in α , β and γ cellulose obtained from spruce cellulose prepared by the Cross and Bevan method. The same investigators have demonstrated that no mannose is present in cotton, and also that the reagents involved in the isolation of the celluloses from white spruce are not responsible for its formation.

The fact that white spruce cellulose on hydrolysis yields considerable quantities of mannose and that cotton yields no mannose on hydrolysis was considered ample proof that considerable difference exists between these two celluloses. In order to investigate further any possible differences in celluloses from different woods it was decided to submit several to the action of concd. hydrochloric acid and to observe the rate of change of optical rotations. Accordingly, celluloses from 2 softwoods, white spruce and Douglas fir, and one hardwood, yellow birch, were prepared by the method of Cross and Bevan and compared with cotton which had received the same treatment.

Experimental Part

The 3 species of wood used in this investigation were ground and screened. Only that which passed through an 80-mesh and was retained by a 100-mesh sieve was used. The material was placed in alundum

crucibles and extracted in a Soxhlet extractor with an equal mixture of alcohol and benzene for a period of 4 hours. The excess of solvent was removed by suction, the residual alcohol and benzene washed out with boiling water, and the extracted material then dried over a water-bath.

The cellulose samples were prepared from these by means of the Cross and Bevan process as modified by Schorger.⁸

The same process was duplicated in the case of raw, ginned cotton wool so that any variation in the hydrolysis curves for cotton and the wood celluloses could not be attributed to a variation in the preliminary preparation of the celluloses.

In order to bring cellulose into solution in hydrochloric acid it is necessary to increase the acid content to 40% or greater. This was accomplished by passing hydrogen chlo-

ride through ordinary coned. hydrochloric acid cooled to -10° . The acid so made was tightly stoppered in a glass-stoppered flask and maintained at a temperature of 0° or lower until used. The strength of the acid was determined by means of specific-gravity determinations. For this purpose an hydrometer calibrated between 1.180 and 1.240 was employed.

It was found undesirable to use an acid of higher concentration because when the temperature of such an acid was raised from 0° to —20° considerable hydrogen chloride was evolved, making it unsafe to bring the acid to the required temperature in a closed flask.

Two hundred cc. of hydrochloric acid prepared as above was added to about 2 g. of the prepared cellulose in a glass-stoppered flask. The flask was tightly closed and the mass vigorously shaken until the cellulose completely dissolved.

⁸ Schorger, J. Ind. Eng. Chem., 9, 561 (1917).

In a preliminary experiment the curves of specific rotation plotted against the time showed a break common to the 4 celluloses at about the twelfth hour. tained a similar break between the second and third hours. The question immediately arose as to whether any relationship existed between the break in the curve obtained by Willstätter at the second hour and the break obtained in the curves of the hydrolysis of the 4 celluloses at the twelfth hour. Consequently, the 4 celluloses were hydrolyzed with a 41% hydrochloric acid and the course of hydrolysis followed from the first hour until a constant optical rotation was obtained; the following quantities of cellulose in 200 cc. of acid were used: 1.9714 g. of cotton cellulose, 1.9940 g. of white spruce cellulose, 2.0000 g. of Douglas fir cellulose, and 2.0000 g. of vellow birch cellulose. The cotton cellulose dissolved to a colorless solution in 20 minutes, which changed after 1.5 hours to a light straw-yellow, at about the fourth hour became much darker, and after 25 hours was light brown. The white spruce cellulose also required 20 minutes' shaking with the acid to complete its solution. This light brown solution became markedly deeper in color at about the fourth hour and after 25 hours the color was medium brown. The Douglas fir cellulose gave a colorless solution after 45 minutes' vigorous shaking. The particles before solution were very light brown while in contact with the acid. After 1.75 hours a trace of light yellow developed which became gradually darker. The yellow birch cellulose dissolved in 30 minutes to give a light brown solution.

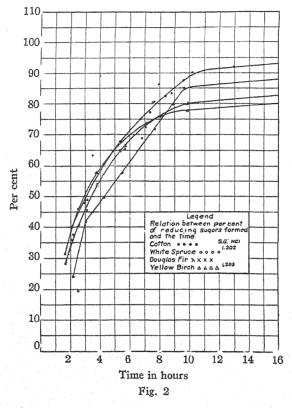

The change in specific rotation that occurs with time is illustrated in the curves of Fig. 1. The position of the curve is greatly influenced by the strength of the acid used, the rate of hydrolysis increasing as the concentration of the acid is increased so that the effect of a stronger acid on the curve is to displace it to the left.

Willstätter showed that the specific rotation of a solution of pure glucose in fuming hydrochloric acid is much greater than in water. To repeat this work, a 1% glucose solution in hydrochloric acid and water at 20° was prepared, the initial rotation readings were immediately taken, and the mutarotation was followed until no further change was observable. After 4.5 hours the glucose acquired a constant specific rotation of 51.81° in water, while in the 41% hydrochloric acid this amounted to 100.16° after 3 hours. Assuming that glucose is the only sugar formed on hydrolysis of cellulose and that it is formed quantitatively, the yields from the 4 celluloses determined by the known formula, $C = \frac{100\alpha}{1.(\alpha)_D}$, were found to be cotton cellulose, 91.40%; white spruce cellulose, 90.58; Douglas fir cellulose, 90.10; and yellow birch cellulose, 90.10.

During the progress of the hydrolysis, samples were periodically removed from the flask, diluted, neutralized and the content of reducing sugar was determined by means of Fehling solution. These results are plotted in Fig. 2.

The first few 5cc. samples removed for analysis by reduction with copper became turbid when they were diluted to 20 cc. with water. A light precipitate of cellulose settled on standing, the amount of which gradually decreased until after the fifth hour dilution no longer caused precipitation of cellulose. Those samples, which became turbid were filtered before analysis.

No direct relationship is evident between the values obtained by the polariscope and those by reduction of Fehling solution. The curves obtained by the latter method are smooth and increase rapidly until the tenth hour. The reaction then becomes much slower and a maximum is reached

only after about 25 hours. The values for dextrose obtained from the different celluloses by the reduction of Fehling solution are as follows:

			Douglas fir	Yellow birch
Time, h., m	22:55	22:50	25:20	25:20
Reducing sugar, %	97.8	93.9	87.57	85.60

Theory and Discussion

In the curves where specific rotations at 20° are plotted against time it is seen that those for spruce cellulose and cotton are practically identical regardless of the presence of mannose in the former. However, distinctly different curves were obtained for Douglas fir and yellow birch, the difference lying in the fact that the specific rotation of the yellow birch rises much more rapidly than that of any of the other celluloses used. A marked difference in the case of yellow birch was expected since it

contains about 28% of pentosan⁴ as compared with 5.5% and 9.5% for Douglas fir and white spruce, respectively. Further, the curves for all 3 wood celluloses are distinctly different from one another and with the exception of spruce cellulose are quite different from that for cotton.

An interesting relationship exists between all 4 curves. It will be noted that 2 breaks in the curve are common to each cellulose, the first break occurring at about the second hour, and the second one at about the sixth or seventh hour. Willstätter and Zechmeister9 call attention to the first break in the curve for cotton as indicated between the second and third hour but neglected to take readings often enough between the seventh and eighth. They attribute the first break to the intermediate formation of cellobiose. This idea, however, is open to question. From a consideration of the last curves, showing optical rotation, apparently three reactions occur. These sharply defined stages of the reaction may indicate successive steps in the conversion of the cellulose to the final products or to secondary reactions of the products among themselves or with the hydrochloric acid. They may also be due to changes in the optical activity of the liberated sugars. It may also be assumed that from the start of the reaction 3 sugars are simultaneously formed. Under these circumstances the observed rotation would be the sum of the rotations of the individual sugars. If at some intermediate point along the curve the formation of one of the sugars ceases and its specific rotation becomes constant then a break in the curve would be produced such as was obtained experimentally. When it is assumed that 3 sugars act in this manner at 3 different points on the curve, then specific rotation curves would be produced having breaks identical in character with those obtained experimentally. On the other hand, instead of having several reactions taking place simultaneously, it would be entirely feasible to look upon the specific-rotation curves as resulting from a number of successive reactions. In this case the initial product would be a sugar whose rotation becomes constant after several hours, because after that time the sugar is no longer a reaction product. Just at this time another reaction results in which another sugar is formed. This reaction proceeds as in the case of the first sugar formed. If a third reaction of this nature occurs, then again a curve is produced having breaks corresponding to those obtained experimentally.

From the curves which illustrate the rate of formation of reducing sugars it may be seen that the amount of sugar formed gradually increases. The slope of these curves toward the end of the reaction is not as great as the slope during the initial course of the hydrolysis. This may be attributed to a slight reduction in the acid concentration of the solution. Although every precaution was taken to prevent any loss in the acid content of the cellulose solution during hydrolysis, it is recognized that in the

Willstätter and Zechmeister, Ber., 46, 2401 (1913).

frequent handling of the solution some loss in hydrogen chloride was involved, but it is believed that this loss was negligible.

Conclusion

The curves showing the specific rotation for celluloses from spruce, yellow birch, Douglas fir, and cotton in solution in coned. hydrochloric acid, exhibit marked differences, indicating a difference in either the primary or the secondary reactions, which in turn would point to a difference in the celluloses, themselves.

A marked similarity was observed between the curves for cotton and white spruce celluloses. It is known that cotton hydrolyzes only to glucose, while a large percentage of the sugar formed by the hydrolysis of white spruce is mannose, which has a much smaller specific rotation than glucose, so that the solution of hydrolyzed white spruce should show a lower specific rotation than that of cotton cellulose. The curves for cellulose from Douglas fir and yellow birch are also similar in character, although the former contains 5.5% of pentosan while the latter contains as high as 28% of pentosan. This great variation in composition should cause a distinct difference in the specific rotations, but such is not the case, as may readily be seen from the curves.

In view of these facts we are forced to admit with Cunningham¹⁰ that the optical method for determining the quantitative conversion of cellulose to sugar is of little value. It does, however, indicate that considerable differences exist between celluloses from different sources; otherwise, all the curves would be identical in shape.

THE ISOSTERISM OF PHENYL ISOCYANATE AND DIAZOBEN-ZENE-IMIDE

By WALLACE H. CAROTHERS Received October 23, 1922

It was the purpose of the investigation the results of which are reported in this paper to test experimentally a prediction arising from the octet theory of the structure of atoms and molecules.

The structural formula of phenyl isocyanate is usually represented as C_6H_5 —N=C=O (1), and of diazobenzene-imide as C_6H_5 —N=N=N (2), or as C_6H_5 —N=N (3). Applying the principles of the theory of atomic

structure originated by G. N. Lewis¹ these would be C₆H₅:N::C::O:

¹⁰ Cunningham, Trans. Chem. Soc., 113, 173 (1918).

¹ Lewis, This Journal, 38, 762 (1916).

(1A),
$$C_6H_5:N::N::N:$$
 (2A), and $C_6H_5:N:::$ (3A). If it is assumed that the

azo-imide has the structure 2A and the isocyanate the structure 1A then these 2 molecules have the same number of extra nuclear electrons arranged in the same way and differ only in the magnitude of the nuclear charges of some of the atoms. They should, therefore, be very similar in their physical properties. Langmuir³ who pointed out this implication of the

² Since the validity of one of the conclusions of this paper depends upon the justness of the assumption that no other structures than 1A, 2A and 3A are probable for these 2 substances, it may be well to present some arguments in defense of this assumption. The valences here concerned are typically non-polar so that 1A, 2A and 3A may be rep-

resented as R—N=C=O (1B), R—N=N=N (2B) and R—N
$$\stackrel{N}{\parallel}$$
 (3B), and these

formulas will have the same significance as ordinary structural formulas with the added significance that each bond represents a pair of electrons shared between 2 atoms.

Other formulas are possible, such as R—N
$$\equiv$$
N—N, R—N $\stackrel{\sim}{=}$ N, R—N—N \equiv N for the

azo-imide, and R—N=C—O, R—N
$$\stackrel{C}{=}$$
, R—C—N=O, R—O=C=N, etc., for the

isocyanate. To decide among the possibilities, the chemical evidence is examined, and leads to Formulas 1, 2, and 3, of which 1 and 3 may be represented by identical formulas 1B and 3B in terms of the octet theory, and the second by R—N—N (2B).

The question now is whether any of these possible structures other than 1B, 2B and 3B is consistent with the chemical evidence.

It might be thought that the familiar reactions of the isocyanates with R'OH, $R'NH_2$, etc., could be represented by $R-N\equiv C-O$. This is true. But the acceptance of this formula involves one of two assumptions: (a) the urethans and ureas have the formulas R-NH=C(-O)-OR' and R-NH=C(-O)-NHR' instead of the structures usually assigned to them, or (b) rearrangement of bonds takes place after the reaction. The usual formula, R-N=C=O, obviously has the advantage of simplicity and naturalness. Moreover, the formula $R-N\equiv C-O$ is inherently improbable on the basis of the octet theory itself. It represents the nitrogen atom as having completed its sheath by sharing more than 3 pairs of electrons and the oxygen atom as having completed its sheath by sharing only 1 pair of electrons; in the absence of any definite force necessitating such arrangement the substance should spontaneously rearrange into R-N=C=O in accordance with the principle that the "charge" on each atom tends toward a minimum [See Langmuir, *Science*, 54, 59 (1921)].

The corresponding formula, R-N = N-N, for the azo-imide is still less satisfactory. It conflicts still more violently with the principle above mentioned, and for the same reason would spontaneously rearrange into R-N=N-N. Moreover, it scarcely represents any of the chemical properties of the azoimide. Thus, RN_3 reacts with R'Mg-Br to form R-N=N-NHR' [Ber., 38, 670 (1905); 39, 3905 (1906)], whereas the structure R-N=N-N requires that the R' be attached to the first or second nitrogen atom.

Of the other formulas for $R-N_3$ and RNCO possible on the basis of the octet theory, many are obviously entirely incompatible with the chemical evidence and all are less probable than those which have been considered in drawing the conclusions here presented.

³ Langmuir, This Journal, 41, 1543 (1919).

octet theory gave the name isosterism to this type of relationship between molecules. He presented evidence of the existence of isosterism between some pairs of gases and between numerous pairs of crystalline solids. Lack of sufficient data prevented complete verification of his prediction³ that cyanic and hydrazoic acids are isosteric; and no data have been presented on liquid isosteres. The lack of data on cyanic and hydrazoic acids is probably due to their instability. Some of the organic isocyanates and azoimides, which may be regarded as derived from these acids are, however, much more stable; and as the phenyl derivatives are easily available and liquid at ordinary temperatures, it was thought worth while to study some physical properties of these derivatives.

The densities, vapor pressures and viscosities were measured at various temperatures and the following values obtained.

Table I

Densities, Vapor Pressures and Viscosities of Phenyl Isocyanate and Phenyl
Azo-imide

A	bsolute Densi	ties	Vapor P	ressure in mn	1. of Hg.
Temperature C.	PhNCO	PhN ₃	Temperature C.	PhNCO	PhN ₃
0.0	1.1152	1.1175	75.0	36.3	33.8
10.0	1.1049	1.1070	80.0	45.3	41.8
20.0	1.0943	1.0968	85.0	55.9	52.0

```

The agreement between the values calculated by these formulas and the experimental ones is in each case practically within the limits of experi-

mental error, which for the densities is about $\pm 0.03\%$, and for the viscosities and vapor pressures about $\pm 0.7\%$.

The properties of the isocyanate at any given temperature are thus the same as those of the azo-imide at temperatures from 1.7° to 4.8° higher, which is in accordance with the prediction. It is interesting to note also that the disparity between the properties of the two compounds is the same in type and degree as in the properties of the gaseous isosteres which Langmuir originally used to verify the principle of isosterism. The data here presented, then, confirm this principle. Incidentally they also confirm the straight-chain structure for triazo compounds, except that these should probably be written as R-N=N=N as Langmuir predicted instead of as R-N=N=N=N.

Experimental Part

Diazobenzene-imide was prepared by the method of Fischer' as modified by Dimroth.⁸ It was washed with dil. hydrochloric acid and sodium hydroxide several times, then with water, dried with calcium chloride, distilled under diminished pressure, treated with sodium and fractionated under diminished pressure into a Brühl receiver desiccated with phosphorus pentoxide. The phenyl isocyanate was a commercial sample prepared, presumably, from phosgene and aniline. It was treated with sodium and fractionated in the same way. Thus purified, it was water-white and developed no precipitate or turbidity after a month, even when occasionally exposed to the air.

Densities were determined by means of a pycnometer. Vapor pressures were determined by means of the static isoteniscope of Smith and Menzies. The manometer was a simple U-tube 1 meter long and about 8 mm. in internal diameter fastened to a meter stick and made vertical. Readings were made with the naked eye by means of a mirror. The viscosities were determined with a Washburn viscosimeter made from ordinary glass. Times of flow were determined simultaneously by means of 2 stopwatches, from 4 to 8 readings being made at each temperature. All the data represent the means of various determinations, at least 2 different, freshly purified samples being used in each case. The temperatures were regulated by hand to about 0.05° during

 $^{^4}$ The calculated value for the viscosity of the azo-imide at 0° differs from the experimental value by about 3.6%, but since this calculation is equivalent to an extrapolation of the isocyanate curve into a region where the viscosity is changing very rapidly, the disagreement can hardly be considered as serious.

⁵ Langmuir, This Journal, **42**, 285 (1920).

⁶ The structure R—N≡N is, of course, impossible from the point of view of the octet theory. The straight-chain structure for triazo compounds has been proposed and supported by Turrentine [This Journal, 34, 385 (1912); 36, 23 (1914)], by Thiele [(Ber., 44, 2522 (1911)] and by Franklin [Proc. 8th Inter. Cong. App. Chem., 6, 119 (1912)] and the ring structure has been defended by M. O. Forster [ibid., 6, 108 (1912)].

¹¹ The viscometer was made of glass, and the water constant was determined at each temperature at which readings were made. In calculating the viscosities in centipoises from these readings the table of Bingham and Jackson [Bur. Standards Sci. Papers, 298, p. 75] of the viscosity of water was used.

the measurements of densities and vapor pressures, and automatically to 0.005° or better in the determination of the viscosities.

Summary

Assuming the atoms of phenyl isocyanate and of diazobenzene-imide to be arranged as indicated in the formulas, C_6H_5NCO and C_6H_5NNN , application of the octet theory leads to the conclusion that they are isosteric. They should, therefore, be very similar in their physical properties. Their densities, vapor pressures and viscosities have been measured at various temperatures, and this prediction confirmed. These results also confirm the straight-chain structure for triazo compounds.

[Contribution from the Laboratory of Organic Chemistry of the State University of Iowa]

DIACYL DERIVATIVES OF ORTHO-HYDROXYBENZYLAMINE

By L. Chas. Raiford and E. P. Clark Received February 2, 1923

Previous work in this Laboratory has shown (a) that when 2-acetylaminophenol is subjected to the action of benzovl chloride (Schotten-Baumann reaction), the benzovl radical is attached to nitrogen while acetyl migrates of oxygen;1 (b) that this migration is not prevented by the presence of acid-forming substituents (halogen) attached to the nucleus of the aminophenol;2 (c) that the acetyl-benzoyl derivatives of p-aminophenols do not suffer this rearrangement; 3 (d) that the presence of bromine and other heavy radicals adjacent to the reacting groups (amino and hydroxyl), which in many reactions causes marked retardation, does not prevent the migration;4 and (e) that these observations seem to hold with bases derived from naphthalene, namely, 1-amino-2-naphthol and halogenated derivatives.⁵ Since the acetyl-benzoyl derivatives of more than 15 o-amino-phenols, having various substituents at different positions in the molecule, have been tested in this way and all have been found to undergo this migration, it may be assumed that this behavior is general for this class of compounds when the acyl radicals are those specified.

Although the migration of this kind has thus far been observed to take place only in the derivatives of compounds in which both reacting groups

(hydroxyl and amino) were attached directly to the benzene ring. Auwers and his students6 have reported a rearrangement in which acvl wandered from oxygen to nitrogen when oxygen was attached to the ring and nitrogen was on a side chain. Thus, when an O-acyl derivative of o-hydroxybenzyl bromide was heated with aniline, the bromine atom was replaced by the phenylamino radical and at the same time the position of the acyl shifted from oxygen to nitrogen; while McConnan and Titherly7 found that under certain conditions o-acylsalicylamide rearranged to N-acylsalicylamide, and that the change was reversible. The starting compounds in these cases were somewhat different from those heretofore employed in our work, in that in salicylamide not only was the amino radical on a side chain, but the carbon of this chain was in the form of a carbonyl group, while in the benzylamine used by Auwers and collaborators one of the amino hydrogen atoms was replaced by a hydrocarbon radical (phenyl or a homolog).8 Auwers' results, too, differed from ours to the extent that, with only one of the benzylamine derivatives he prepared, apparently, did he observe the migration of acyl from nitrogen to oxygen. In that instance the product was not stable, but rearranged spontaneously to the N-acyl derivative, which would be expected when the amino radical is not already acylated. On account of these differences, and also because of the sharply defined behavior of the products studied by the abovementioned authors, as well as the equally definite results of our own work, it became a matter of interest to study the behavior of acetyl-benzoyl derivatives prepared from a phenolic compound having an unsubstituted amino radical attached to a side chain adjacent to an hydroxyl group.

For this study o-hydroxybenzylamine, prepared as indicated below, was selected. With the exceptions noted in the Experimental Part, the preparation and hydrolysis of the derivatives of this base were carried out as described in previous papers. It may, however, be stated at once that benzoylation of o-hydroxybenzyl-acetamide did not cause the migration of the acetyl radical, and that the introduction of the acyl radicals in different orders gave isomeric acetyl-benzoyl derivatives; this is entirely

- ⁶ Auwers and others, Ber., 33, 1923 (1900).
- ⁷ McConnan and Titherly, J. Chem. Soc., 89, 1318 (1906).

⁸ In this connection it is to be noted that certain well-known rearrangements involving the amino radical do not take place when this hydrogen has been substituted by an alkyl or aryl radical. Thus, Slosson [Ber., 28, 3266 (1895); Am. Chem. J., 29, 295 (1903)] found that "the presence of the hydrogen atom (H⁺) of the acylamine halides, RCONH-Hal is essential for the successful Beckmann rearrangement," while Ransom, [Am. Chem. J., 23, 26 (1900)] proved that in the diacyl derivatives of methyl-o-aminophenol that he studied there was no molecular rearrangement. Stieglitz [Am. Chem. J., 29, 52 (1903)] formulated a theory to account for this behavior and, in addition to the cases cited above, has called attention to the fact that chloro-imido esters, whose parent substances are acid halogen-amides, and hydroxylamine derivatives that can no longer lose water, have lost the tendency to undergo a Beckmann rearrangement.

different from the behavior of such compounds when both the reacting radicals are attached directly to the aromatic nucleus.

Experimental Part

o-Hydroxybenzylamine.—Salicylaldoxime, used in preparing this amine, was obtained in excellent yield by following the general method of Loch⁹ modified by removing under reduced pressure practically all the alcohol used as solvent in the early part of the experiment, and mixing the residue with water before extraction with ether. The extract thus obtained was dried with anhydrous sodium sulfate, the greater part of the ether was distilled, and the residue allowed to crystallize. The product was purified by treatment of its chloroform solution with petroleum ether, which gave colorless crystals that melted at 57° as reported in the literature. Fifty g. of aldehyde gave 55 g. of oxime, a yield of 98%. Loch reported no yield.

To obtain the amine 10 20 g. of the oxime, purified as indicated above, was dissolved in 300 cc. of 50% alcohol and reduced in the usual way with 2.5% sodium amalgam. 11 The temperature was kept below 55° and the excess of alkali continually neutralized by the addition of hydrochloric acid. However, the reaction mixture was kept slightly alkaline to litmus until reduction had been completed. This was indicated by a copious evolution of hydrogen. The solution was then made slightly acid, separated from the mercury and evaporated under reduced pressure until sodium chloride began to crystallize. The residue was diluted with water and concentrated as before, in order to remove as completely as possible the alcohol previously used as solvent. The mixture was again diluted with water to a volume of about 300 cc. and transferred to an Erlenmeyer flask containing about 25 cc. of ether. Ammonium hydroxide was added in small portions until a slight excess was present. The mixture was shaken vigorously after each addition. Upon continued shaking for a few minutes the amine began to crystallize on the sides of the flask. After a short time, the product was removed by filtration. Extraction of the mother liquor with ether and evaporation of the solvent gave more of the

⁹ Loch, Ber., 16, 1782 (1883).

¹⁰ This amine had previously been prepared by Goldschmidt and Ernst [Ber., 23, 2740 (1890)] in accordance with Salkowski's method [Ber., 22, 2142 (1889)] by heating o-anisamine with hydrochloric acid under pressure for several hours. These workers stated that only a poor yield of the base could be obtained by reduction of salicylaldoxime with sodium amalgam, although several different modifications of the method were tried. They recorded 121° as the melting point of their product. Tiemann [Ber., 23, 3016 (1890)], who obtained this base by the reduction of salicyl-m-hydrazone-benzoic acid with zinc dust and dil. sulfuric acid, reported no yield but recorded a melting point of 125°. Auwers and Walker [Ber., 31, 3038 (1898)], who prepared it from o-cyanophenol by the Mendius reaction, reported neither yield nor melting point.

¹¹ This was prepared in accordance with Nef's method [Ann., 280, 307 (1894)] modified as follows: 25 g. of sodium in small pieces was added to 975 g. of purified mercury covered by 400 cc. of toluene in a 1-liter beaker and the mixture stirred constantly. This was most easily done by placing the pieces of sodium on a sharp pointed glass stirring rod and, forcing them under the surface of the mercury; the reaction took place at once. The toluene reached the boiling point before all the sodium had been introduced, but the latter was added quite rapidly toward the end. Finally the toluene was decanted, and the solid amalgam was gently heated in a casserole until it melted and became homogeneous. It was next freed from slag by pouring it slowly upon a large piece of paper, the slag remaining in the casserole. As soon as the pure product thus obtained was sufficiently cool to be handled, it was broken up and placed in a well-stoppered container.

crystals. In this way 20 g. of oxime gave 15.5 g. of amine by direct crystallization and 1.7 g. from the mother liquor, a total of 17.2 g. or a yield of 96%.

It was best recrystallized by treatment of a solution in absolute alcohol with petroleum ether. Purified in this way, it began to soften at 126° and melted at 129° (uncorr.). Analysis (Kjeldahl) indicated that it was pure.

Analysis. Subs., 0.2513: 20.25 cc. of 0.1 N HCl. Calc. for C_7H_9ON : N, 11.37. Found: 11.29.

o-Acetyloxybenzyl-acetamide.—Two g. of o-hydroxy-benzylamine was added slowly to a hot solution of 2 drops of concd. sulfuric acid in 8 g. of acetic anhydride, after which the mixture was boiled gently for 5 minutes and then allowed to stand for 2 hours. It was poured into water and neutralized with sodium hydrogen carbonate. The acetyl derivative was removed by extraction with chloroform, the solution dried and evaporated to a small volume, after which petroleum ether was added. The crystals weighed 2.8 g.; yield, 12 83%. Recrystallization by the same method gave hexagonal plates; m. p., $^{102-103}$ °. Analysis (Kjeldahl) indicated the presence of 2 acetyl radicals.

Analysis. Subs., 0.3041: 14.58 cc. of 0.1 N acid. Calc. for $C_{11}H_{13}O_{3}N$: N, 6.76. Found: 6.72.

o-Hydroxybenzyl-acetamide.—This compound, previously prepared by Goldschmidt and Ernst¹⁰ by direct acetylation, was obtained by hydrolysis of the diacetyl derivative described above. One g. of the latter was dissolved in 50 cc. of 95% alcohol containing slightly more than 2 molecular proportions of potassium hydroxide. The solution was allowed to stand for about 5 minutes, and then made acid to congo red with hydrochloric acid. Potassium chloride was removed, the filtrate evaporated under reduced pressure to a small volume, and 20 cc. of water added. This gave 0.59 g. of a crystalline product. The mother liquor was extracted with chloroform, the extract dried and reduced to a small volume, and petroleum ether added. A further quantity of substance, 0.21 g. was obtained; yield, 0.80 g. (quantitative). The combined product was recrystallized as just indicated, and gave thick rectangular plates that melted at 140°, as found by Goldschmidt and Ernst. Analysis (Kjeldahl) indicated the presence of only 1 acetyl radical.

Analysis. Subs., 0.3014: 18.10 cc. 0.1 N acid. Calc. for $C_9H_{11}O_2N$: N, 8.46 Found: 8.41.

o-Benzoyloxybenzyl-acetamide.—A compound having apparently this composition and structure was obtained by Auwers and Eisenlohr, 13 but they gave neither yield nor analysis of their product; the melting point they recorded is 108–109°; that found by us is 116°; yield, 93%.

Hydrolysis of the Acetyl-benzoyl Derivative.—A solution of 1.8 g. of the diacyl derivative just described, in 75 cc. of alcohol containing 0.85 g. (2.25 molecular equivalents) of potassium hydroxide, was allowed to stand for half an hour, after which it was made acid to congo red with hydrochloric acid. This caused the development of a pronounced odor of ethyl benzoate and a precipitation of potassium chloride. The salt was removed by filtration, the filtrate concentrated almost to dryness, and the residue

 $^{^{12}}$ Goldschmidt and Ernst tried to prepare this product by boiling the amine with acetic anhydride and anhydrous sodium acetate, but they obtained only the N-acetyl derivative and a small portion of an oily material having weak basic properties, which they assume may have been an anhydro base. We found that when a mixture of 1 part of base, 0.25 parts of dry sodium acetate and 4 parts of acetic anhydride, was treated as directed in our experiment described above, a yield of 74% of the diacetyl derivative was obtained.

¹³ Auwers and Eisenlohr, Ann., 369, 236 (1909).

then mixed with 25 cc. of water containing sufficient potassium hydroxide to bring about solution. After filtration, hydrochloric acid was added until a Sörensen value of 6–7 was reached, which caused the precipitation of 0.82 g. of solid. Removal of this and extraction of the mother liquor with chloroform gave 0.17 g. additional, a total of 0.99 g., which corresponds to a yield of 89.5% on the basis of the N-acetyl derivative as the product. The crude material melted at 135°, but purification by treatment of its chloroform solution with petroleum ether gave colorless irregular plates that melted at 140–141°. A mixture of this product and the N-acetyl derivative previously described melted at the same temperature as either of them separately.

o-Hydroxybenzyl-benzamide.—This compound was first obtained by treatment of 2.0 g. (2 molecular equivalents) of the free base suspended in 50 cc. of dry ether with 1 molecular proportion of benzoyl chloride dissolved in ether, according to Ransom's method. The product weighed 0.8 g., corresponding to a yield of only 43.4%. After solution in chloroform and precipitation by the addition of petroleum ether, it melted at $110-115^{\circ}$.

Recrystallization by treatment of a solution in absolute alcohol with petroleum ether gave short, thick needles that softened at 140° and melted at 142°. Further crystallization caused no change in melting point. The low yield here obtained made it advisable to find some other way to obtain this product, and this was done by hydrolysis of the dibenzoyl derivative (see below).

o-Benzoyloxybenzyl-benzamide.—To a solution of 3 g. of the free base in 300 cc. of water containing 2.1 molecular proportions of potassium hydroxide, was added 2.75 g. (2.15 molecular proportions) of benzoyl chloride, after which the material was shaken until the precipitation was complete; the liquid was still slightly acid to litmus. The solid, collected on a filter, washed and dried, weighed 8.5 g., which is more than the theoretical requirement. The excess may possibly be due to the formation of a tribenzoyl derivative. When the substance was purified by dissolving it in absolute alcohol and adding petroleum ether it separated in masses of long, thin needles that with the unaided eye had the appearance of paper pulp. It softened at 137° and melted to a clear liquid at 142–143°. Four recrystallizations caused no change in melting point. Analysis of an air-dried sample (Kjeldahl) indicated the presence of 2 benzoyl radicals.

Analysis. Subs., 0.6013: 18.02 cc. of 0.1 N acid. Calc. for $C_{21}H_{17}O_2N$: N, 4.23. Found: 4.20.

Preparation of o-Hydroxybenzyl-benzamide by Hydrolysis of the Dibenzoyl Derivative.—A solution of 3 g. of the dibenzoyl derivative just described in 150 cc. of alcohol containing 1.2 g. (2.25 molecular proportions) of potassium hydroxide was allowed to stand for 20 minutes, after which it was made acid to congo red by the addition of hydrochloric acid. The potassium chloride was removed and the filtrate evaporated under reduced pressure almost to dryness, after which 40 cc. of water was added, containing enough potassium hydroxide to dissolve the benzoyl derivative present. The mixture was filtered, and the ethyl benzoate removed by distillation in a vacuum. The remaining liquid was diluted to a volume of about 50 cc. and hydrochloric acid was added until a Sörensen value of 6–7 was reached. The precipitated benzoyl derivative was collected on a filter, washed and dried; yield, quantitative. It softened at 139° and melted to a clear liquid at 142–143°. After purification by solution in chloroform and the addition of petroleum ether, it was obtained in the form of rhombohedral plates that softened at 140° and melted sharply at 142°.

This material was shown not to be an impure sample of the dibenzoyl derivative

¹⁴ Ransom, Am. Chem. J., 23, 1 (1900).

¹⁵ Auwers and Eisenlohr, Ref. 13, p. 228, reported such a product from o-amino-p-cresol.

(m. p., 142-143°) from which it was prepared, by (a) the determination of the melting point of a mixture of the 2 products, found to be 110-115°; (b) by melting a mixture of the product here in question and the monobenzoyl compound obtained by Ransom's method (see above), in which case no depression was observed, and (c) by analysis for nitrogen, which indicated the presence of one benzoyl radical.

Analysis. Subs., 0.4013: 17.51 cc. of 0.1 N acid. Calc. for $C_{14}H_{15},O_2N$: N, 6.17. Found: 6.11.

Acetylation of the N-Benzoyl Derivative.—A mixture of $2.8~\rm g$. of the monobenzoyl compound, $0.75~\rm g$. of dry sodium acetate and $12~\rm g$. of acetic anhydride was gently boiled for $10~\rm minutes$. After the product had cooled, $50~\rm cc$. of water was added and the greater part of the acid and anhydride was neutralized by the addition of sodium bicarbonate. This caused crystals of the acetyl-benzoyl derivative to separate almost completely within a few minutes; yield $3.2~\rm g$., or $97~\rm \%$. The crude product softened at $70~\rm °$ and melted to a milky liquid at $80-83~\rm °$. Purification by solution in benzene and precipitation with petroleum ether gave irregular masses of poorly defined needles that softened at $80~\rm °$ and melted to a milky liquid at $85~\rm °$. Recrystallization from several other solvents caused no change in melting point. This product was further identified by analysis (Kjeldahl), which indicated the presence of both acetyl and benzoyl radicals.

Analysis. Subs., 0.5005: 18.42 cc. of 0.1 N acid. Calc. for $C_{16}H_{15}O_3N$: N, 5.20. Found: 5.17.

Finally, the melting point of a mixture of this material and the acetyl-benzoyl derivative (m. p., 116°) obtained by benzoylation of o-hydroxybenzyl-acetamide, was found to be 70–75°. This together with the analyses and the fact that these compounds give different products when hydrolyzed, indicates that they are isomeric and not identical, and that in the benzoylation of a phenol containing an acetylamino group attached to a side chain the migration characteristic of a derivative of o-aminophenol does not take place.

Hydrolysis of o-Acetyloxybenzyl-benzamide.—A solution of 1 g. of the product in 50 cc. of alcohol containing 0.47 g. (2.25 molecular proportions) of potassium hydroxide, was allowed to stand for 30 minutes. Hydrochloric acid was then added until the mixture reacted acid to congo red. The potassium chloride that had been precipitated was removed by filtration, and the filtrate concentrated under reduced pressure almost to dryness. The residue was washed from the flask with about 50 cc. of water and dried. The product weighed 0.7 g.; yield, 91%. It softened at 140° and melted at 142°. A mixture of this material and the N-benzoyl derivative prepared by the two methods indicated above showed no depression in melting point, while a mixture of this substance and the product (m. p., 140–141°) obtained by hydrolysis of o-benzoyloxybenzyl-acetamide melted at 110–120°.

Summary and Conclusions

- 1. An improvement of Nef's method for the preparation of sodium amalgam has been described.
- 2. It has been shown that, contrary to the results of Goldschmidt and Ernst, a very high yield of o-hydroxybenzylamine may be obtained by reduction of salicylaldoxime with sodium amalgam.
- 3. The observations here reported indicate that the migration of acyl previously shown to be characteristic of diacylated o-aminophenols does not occur when the amino radical is attached to a side chain.

PRODUCTION OF IMIDO THIOL ESTERS BY THE CONDENSATION OF THIOCYANATES WITH RESORCINOL OR PHLOROGLUCINOL

By R. J. Kaufmann with Roger Adams¹ Received February 12, 1923

The similarity in the reactivity of the cyano grouping in organic thiocyanates and cyanides is striking. The following table represents some of the commoner reactions of each which have already been described in the literature.

Reagent	Product with RCN	Product with RSCN
H_2	RCH_2NH_2	$RSH + CH_3NH_2^2$
H ₂ O (HCl)	RCONH ₂	$RSCONH_2$, $[RSC(=NH)(OH)]^3$
R'OH (HCl)	RC(=NH.HCI)OR'	$RSC(=NH.HCl)OR'^{4}$
H ₂ S	RCSNH ₂	$RSCSNH_2$, $[RSC(=NH)(SH)]^5$

In this communication is described the condensation of alkyl and aryl thiocyanates with resorcinol and phloroglucinol in the presence of hydrogen chloride and zinc chloride. This reaction corresponds to that studied by Hoesch in which alkyl and aryl cyanides are condensed with resorcinol and phloroglucinol under similar conditions. Whereas the cyanides yield imido hydrochlorides which hydrolyze to ketones, the thiocyanates readily yield imido thiol ester hydrochlorides, the expected products providing the cyano grouping in the thiocyanates react in the same way as the cyano in the cyanides. Methyl, ethyl, n-butyl and phenyl thiocyanates

HO OH RCN HO OH
$$C(=NH.HCl)R$$
 HO OH COR HO OH $C(=NH.HCl)SR$

were condensed with resorcinol, thus showing the reaction to be a general one. Only methyl thiocyanate was condensed with phloroglucinol, but

unquestionably the other thiocyanates would condense in an analogous way. The products thus obtained resembled in chemical reactivity known imido thiol ester hydrochlorides. Their exact constitution was proved by conversion into substances of known structure.

By the action of sodium bicarbonate these imido thiol ester hydrochlorides were decomposed into the free imido thiol esters. The latter substances, in contrast to many of this class of compounds previously described, were perfectly stable.⁶

The imido thiol ester hydrochlorides were readily decomposed into thiol esters by refluxing in very dilute aqueous hydrochloric acid solution. Since the thiol esters thus obtained were converted by alkali into the corresponding carboxylic acids which were made directly from resorcinol or phloroglucinol, the constitution of the original substances was definitely established.

The free imido thiol esters reacted readily with alcohols to give the corresponding imido esters and mercaptans. This is a reaction that is being investigated further. The imido esters obtained by this latter reaction were converted by hydrochloric acid to the corresponding salt and by boiling with dil. hydrochloric acid into the corresponding esters which, in the examples at hand, were known compounds and could readily be made by the esterification of the corresponding acids. The following chart gives in concise form the various reactions just discussed.

The formation of the imido thiol ester hydrochlorides was very simple but there was some difficulty in their isolation on account of the zinc chloride used as a condensing agent. Washing with acetone removed a large amount of impurity from the crude condensation products but solution of the crude product in cold hydrochloric acid and reprecipitation of the base was necessary in order to eliminate completely the impurity of zinc. At least part of the zinc in the crude products was present not

⁶ Autenrieth and Brüning, Ber., 36, 3464 (1903). Bernthsen, Ann., 197, 341 ff, (1879).

merely as zinc chloride, but actually as a zinc salt of the phenol and in the condensation of the phenyl thiocyanate with resorcinol, it was actually possible to isolate and purify such a zinc compound. The initial condensations were also carried out without any zinc chloride, but under these conditions the reactions went much more slowly and did not yield so great an amount of the products. The materials obtained in this way, however, were always much purer.

Experimental Part

General Procedure for the Condensation of Alkyl and Aryl Thiocvanates with Resorcinol and Phloroglucinol.—A 1.5-liter wide-mouth bottle was equipped with a 3-hole rubber stopper through which were passed a mechanical stirrer with a mercury seal, an inlet tube with a wide mouth reaching to the bottom of the bottle, and an outlet tube which extended just through the stopper. To this outlet tube was attached a small upright water condenser, the upper end of which was closed with a tube leading through a sulfuric acid wash bottle. The moisture was thus prevented from returning to the reaction bottle and at the same time the speed with which the hydrogen chloride was flowing could be determined. In the bottle were placed 1 molecular equivalent each of phenol and thiocyanate, 0.2 to 1 molecular equivalent of pulverized anhydrous zinc chloride, and 250 to 1000 cc. of anhydrous ether. The stirrer was started and the mixture agitated for about 1 hour, until solution was complete. Dry hydrogen chloride was then bubbled into the solution for 30 to 40 hours, while rapid agitation was constantly maintained. Noticeable warming took place at the beginning and continued for 2 to 3 hours.

After 15 to 25 hours the separation of orange to deep red crystals began and continued for some time until complete. In some cases the reaction mixture at the end was semisolid, particularly when the smaller amounts of ether mentioned were used. The mixture was allowed to settle and the clear mother liquors decanted. The residue which was frequently sticky and dark colored, was extracted with cold acetone until a test portion imparted practically no further color to fresh solvent. The products thus obtained were light colored, granular solids.

It was advisable to return the mother liquors to the reaction bottle and again to pass in dry hydrogen chloride for some hours with vigorous stirring. In many cases an additional quantity of condensation product was thus obtained.

The further purification varied somewhat with the individual substances.

Methyl-thiol- β -resorcylate-imide Hydrochloride, (HO)₂C₆H₃C(\rightleftharpoons NH.HCl)SCH₃.—From 110 g. of resorcinol, 73 g. of methyl thiocyanate, 136 g. of zinc chloride and 275 cc. of anhydrous ether was obtained 130 to 160 g. of crude dry condensation product. In order to purify it from the zinc which it contained, it was crystallized twice from hot 15%

hydrochloric acid, washed with cold acetone and then dried at 100–110°. The product thus obtained was practically pure white and melted at 244–245° (corr.) decomp.

Analyses. Subs., 0.1340, 0.1944: AgCl, 0.0886, 0.1289. Subs., 0.1963, 0.2242: BaSO₄, 0.2085, 0.2399. Subs., 0.2190, 0.2042: 5.290, 5.041 cc. of 0.1930 N HCl. Calc. for $C_8H_{10}O_2CINS$: Cl, 16.15; S, 14.60; N, 6.38. Found: Cl, 16.36, 16.40; S, 14.59, 14.69; N, 6.53, 6.67.

Methyl-thiol- β -resorcylate-imide Sulfate, (HO)₂C₆H₃C (=NH. $\frac{1}{2}$ H₂SO₄)SCH₃.—A solution of 5 g. of the crude hydrochloride in 10 cc. of water was filtered and the filtrate treated with 10 cc. of 50% (by volume) sulfuric acid. After 24 hours, crystals of the sulfate separated. These were recrystallized once from 25% (by weight) sulfuric acid, then from alcohol and finally washed with dry ether. The product formed white crystals; m. p., 230–231.5° (corr.).

Analyses. Subs., 0.2305, 0.2339; 4.951, 5.071 cc. of 0.1917 N HCl. Calc. for $C_{16}H_{20}O_8N_2S_3$: N, 6.03. Found: 5.77, 5.82.

Ethyl-thiol- β -resorcylate-imide Hydrochloride, (HO)₂C₆H₃C(=NH.HCl)SC₂H₅.— From 110 g. of resorcinol, 87 g. of ethyl thiocyanate, 136 g. of zinc chloride and 275 cc. of ether was obtained 140–160 g. of crude solid. This product tended to remain pink even after action of the acetone. The color could be removed, however, by dissolving the product in ice water and adding coned. hydrochloric acid. The cream-colored product was then recrystallized from 15% hydrochloric acid and, after it had dried, melted at 229.5–231.5° (corr.) decomp.

Analyses. Subs., 0.3452, 0.3499; 7.534, 7.627 cc. of 0.1930 N HCl. Calc. for $C_0H_{12}O_2NCIS$: N, 6.00. Found: 5.90, 5.89.

Ethyl-thiol- β -resorcylate-imide Sulfate, (HO)₂C₆H₃C(=NH. $\frac{1}{2}$ H₂SO₄)SC₂H₅.—The method of preparation was similar to that of the corresponding methyl compound. The substance was purified by crystallization from 95% alcohol or glacial acetic acid. It formed a white powder; m. p., 214–217° (corr.).

Analyses. Subs., 0.2112, 0.4461; 4.285, 8.870 cc. of 0.1930 N HCl. Calc. for $C_{18}H_{24}O_8N_2S_3$: N, 5.69. Found: 5.49, 5.38.

n-Butyl-thiol-β-resorcylate-imide Hydrochloride, (HO)₂C₆H₃C(\rightleftharpoons NH.HCl)SC₄H₉ (n).—The butyl derivative was readily obtained from resorcinol, n-butyl thiocyanate,⁷ zinc chloride and anhydrous ether. It was purified by crystallization from a mixture of equal volumes of 95% alcohol and 15% hydrochloric acid. When pure the substance was white and melted at 226–228° (corr.) decomp.

Analyses. Subs., 0.1591, 0.1146: AgCl, 0.0865, 0.0608. Subs., 0.2083, 0.1265: BaSO₄, 0.1856, 0.1115. Subs., 0.3332, 0.4236; 6.701, 8.218 cc. of 0.1930 N HCl. Calc. for $C_{11}H_{16}O_2NSCl$: CI, 13.55; S, 12.26; N, 5.35. Found: Cl, 13.45, 13.13; S, 12.24, 12.11; N, 5.44, 5.25.

Phenyl-thiol- β -resorcylate-imide Hydrochloride, $(HO)_2C_6H_3C$ (=NH.HCl)SC $_6H_5$. —From 22 g. of resorcinol, 27 g. of phenyl thiocyanate, 5 g. of zinc chloride and 250 cc. of anhydrous ether was obtained 12 g. of crude product. When this substance was crystallized from approximately 2% aqueous hydrochloric acid, a white product was formed. This was crystallized further by dissolving in the smallest amount of alcohol

 $^{^7}$ n-Butyl thiocyanate has not been described in the literature. It was made by the general procedure described in Ann., 178, 85 (1882) from n-butyl bromide and ammonium thiocyanate; yield, 85–90%. The product had the following constants: b. p., 744 mm. 184.5–185.5°; d_*^{25} , 0.9563; $n_D^{21.5}$, 1.4636.

Analysis. Subs., 0.3369, 0.3084: 14.940, 13.959 cc. of 0.1917 N HCl. Calc. for C_5H_9NS : N, 12.17. Found: 11.91, 12.16.

possible and gradually precipitating with dry ether in the cold. The substance was then pure and white, and melted at 220–222° (corr.) decomp.

Analysis. Subs., 0.1511, 0.1533: BaSO₄, 0.1228, 0.1252. Subs., 0.0950, 0.3681: 1.771, 6.850 cc. of 0.1892 N HCl. Calc. for $C_{13}H_{12}O_2NCIS$: S, 11.38; N, 4.98. Found: S, 11.16, 11.22; N, 4.95, 4.93.

The crude material was apparently a fairly pure zinc salt of the condensation product. The zinc salt was prepared for analysis by dissolving the acetone-washed substance, in 10 times its weight of cold 95% alcohol, filtering the solution and adding an equal volume of concd. hydrochloric acid. The substance then separated in the form of small, light-yellow crystals which were finally washed with acetone. Repetition of this treatment did not raise the melting point, which was $225-227^{\circ}$ (corr.) decomp.

Analysis. Subs., 0.1711, 0.1663; BaSO₄, 0.1105, 0.1099. Subs., 0.2517, 0.2756; 3.769, 4.202 cc. of 0.1892 N HCl. Calc. for $C_{13}H_{10}O_2NClSZn$: S, 9.29; N, 4.06. Found: S, 8.87, 9.08; N, 3.97, 4.04.

Methyl-thiol-2,4,6-trihydroxy-benzoate-imide Hydrochloride, (HO) $_3$ C $_6$ H $_2$ C(:=NH. HCl)SCH $_3$.—From 35 g. of phloroglucinol, 21 g. of methyl thiocyanate, 7 g. of zinc chloride and 250 cc. of anhydrous ether, was obtained after about 20 hours 22 g. of crude product. When the filtrate was treated for another 10–15 hours with dry hydrogen chloride, an additional 14.3 g. of crude product was formed. It was purified by dissolving it in a hot mixture of 2 parts by volume of alcohol and 3 parts of 15% hydrochloric acid, boiling the mixture with charcoal, filtering and cooling the filtrate. The product was white when pure and melted at 255–256° (corr.).

Analyses. Subs., 0.2299, 0.3698; 4.842, 8.000 cc. of 0.1892 N HCl. Calc. for C_8H_{10} -O₃NClS; N, 5.95. Found: N, 5.58, 5.73.

General Procedure for Conversion of the Imido Thiol Ester Hydrochlorides to Imido Thiol Esters.—The pure imido thiol ester hydrochlorides were dissolved in 3 to 5 times their weight of water, the solutions cooled and sufficient saturated sodium bicarbonate solution was added to make the mixtures alkaline. The bases which precipitated were filtered, and washed with water.

When the crude imido thiol ester hydrochlorides which contained zinc were converted into the free bases, it was necessary to add only enough sodium bicarbonate in the precipitation to leave the mixture just acid to litmus. The major portion of the zinc thus remained in solution. The bases were filtered, dissolved again in the minimum amount of dil. hydrochloric acid, and again precipitated as just described. In this way bases entirely free from zinc salts were obtained.

Methyl-thiol- β -resorcylate-imide, (HO)₂C₆H₃C(=NH)SCH₃.—For complete purification, this substance was crystallized from hot methyl alcohol. This must be done rapidly since methyl alcohol gradually reacts with the compound. When pure, the substance was obtained in the form of small yellow needles; m. p., 197–199° (corr.) decomp.

Analyses. Subs., 0.1397, 0.1115: BaSO₄, 0.1744, 0.1409. Subs., 0.1585, 0.2298: 4.394, 6.710 cc. of 0.1930 N HCl. Calc. for C₈H₉O₂NS: S, 17.50; N, 7.65. Found: S, 17.14, 17.35; N, 7.50, 7.90.

Ethyl-thiol- β -resorcylate-imide, (HO)₂C₅H₃C(\Longrightarrow NH)SC₂H₅.—This product was crystallized from ethyl alcohol from which it formed yellow crystals; m. p., 196–197°

(corr.) decomp. It was not allowed to stand with the ethyl alcohol since these substances gradually reacted.

Analyses. Subs., 0.2482, 0.2814: 6.383, 7.378 cc. of 0.1930 N HCl. Calc. for $C_9H_{11}O_2NS$: N, 7.11. Found: 6.95, 7.09.

n-Butyl-thiol- β -resorcylate-imide, (HO) $_2$ C $_6$ H $_3$ C(\Longrightarrow NH)SC $_4$ H $_9$ (n).—This substance was finally purified by crystallization from methyl alcohol. It was not allowed to stand with the methyl alcohol since the 2 substances gradually reacted. Bright yellow needles were formed; m. p., 173–174° (corr.) decomp.

Analyses. Subs., 0.1626, 0.1613: BaSO₄, 0.1661, 0.1630. Subs., 0.3710, 0.4816; 8.575, 10.860 cc. of 0.1930 N HCl. Calc. for $C_{11}H_{15}O_2NS$: S, 14.24; N, 6.22. Found: S, 14.03, 13.88; N, 6.25, 6.10.

Phenyl-thiol- β -resorcylate-imide, $(HO)_2C_6H_3C(\rightleftharpoons NH)SC_6H_5$.—The base was crystallized by solution in alcohol and precipitation with water or by partial evaporation of an alcohol-ether solution. The compound formed yellow crystals which, after they were dried at 80°, melted at 156–158° (corr.) decomp.

Analyses. Subs., 0.1882, 0.1568: 3.880, 3.340 cc. of 0.1892 N HCl. Calc. for $C_{13}H_{11}O_{2}NS$: N, 5.72. Found: 5.47, 5.65.

Methyl-thiol-2,4,6-trihydroxy-benzoate-imide, $(HO)_5C_6H_2C(=NH)SCH_3$.—This substance proved to be very much less soluble in the common organic solvents than any of the other imido thiol esters studied. No satisfactory solvent was found. The base was made from very pure hydrochloride and prepared for analysis by washing with boiling water, boiling alcohol, and absolute ether, giving then a cream colored product; m. p., 223–226° (corr.).

Analyses. Subs., 0.1386, 0.2258: BaSO₄, 0.1586, 0.2632. Subs., 0.2150, 0.3040: 5.331, 7.601 ee. of 0.1917 N HCl. Cale. for $C_8H_9O_5NS$: S, 16.10; N, 7.04. Found: S, 15.71, 16.01; N, 6.66, 6.72.

General Procedure for the Formation of Thiol Esters from the Imido Thiol Ester Hydrochlorides.—Pure imido thiol ester hydrochloride was dissolved in very dilute hydrochloric acid and refluxed for 2 to 5 hours in the case of the resorcinol derivatives, or 8 to 10 hours in the case of phloroglucinol derivatives which were more difficult to hydrolyze. Solid products, which separated as the solutions cooled, were filtered directly; liquids were extracted with ether.

Methyl-thiol-β-resorcylate-monohydrate, (HO)₂C₆H₃COSCH₃.H₂O.—From 35 g. of once recrystallized methyl-thiol-β-resorcylate-imide hydrochloride in 1500 cc. of water and 5 cc. of coned. hydrochloric acid was obtained after 5 hours 25 g. of product which, solidified as the reaction mixture cooled. This was purified by solution in a little boiling alcohol to which bone charcoal was added, filtration and reprecipitation with water. Finally, it was recrystallized from 50% alcohol, as colorless needles; m. p., 70–71° (corr.).

Analyses. Subs., 0.1424, 0.1510: BaSO₄, 0.1625, 0.1699. Subs., 0.9051: H_2O , 0.0823. Calc. for $C_8H_8O_8S.H_2O$: S, 15.87; H_2O , 8.92. Found: S, 15.67, 15.45; H_2O , 9.09.

The monohydrate was readily converted to the anhydrous ester by drying it in a vacuum desiccator or by warming it first at 55° and later at 70° for 4–6 hours. The anhydrous ester was recrystallized from benzene or chloroform, and when pure melted at 97–98° (corr.).

Analyses. Subs., 0.1447, 0.1409: BaSO₄, 0.1833, 0.1762. Calc. for C₈H₈O₈S: S, 17.41. Found: 17.40, 17.17.

Bis(p-nitrobenzoyl)-methyl-thiol- β -resorcylate, ((p)NO₂C₆H₄CO₂)₂C₆H₃COCSH₃.—Three g. of methyl-thiol- β -resorcylate in 40 cc. of 10% sodium hydroxide solution was shaken with 11.1 g. of pulverized p-nitrobenzoyl chloride and the shaking continued until heat was no longer evolved and the acid chloride had disappeared. The precipitate was filtered, washed with water, extracted with boiling alcohol and finally recrystallized from ethyl acetate as colorless crystals; m. p., 214–216° (corr.).

Analyses. Subs., 0.1203, 0.1176: BaSO₄, 0.0597, 0.0570. Subs., 0.1351, 0.3062: 2.881, 6.399 cc. of 0.1930 N HCl. Calc. for $C_{22}H_{14}O_{9}N_{2}S$: S, 6.65; N, 5.81. Found: S, 6.81, 6.66; N, 5.77, 5.65.

Ethyl-thiol- β -resorcylate, $(HO)_2C_6H_3COSC_2H_5$.—Five g. of pure imide hydrochloride in 200 cc. of water and 5 cc. of 15% hydrochloric acid, refluxed for 2 hours, gave a reddish oil. This was extracted with ether and the solution washed with dil. hydrochloric acid, then dil. sodium bicarbonate and finally with water. The ether solution was placed in a vacuum desiccator over sulfuric acid. The ether was evaporated and an oil was left which gradually solidified. It was a substance difficult to purify. The crude product was dissolved in a little ether, and a little petroleum ether added to precipitate the colored material, the solution filtered, evaporated in a vacuum desiccator over sulfuric acid, and the residual oil inoculated with a crystal of thiol ester. After two such treatments, white crystals were obtained melting at 60–61°.

Analyses. Subs., 0.1614, 0.1241: BaSO₄, 0.1846, 0.1410. Calc. for $C_9H_{10}O_9S$: S, 16.18. Found: 15.71, 15.60.

Bis(p-nitrobenzoyl)-ethyl-thiol- β -resorcylate, $((p)NO_2C_6H_4CO_2)_2C_6H_3COSC_2H_5$.—This substance was made by the method described for the methyl derivative. The product was crystallized from ethyl acetate as white crystals; m. p., 190–191° (corr.).

Analyses. Subs., 0.1962, 0.2413: 4.210, 5.190 cc. of 0.1917 N HCl. Calc. for $C_{28}H_{15}O_{9}N_{2}S$: N, 5.65. Found: 5.76, 5.78.

n-Butyl-thiol- β -resorcylate, $(HO)_2C_6H_3COSC_4H_9(n)$.—After refluxing 13 g. of pure n-butyl-thiol- β -resorcylate-imide hydrochloride in 200 cc. of water for 2–3 hours, thiol ester was obtained in the form of a light brown oil. To obtain this as a solid was impossible and consequently purification was difficult. For identification it was converted into the bis-p-nitrobenzoate.

Bis(p-nitrobenzoyl)n-butyl-thiol- β -resorcylate, $((p)\mathrm{NO}_2\mathrm{C}_6\mathrm{H}_4\mathrm{CO}_2)_2\mathrm{C}_6\mathrm{H}_3\mathrm{COSC}_4\mathrm{H}_9$ -(n).—Upon treatment of this oil with p-nitrobenzoyl chloride as described for the methyl ester, a solid product was obtained. This was extracted twice with boiling alcohol, then recrystallized from ethyl acetate. When pure it was a colorless compound; m. p., 115–116° (corr.).

Analyses. Subs., 0.1555, 0.1200: BaSO₄, 0.0657, 0.0561. Subs., 0.2968, 0.2819; $^\circ$ 6.073, 5.518 cc. of 0.1930 N HCl. Calc. for $C_{26}H_{20}O_9N_2S$: S, 6.12, N, 5.35. Found: S, 5.80, 6.42; N, 5.53, 5.29.

Methyl-thiol-2,4,6-trihydroxy-benzoate, $(HO)_3C_6H_2COSCH_3$.—A solution of 3.5 g. of pure methyl-thiol-2,4,6-trihydroxy-benzoate-imide hydrochloride in 250 cc. of water and 15 cc. of 15% hydrochloric acid was refluxed for 8 to 10 hours, cooled and extracted with ether. A pink solid was obtained which was purified by recrystallization from 10% alcohol. After drying at $100-110^\circ$ the product was white and melted at 190° (corr.).

Analyses. Subs., 0.1474, 0.1142: BaSO₄, 0.1735, 0.1341. Calc. for C₈H₈O₄S: S. 16.02. Found: 16.16, 16.13.

Methyl- β -resorcylate-imide, (HO)₂C₆H₃C(\rightleftharpoons NH)OCH₃.—A mixture of 200 cc. of absolute methyl alcohol and 7 g. of methyl-thiol- β -resorcylate-imide was refluxed for 2 hours. The alcohol was then distilled, leaving a reddish-brown solid. This was recrystallized from methyl alcohol, giving white needles; m. p., 210° (corr.).

Analyses. Subs., 0.1648, 0.1809: 5.026, 5.643 cc. of 0.1930 N HCl. Calc. for $C_8H_9O_8N$: N, 8.39. Found: 8.25, 8.44.

This base was converted into the corresponding hydrochloride by saturation of a small amount of a hot 15% hydrochloric acid solution with the free imide ester and filtration. The crystals, formed as the solution cooled, were purified by recrystallization from 15% hydrochloric acid, and the purified product melted at 166–168° and was presumably a hydrate, since upon drying in a vacuum desiccator the melting point changed to 224–226° (corr.) where it remained constant.

Analyses. Subs., 0.2585, 0.2182: 6.399, 5.415 cc. of 0.1930 N HCl. Calc. for $C_8H_{10}O_3NCl$: N, 6.88. Found: 6.70, 6.71.

n-Butyl-thiol- β -resorcylate-imide also was readily converted into the methyl- β -resorcylate-imide in the same way. After a mixture of 5 g. of pure n-butyl-thiol- β -resorcylate-imide and 50 cc. of absolute methyl alcohol was refluxed for about 1 hour a homogeneous solution formed and in another hour colorless crystals began to appear. The refluxing was continued for 2–3 hours longer and then the mixture was allowed to stand overnight. The product was filtered and more crystals were obtained by dilution of the filtrate. The material was purified from methyl alcohol after which it melted at 210° (corr.). This material was also converted into the hydrochloride which corresponded exactly to the one described just above.

Ethyl- β -resorcylate-imide, (HO)₂C₆H₃C(\rightleftharpoons NH)OC₂H₅.—A mixture of 5 g. of pure ethyl-thiol- β -resorcylate-imide and 100 cc. of absolute ethyl alcohol was refluxed for 5 hours and then cooled when crystals separated. These were removed and from the filtrate more were recovered by evaporation of the alcohol. The product was purified by crystallization from ethyl alcohol; m. p., 214° (corr.).

Analyses. Subs., 0.2301, 0.1681: 6.461, 4.896 cc. of 0.1930 N HCl. Calc. for $C_9H_{11}O_3N$: N, 7.74. Found: 7.59, 7.88.

Methyl- β -resorcylate from Methyl- β -resorcylate-imide, (HO)₂C₆H₃CO₂CH₃.—A suspension of 0.5 g. of methyl- β -resorcylate-imide in 20 cc. of water, treated with just enough dil. hydrochloric acid to cause complete solution, was refluxed for 2 hours and then cooled, whereupon white crystals separated. These were filtered, washed with a little cold water and crystallized from benzene or a little 50% alcohol. After crystallization they melted at 116–117° (corr.) and proved to be identical with methyl- β -resorcylate made by esterification of β -resorcylate-imide hydrochloride with water.

Ethyl- β -resorcylate from Ethyl- β -resorcylate-imide (HO)₂C₆H₃CO₂C₂H₅.—A solution of 0.75 g. of ethyl- β -resorcylate-imide in 30 cc. of water and 1 cc. of 15% hydrochloric acid was refluxed for about 1 hour. Hydrolysis took place and ethyl- β -resorcylate separated as an oil. This was cooled with ice until it solidified, and the solid was filtered and recrystallized from water. After drying for 36 hours in a desiccator it melted at 69–70° (corr.). The same product was obtained also from β -resorcylic acid by refluxing it for 10 hours with absolute alcohol saturated with dry hydrogen chloride. The alcohol was then distilled, the residue washed with dil. sodium bicarbonate solution, and the red oil which resulted was distilled under diminished pressure (b. p., 13–15 mm., 170–176°). The distillate solidified and was purified further by crystallization from water. After drying, it melted at 69–70° and proved to be identical with the product described above.

Analysis. Subs., 0.2605: 331 cc. of CO₂ (25°, 742.5 mm.). Calc. for $C_9H_{10}O_4$: C, 59.31. Found: 59.00.

 β -Resorcylic Acid from Methyl-thiol- β -resorcylate.—A solution of 10 g. of methyl-thiol- β -resorcylate in 100 cc. of 10% potassium hydroxide solution was heated on a water-

⁸ Baeyer, Ann., 372, 85 (1910).

bath at about 70° for 30 hours, cooled and acidified just to the point at which congo red paper changed color, when a precipitate of β -resorcylic acid formed. The solution and precipitate were extracted a few times with ether, and the β -resorcylic acid again obtained in an aqueous solution by shaking the ether extract with a solution of sodium bicarbonate. The aqueous solution was neutralized as before, the free acid extracted with ether, and the ether solution dried and then evaporated. About 4 g. of solid was thus obtained which was crystallized once from water and bone charcoal and once from water. White crystals resulted which after drying melted at 215–217° with evolution of carbon dioxide. A mixed melting point with resorcylic acid® made in the usual way gave no depression.

Summary

- 1. Alkyl and aryl thiocyanates, as represented by methyl, ethyl, n-butyl and phenyl thiocyanates, were condensed with resorcinol and phloroglucinol in the presence of anhydrous ether, dry hydrogen chloride and anhydrous zinc chloride. The products which were obtained were imido thiol ester hydrochlorides.
- 2. These substances, upon treatment with sodium bicarbonate, were converted into the imido thiol esters.
- 3. The imido thiol ester hydrochlorides, refluxed in aqueous solution, were hydrolyzed to thiol esters. These substances, upon saponification, yielded compounds containing a carboxyl group.
- 4. The imido thiol esters, upon treatment with alcohols as represented by the formula R'OH, were converted upon long standing or refluxing into the corresponding imido esters. These oxygen imido esters, upon treatment with acids, yielded the corresponding salts, or when boiled with acids were decomposed into the corresponding carboxylic esters.
- 5. From these results it is obvious that the cyanogen group in thiocyanates acts similarly to the cyanogen group in alkyl cyanides when treated with certain types of phenols, hydrogen chloride and anhydrous zinc chloride.

SOME MERCURY DERIVATIVES OF PHENOL ETHERS1

By Frank C. Whitmore and Edmund Burrus Middleton²
Received February 23, 1923

In an earlier paper³ it was shown that mercurated phenols react with iodides of alkali metals to give the original phenols, inorganic mercury compounds and 1 equivalent of alkali for each carbon-mercury linkage broken. When, however, the hydroxyl group is protected by acylation iodides react in quite a different way giving mercuri-bis compounds and inorganic mercury compounds but not alkali. The two processes may be illustrated as follows.

$$\begin{array}{c} \text{HO---}C_6H_4\text{---}HgI + 3 \text{ KI} + H_2O \longrightarrow C_6H_6OH + K_2HgI_4 + KOH} \\ \text{2 AcO---}C_6H_4\text{---}HgI + 2 \text{ KI} \longrightarrow (AcO---C_6H_4)_2Hg + K_2HgI_4 \end{array}$$

The present work was undertaken to determine the effect of replacing the phenolic hydrogen by an alkyl group instead of an acyl group. An observation made by Dimroth⁴ indicated that the effect of the 2 groups might be similar. In determining the structure of o-chloromercuri-phenol, he treated it with ethyl iodide in alkaline alcoholic solution to prepare the known o-phenetylmercuric iodide. Besides the desired product he obtained a good yield of o-mercury-diphenetyl. Since sodium iodide is formed in the reaction it seemed reasonable that it might change the mercurated phenetole first formed to the mercuri-bis compound. Dimroth's results may then be formulated as follows.

$$\begin{array}{c} NaO-C_6H_4-HgCl+RI \longrightarrow RO-C_6H_4-HgCl+NaI\\ 2\;RO-C_6H_4-HgCl+4\;NaI \longrightarrow (RO-C_6H_4)_2Hg+Na_2HgI_4+2\;NaCl \end{array}$$

In order to test this theory and to study further the effect of protecting a phenolic hydroxyl group upon the stability of the carbon-mercury linkage, the action of potassium iodide on mercurated phenol ethers was studied.

Iodomercuri-anisoles and -phenetoles were prepared by the method of Dimroth.⁴ As the *ortho* mercurated compounds are much more soluble than the *para* compounds, the study was limited to the former. When an alcoholic solution of *o*-iodomercuri-anisole or of *o*-iodomercuri-phenetole is refluxed with potassium iodide, no splitting of the carbon-mercury linkage takes place as no alkali is formed. *o*-Mercury-dianisyl or *o*-mercury-diphenetyl is obtained in good yield. The mother liquors contain large amounts of inorganic mercury compounds. Potassium thiocyanate acts

- ¹ Presented at the Rochester Meeting of the American Chemical Society, April, 1921.
- ² Research Fellow under a grant from the U. S. Interdepartmental Social Hygiene Board, General M. W. Ireland, Chairman. Some of the organic mercury compounds related to those studied are being investigated pharmacologically under the direction of Dr. A. S. Loevenhart of the Department of Pharmacology of the University of Wisconsin.
 - ³ This Journal, 43, 622 (1921).
 - 4 Dimroth, Ber., 32, 763 (1899).

like potassium iodide but gives poorer yields of the mercuri-bis compounds.

The para mercurated phenol ethers react to some extent with potassium iodide or with potassium thiocyanate; some inorganic mercury is formed. No alkali is found. The corresponding mercuri-bis compounds are not obtainable in a pure state by these reactions.

Sodium thiosulfate is the most convenient reagent for making the mercuri-bis compounds of the phenol ethers. The *o*-iodomercuri compounds dissolve readily in it giving solutions from which the mercuri-bis compounds separate on standing.

o-Mercury-dianisyl and o-mercury-diphenetyl react normally with mercuric chloride; quantitative yields of the chloromercuri compounds are obtained.

Experimental Part

Preparation of o- and p-Iodomercuri-phenetoles.—A mixture of 5 g. of o-chloromercuri-phenol³ in 50 cc. of 50% ethyl alcohol, 0.7 g. of sodium hydroxide, and 3.5 g. of ethyl iodide is heated gently for 1 hour. A small amount of o-mercury-diphenetyl separates as the solution cools. This is removed and the filtrate is diluted with water to precipitate the o-iodomercuri-phenetole which is recrystallized from alcohol; yield, 7 g. The para compound is prepared in a similar way. Five g. of p-chloromercuri-phenol gives 5 g. of a mixture of the corresponding iodomercuri and mercuri-bis-compounds which is difficult to separate. Because the ortho compounds are obtained more easily, the experiments with potassium iodide, with thiocyanate, and with thiosulfate were carried out with o-iodomercuri-phenetole and o-iodomercuri-anisole.

Preparation of o-Iodomercuri-anisole.—Eight g. of o-chloromercuri-phenol, 1 g. of sodium hydroxide, 50 cc. of alcohol, and 3 g. of methyl iodide are heated for half an hour. About 1 g. of o-mercury-dianisyl separates as the solution cools. Dilution of the mother liquor with water gives 7 g. of the iodomercuri compound.

Reaction of Potassium Iodide with o-Iodomercuri-anisole and with o-Iodomercuri-phenetole.—Four g. of o-iodomercuri-anisole, recrystallized from alcohol, is heated under a reflux condenser for 6 hours with 3 g. of potassium iodide and 50 cc. of alcohol. When the product is cooled and diluted somewhat the o-mercury-dianisyl is precipitated. It is recrystallized from alcohol; yield, 1.5 g.; m. p., 108°. The filtrate from the reaction mixture is neutral and gives an immediate precipitate with hydrogen sulfide.

A solution of 2 g. of o-iodomercuri-phenetole in 50 cc. of alcohol together with 2 g. of potassium iodide is refluxed for 1 hour. When this product is cooled and diluted with water, 1.5 g. of o-mercury-diphenetyl separates. After crystallization from alcohol it melts at 81°. The filtrate is not alkaline. It contains inorganic mercury compounds.

Reaction of Potassium Thiocyanate with the o-Iodomercuri-phenol Ethers.—A mixture of 2 g. of o-iodomercuri-anisole, 2 g. of potassium thiocyanate and 50 cc. of alcohol was heated under a reflux condenser for 3 hours. The product, cooled and diluted, gave 1.5 g. of the mercuri-bis compound. Recrystallization from alcohol raised the melting point only to 75–80°. The filtrate contains inorganic mercury compounds but is neutral.

A mixture of 1.6 g. of o-iodomercuri-phenetole, 2 g. of potassium iodide and 50 cc. of alcohol, heated under a reflux condenser for 3 hours gives 0.8 g. of the mercuri-bis compound melting at 80° after several crystallizations from alcohol.

Reaction of Sodium Thiosulfate with the o-Iodomercuri-phenol ethers.—Two g. of o-iodomercuri-phenetole dissolved in a solution of 4 g. of sodium thiosulfate in 50 cc. of water deposits 1.2 g. of the mercuri-bis compound on standing; m. p., 81–83°.

Similarly, o-iodomercuri-anisole gives the mercuri-bis compound melting at 108° .

Reaction of the p-Iodomercuri-phenol Ethers with Potassium Iodide and with Potassium Thiocyanate.—The reactions between these substances apparently lead to the formation of mercuri-bis compounds, as the filtrates contain inorganic mercury and are not alkaline. However, the products are very difficult to purify.

Reaction of Mercuric Chloride with the Mercuri-bis-phenol Ethers.—One g. of o-mercury-dianisyl is heated with 0.7 g. of mercuric chloride in 25 cc. of alcohol for 15 minutes. The chloride deposits on cooling, and is recrystallized from alcohol; m. p., $177-178^\circ$. Dimroth obtained the same compound in small amount by direct mercuration of anisole. He gives the melting point as $173-174^\circ$.

Similarly, o-mercury-diphenetyl reacts with mercuric chloride to give pure o-chloromercuri-phenetole.

Summary

- 1. Protection of the hydroxyl groups in mercurated phenols by alkylation has the same effect as protection by acylation, that is, the stability of the carbon-mercury linkage to iodides, thiocyanates, and to thiosulfates is increased.
- 2. Mercurated phenol ethers react with iodides, with thiocyanates, and with thiosulfates to form the corresponding mercuri-bis compounds giving solutions which contain inorganic mercury but no alkali, showing that the protection of the phenolic hydroxyl has prevented the splitting of the carbon-mercury linkage with the accompanying formation of alkali which occurs with the mercurated phenols.
- 3. The formation of the mercuri-bis compounds takes place much more readily in the case of the *ortho* compounds than with the *para* compounds.

THE PREPARATION OF ALKYLGUANIDINES

By Ross Phillips and H. T. Clarke Received February 24, 1923

In a recent paper, Arndt¹ describes a new and convenient reagent, methyl iso-thio-urea sulfate, from which methyl mercaptan may be obtained in a pure condition by warming it with dil. alkalies; dicyanodiamide is formed as a by-product. This reagent, produced by the addition of dimethyl sulfate to thio-urea, bears a close relation to the alkyl iodide addition products of thio-urea,² which react with primary and secondary aliphatic amines to form alkyl guanidines and alkyl mercaptans.

We have found that methyl iso-thio-urea sulfate undergoes an exactly analogous reaction with methylamine and dimethylamine, methyl mercap-

¹ Arndt, Ber., 54B, 2236 (1921).

² Wheeler and Jamieson, J. Biol. Chem., 4, 111 (1907). Schenck, Z. Physiol. Chem., 77, 328 (1912).

tan and methylguanidine sulfate (and α , α -dimethylguanidine sulfate) being produced in excellent yield, without the use of an appreciable excess of the base. As far as we can ascertain, these sulfates have hitherto never been described; they crystallize well from water and are practically insoluble in methyl alcohol. The reaction does not take place with aniline, either alone or in the presence of alkali.

Incidentally to the isolation of the methyl mercaptan, which is formed as a by-product, we have found that when the gas is passed into a 25% solution of sodium hydroxide the sodium salt of methyl mercaptan crystallizes in long, flat needles of the composition, $2CH_3SNa.9H_2O$.

Experimental Part

Methylguanidine Sulfate.—To a suspension of 700 g. of methyl iso-thio-urea sulfate in 700 cc. of cold water is added, all at once, 525 g. of a 33% aqueous solution of methylamine. The vessel is immediately fitted with a reflux condenser, from the upper end of which tubes lead the evolved gas through a wash bottle containing 250 cc. of 10% hydrochloric acid (to remove any entrained methylamine) into 700 cc. of a 25% solution of sodium hydroxide cooled by running water. When the mixture in the flask is shaken and gently warmed, a vigorous reaction sets in at about 30°; methyl mercaptan is evolved at a steady rate without application of heat. When the reaction slackens, the mixture is heated until finally it boils; it is then concentrated under reduced pressure until the weight is about 1000 g. The resulting sirup is chilled to —5°, whereupon it sets to a mass of crystals; 300 cc. of methyl alcohol is then added and the crystals are collected by suction and washed with cold methyl alcohol in which the product is practically insoluble. The yield of pure dry methylguanidine sulfate is about 500 g., or 82%; m. p., 239–240°.

Analysis. Subs., dried at 120°, 0.4826: BaSO₄, 0.4675. Calc. for $C_4H_{16}O_4N_6S$: S, 13.12. Found: 13.30.

The combined filtrates and washings are concentrated to 300 g., cooled to 50°, and treated with 60 cc. of nitric acid (d., 1.42). The mixture is chilled to 0° and the resulting crystals of the nitrate are collected: when dry, this material weighs about 90 g., a 13% yield. After recrystallization from rather less than its own weight of water, it melts at 149–150°.

The picrate 3 (prepared both from the sulfate and from the nitrate) melts at 199–200 $^{\circ}.^4$

 α, α -Dimethylguanidine Sulfate.—A suspension of 250 g. of methyl iso-thio-urea sulfate in 300 cc. of cold water is treated exactly as above with 285 g. of a 33% aqueous solution of dimethylamine. After the reaction is complete, the solution is concentrated under reduced pressure until crystals begin to form, chilled to 0°, and the crystals are collected on a filter and washed with methyl alcohol. The mother liquors are again concentrated, and the recrystallization process is repeated twice. In this way 200 g. of α, α -dimethylguanidine sulfate, melting with decomposition at 285–288°, is obtained, an 82% yield.

Analysis. Subs., dried at 120°, 0.4581: BaSO₄, 0.4052. Calc. for $C_6H_{18}O_4N_6S$: S, 12.40. Found: 12.13.

³ Fischer, Ber., 30, 2414 (1897), gives the melting point as 200°.

⁴ Werner and Bell, *J. Chem. Soc.*, **121**, 1790 (1922), describe a picrate, prepared from the reaction product of dicyandiamide and methylamine hydrochloride, which decomposes at 285° without melting.

The picrate is precipitated by the addition of a solution of sodium picrate to aqueous dimethylguanidine sulfate; after recrystallization from water, it melts sharply at $229-230^{\circ}.5$

Methyl Mercaptan Sodium Salt.—When methyl mercaptan is passed into a 25% solution of sodium hydroxide, absorption takes place with evolution of heat; after saturation, the solution on standing deposits flat needles which may attain a length of several centimeters. These crystals rapidly effloresce on exposure to air, apparently giving up water of crystallization. The salt is readily soluble in cold water and even more so in cold methyl alcohol. Although a boiling alkaline solution of methyl mercaptan (unlike ethyl mercaptan and its homologs) does not yield the free mercaptan in appreciable quantities to the distillate, the salt possesses a powerful odor; attempts to determine directly the percentage of water of crystallization were unsuccessful, owing to loss of substance other than moisture. When the crystals are heated above 200° decomposition sets in, sodium disulfide being formed in considerable amount.

Analyses. Subs., 0.5468: Na₂SO₄, 0.2540. Subs., 0.6584: NaCl, 0.2489. Calc. for 2CH₃SNa_.9H₂O: Na, 15.23. Calc. for CH₃SNa_.5H₂O: Na, 14.75. Found: Na, 15.04, 14.90.

Summary

A convenient method is described for the preparation of mono- and dialkylguanidines.

A description is given of 3 crystalline salts hitherto not mentioned in the literature: methylguanidine sulfate, α,α -dimethylguanidine sulfate, and the sodium salt of methyl mercaptan.

SOME DIALKYLBARBITURIC ACIDS WITH TERTIARY AMINO GROUPING

By Arthur W. Dox and Lester Yoder Received March 1, 1923

In continuation of the investigations in the barbituric acid series which have been in progress in this Laboratory during the past 2 years, it seemed worth while to prepare certain more complex derivatives for the purpose of studying their physiological activity. Previous work has shown that the dialkylbarbituric acids of the veronal type exhibit hypnotic properties over quite a range of molecular weight. Our aim was now to add to the dialkylbarbituric acid another grouping with known physiological activity, but united through a stable linkage so that the substance would not readily undergo hydrolysis and enable the two components to exert their separate activities independently. The phenomenon of "synergy," familiar to pharmacologists, has been studied rather extensively in the case of simple mixtures of physiologically active substances, but comparatively little

⁶ Schenck, Ref. 2, gives the melting point as 230°. Werner and Bell, Ref. 4, give 227°.

is known concerning the effect of combining two or more such substances in a stable union.

The derivatives described in this paper may be considered as dialkylbarbituric acids (5-ethyl-5-propyl- and 5-isoamyl-5-propyl-barbituric acids) with diethylamine, ethylaniline, acetanilide and phenacetin, respectively, attached to the γ -carbon of the propyl group.

The steps by which these syntheses were accomplished may be illustrated in the case of 5-ethyl-5-diethylamino-propyl-barbituric acid as follows,

$$\begin{array}{c} C_2H_5-CH(COOC_2H_5)_2 \longrightarrow Br(CH_2)_3 \\ C_2H_5-CH(COOC_2H_5)_2 \longrightarrow CCOOC_2H_5 \\ C_2H_5-COOC_2H_5 \longrightarrow CCOOC_2H_5 \end{array}$$

Experimental Part

In the double alkylation of ethyl malonate it is preferable to introduce the unsubstituted alkyl first. Otherwise, the alkylene bromide tends to form a cyclic derivative in which both reactive hydrogens of the ethyl malonate are substituted.1 Ethylene and trimethylene bromides are the only alkylene halides readily available. Attempts to introduce a β bromo-ethyl group by treatment of the alkyl malonic ester with ethylene bromide were much less successful than the introduction of the \gamma-bromopropyl group with trimethylene bromide. The latter was accordingly used throughout in these preparations. The yields, however, were smaller than those obtained in the preparation of the ordinary dialkylmalonic esters. The loss was obviously due to a side reaction in which hydrobromic acid is removed from the trimethylene bromide, giving allyl bromide which was easily recognized by its odor. By using benzene in place of alcohol, this difficulty was largely overcome, but a further loss was the formation of a considerable amount of a high-boiling product, probably a tetracarboxylic ester resulting from a reaction between 2 molecules of sodium alkylmalonic ester and 1 of trimethylene bromide. This secondary reaction was reduced to a minimum by the use of a great excess of trimethylene bromide. The alkyl-γ-bromopropyl-malonic esters then reacted readily with basic secondary amines and with the sodium salt of acvl amines to form alkyl-y-alkylaminopropyl-malonic esters, which in turn condensed with urea with ring closure giving the desired barbituric acids with alkylamine substitution on the γ-carbon of the propyl group.

Ethyl- γ -bromopropyl-malonate.—Twelve g. of finely divided sodium was gradually added to a cold solution of 95 g. of ethyl ethylmalonate in 250 cc. of anhydrous benzene. Practically all of the sodium dissolved with evolution of hydrogen. To the cold solution 200 g. (calc., 107 g.) of trimethylene bromide was added. The temperature of the cooling bath was gradually raised and finally the mixture was refluxed until it became neutral to litmus. The product was shaken with water to remove the sodium

¹ Dox and Yoder, This Journal, 43, 680, 1368, 2097 (1921).

bromide, then dried with calcium chloride and finally distilled under diminished pressure. The first portion of the distillate consisted of benzene, trimethylene bromide and ethyl ethylmalonate, then the condensation product came over between 160° and 180° at 20 mm., leaving about 8 g. of a high-boiling residue. After three fractionations, we obtained 50 g. of an oil boiling at 169–174° at 20 mm. pressure.

Analysis. Subs., 0. 1780: AgBr, 0.1037. Calc. for $C_{12}H_{21}O_4Br$: Br, 25.8. Found: 24.8.

Ethyl Ethyl- γ -diethylaminopropyl-malonate.—A mixture of 50 g. of ethyl ethyl- γ -bromopropyl-malonate and 30 g. of diethylamine was gently refluxed for 2 hours on a water-bath. Diethylammonium bromide separated rapidly at first. The reaction product was shaken with a concd. solution of sodium hydroxide and the latter drawn off through a funnel. The remaining oily layer was dried with solid sodium hydroxide and distilled under diminished pressure. After two fractionations, 40 g. of a yellow oil boiling at $143-149^{\circ}$ at 6 mm. pressure was collected.

Analyses. Subs., 0.2012, 0.2080: NH₃, 6.7, 6.9 cc. of 0.1 N acid. Calc. for $C_{16}H_{31}$ -O₄N: N, 4.65. Found: 4.66, 4.64.

5-Ethyl-5- γ -diethylaminopropyl-barbituric Acid.—A mixture of 10 g. of ethyl ethyl- γ -diethylaminopropyl-malonate, 3 g. of urea, and 40 cc. of absolute alcohol in which 2.5 g. of sodium had been dissolved, was heated in an autoclave at 108° for 7 hours. The white pasty product was made neutral to litmus by the addition of concd. hydrochloric acid, the precipitated sodium chloride removed by filtration, and the alcoholic filtrate evaporated to a sirup on the steam-bath. On the addition of sodium hydroxide solution, crystals of the barbituric acid separated, which were dried by suction and purified by recrystallization from water; yield, 3.5 g.; m. p., 165–166°. The substance is insoluble in strong alkali, ether or benzene but readily soluble in water or alcohol. It is basic and forms salts with acids.

Analyses. Subs., 0.2, 0.2: NH₃, 22.35, 22.35 cc. of 0.1 N acid. Calc. for $C_{13}H_{23}$ - O_3N_3 : N, 15.61. Found: 15.64, 15.64.

Ethyl- γ -acetanilinopropyl-malonate.—The sodium salt of acetanilide was first prepared by refluxing 9.5 g. of acetanilide in 200 cc. of anhydrous benzene with 1.6 g. of sodium. After this mixture cooled, 22 g. of ethyl ethyl- γ -bromopropyl-malonate was added and the suspension was gently heated under a reflux condenser for 12 hours. The sodium bromide was washed out with water, and the oil dried with calcium chloride and distilled. Fractionation gave 15 g. of a viscous yellow oil boiling at 244–250° at 17 mm.

Analyses. Subs., 0.2, 0.2: NH₃, 5.3, 5.4 cc. of 0.1 N acid. Calc. for $C_{20}H_{29}O_5N$: N, 3.85. Found: 3.71, 3.78.

5-Ethyl-5- γ -acetanilinopropyl-barbituric Acid.—To a solution of 2.5 g. of sodium in 40 cc. of absolute alcohol, 12 g. of ethyl ethyl- γ -acetanilinopropyl-malonate and 3 g. of urea were added. The mixture was heated in an autoclave at 108° for 7 hours. After neutralization with concd. hydrochloric acid the product was filtered and the filtrate evaporated to a small volume. Addition of water resulted in the separation of an oil which solidified after a time. This was recrystallized from benzene containing a little alcohol; yield, 9 g.; m. p., 180° The substance is readily soluble in alcohol, but sparingly soluble in benzene or hot water.

Analyses. Subs., 0.2, 0.2: NH₃, 18.0, 18.1 cc. of 0.1 N acid. Calc. for $C_{17}H_{21}O_4N_3$: N, 12.68. Found: 12.60, 12.67.

Ethyl Ethyl- γ -acetophenetidinopropyl-malonate.—Molecular proportions were used and the same procedure followed as that employed in the preparation of ethyl ethyl- γ -acetanilinopropyl-malonate, but with phenacetin in place of acetanilide. The

washed and dried oil was fractionated under diminished pressure, and the fraction boiling at 237–240° at 4 mm. was collected.

Analyses. Subs., 0.2, 0.2: NH₃, 4.7, 4.8 cc. of 0.1 N acid. Calc. for $C_{22}H_{33}O_6N$: N, 3.44. Found: 3.29, 3.36.

5-Ethyl-5- γ -acetophenetidinopropyl-barbituric Acid.—A solution of 13 g. of ethyl ethyl- γ -acetophenetidinopropyl-malonate and 3 g. of urea in 40 cc. of absolute alcohol containing 2.5 g. of sodium was heated in an autoclave at 108° for 7 hours. The alcoholic filtrate from the neutralized and filtered mixture was evaporated to a small volume and then diluted with water until no more oil separated. Some unchanged ester which interfered with crystallization was removed by treatment with alkali and extraction with ether. The alkaline solution was then neutralized and warmed for a short time on the steam-bath until the product began to crystallize. After recrystallization from benzene containing a small amount of alcohol, 8.8 g. of a product melting at 158–159° was obtained. The substance is very soluble in alcohol, but only sparingly soluble in benzene or hot water.

Analyses. Subs., 0.2, 0.2: NH₃, 15.9, 16.0 cc. of 0.1 N acid. Calc. for $C_{19}H_{25}O_5N_3$: N, 11.20. Found: 11.13, 11.20.

Ethyl isoAmyl- γ -bromopropyl-malonate.—A solution of 75 g. of ethyl isoamyl-malonate in 150 cc. of benzene was cooled and 7.7 g. of finely divided sodium was added. After the sodium had dissolved, 135 g. of trimethylene bromide was added and the mixture was heated in a bath at about 85° for 2 hours, until the reaction of the solution was neutral, when the mixture was washed, dried and distilled in a vacuum. Two fractionations gave 50 g. of a viscous oil boiling at 175–182° at 13 mm. About 25 g. of a higher-boiling residue remained in the distilling flask.

Analysis. Subs., 0.1589: AgBr, 0.0815. Calc. for $C_{15}H_{27}O_4Br$: Br, 22.7. Found: 21.8.

Ethyl isoAmyl- γ -diethylaminopropyl-malonate.—A solution of 36 g. of ethyl isoamyl- γ -bromopropyl-malonate in 20 g. of diethylamine was refluxed for 4 hours. A copious separation of diethylammonium bromide occurred. The mixture was washed and dried, as in the preparation of the corresponding ethyl derivative, and fractionated twice, yielding 29 g. of a thick yellow oil that boiled at $155-161^\circ$ at 5 mm.

Analyses. Subs., 0.25, 0.25: NH₃, 6.7, 6.9 cc. of 0.1 N acid. Calc. for $C_{19}H_{a7}O_4N$: N, 4.08. Found: 3.76, 3.87.

5-isoAmyl-5- γ -diethylaminopropyl-barbituric Acid.—A solution of 11 g. of ethyl isoamyl- γ -diethylaminopropyl-malonate and 3 g. of urea in 40 cc. of absolute alcohol containing 2.5 g. of sodium was heated in an autoclave at 108° for 7 hours. To the white pasty mass thus obtained, coned. hydrochloric acid was added until the reaction was neutral, the sodium chloride was removed by filtration and the alcoholic filtrate evaporated to a sirup. Upon the addition of water an oil separated which consisted largely of unchanged ester and was discarded. The aqueous solution was evaporated to crystallization and finally yielded 5 g. of a product melting at 133°. This isoamyl derivative is somewhat less soluble in water and more soluble in alcohol, ether or benzene than the homologous ethyl derivative described above.

Analyses. Subs., 0.2, 0.2: NH₃, 18.95, 18.90 cc. of 0.1 N acid. Calc. for $C_{16}H_{29}$ - O_3N_3 : N, 13.50. Found: 13.30, 13.26.

Ethyl isoAmyl- γ -ethylanilinopropyl-malonate.—A mixture of 25 g. of ethyl isoamyl- γ -bromopropyl-malonate and 18 g. of ethylaniline was heated in an oil-bath at 160° for 4 hours. The dark, viscous oil was washed with dil. sodium hydroxide solution, then with water, dried with solid sodium hydroxide and distilled; 15 g. of a yellow oil boiling at 194-201° at 4 mm. was collected.

Analyses. Subs., 0.2, 0.2: NH₃, 5.0, 5.0 cc. of 0.1 N acid. Calc. for $C_{23}H_{57}O_4N$: N, 3.58. Found: 3.50, 3.50.

5-isoAmyl-5- γ -ethylanilinopropyl-barbituric Acid.—A solution of 10 g. of ethyl isoamyl- γ -ethylanilinopropyl-malonate and 2.5 g. of urea in 40 cc. of absolute alcohol containing 2 g. of sodium was heated in an autoclave at 108° for 7 hours. The product was neutralized with hydrochloric acid, the chlorides were removed by filtration and the alcoholic filtrate concentrated to a sirup. On the addition of water, an oil separated. This failed to crystallize until the impurities had been removed by extraction of the alkaline solution with ether. The oil obtained by acidifying the alkaline solution was dissolved in benzene, and the addition of ligroin then caused the product to separate gradually in needle-shaped crystals; yield, 3 g.; m. p., 135°. The substance is insoluble in water, but readily soluble in benzene, ether or alcohol.

Analyses. Subs., 0.2, 0.2: NH₃, 16.0, 16.2 cc. of 0.1 N acid. Calc. for $C_{20}H_{29}O_2N_8$: N, 11.69. Found: 11.20, 11.34.

Ethyl isoAmyl- γ -acetophenetidinopropyl-malonate.—The sodium salt of phenacetin was first prepared by refluxing a solution of 12.5 g. of phenacetin in 200 cc. of benzene with 1.6 g. of finely divided sodium. To the suspended sodium salt 24 g. of ethyl isoamyl- γ -bromopropyl-malonate was added, and the mixture was refluxed for several hours until it was neutral to litmus. The sodium bromide was removed with water and the oily layer dried with calcium chloride. Two fractionations under diminished pressure gave 18 g. of a viscous, yellow oil boiling at 245–250° at 4 mm.

Analyses. Subs., 0.2, 0.2: NH₃, 4.4, 4.3 cc. of 0.1 N acid. Calc. for $C_{25}H_{39}O_6N$: N, 3.12. Found: 3.08, 3.01.

5-isoAmyl-5- γ -acetophenetidinopropyl-barbituric Acid.—A solution of 10 g. of ethyl isoamyl- γ -acetophenetidinopropyl-malonate and 2.5 g. of urea in 40 cc. of absolute alcohol containing 2 g. of sodium was heated in an autoclave at 108° for 7 hours. The product was neutralized and filtered as usual and evaporated to a sirup. The addition of water resulted in the separation of the barbituric acid in small crystals. These were dried and recrystallized from benzene containing a little alcohol; yield, 5 g.; m. p., 155°. The substance is practically insoluble in hot water, slightly soluble in benzene, and readily soluble in alcohol. The acetyl group is not easily split off. After successive treatment with hot alkali and concd. hydrochloric acid the original substance was recovered.

Analyses. Subs., 0.1, 0.1: NH₃, 7.2, 7.3 cc. of 0.1 N acid. Calc. for $C_{22}H_{31}O_5N_3$: N, 10.07. Found: 10.08, 10.22.

Physiological Properties

The barbituric acids described above have a bitter taste similar to that of veronal. Some were tested physiologically by oral administration to dogs, others by intraperitoneal injection of the alkali solution into white mice. Only the possibility of sedative action was considered in these preliminary tests. The following results recorded by way of illustration are typical.

Barbituric acid	Dose G.	Wt. of dog Kg.	Effect
Ethyl-γ-acetophenetidinopropyl	2	16	slight drowsiness
Ethyl-γ-diethylaminopropyl	2	15	none
isoAmyl-γ-acetophenetidinopropyl	1.8	15	none

It will be noted from the foregoing descriptions that the basic diethylamino derivatives are soluble in water but insoluble in neutral organic

solvents other than alcohol. The distribution coefficient is, therefore, less than unity. On the other hand, the neutral derivatives are practically insoluble in water. In the case of the phenacetin derivatives a possible antagonistic action of the two components was shown to be negligible. A mixture of 1 g. of dipropylbarbituric acid with 0.8 g. of phenacetin produced a very pronounced hypnotic effect on a dog of 18 kg. The explanation of the lack of hypnotic properties of these complex barbituric acids is, we believe, in some cases their insolubility which prevents absorption and their stability which precludes the possibility of hydrolysis at the point of union of the two components, and in others, the reversal of the distribution coefficient. Similarly, the intraperitoneal injection of the sodium salts into mice in doses twice as large as the effective dose of veronal produced no noteworthy symptoms, except in the case of 5-isoamyl-5-γ-diethylaminopropyl-barbituric acid which appeared to be toxic without preliminary sedative action. Even when the substance is administered as the sodium salt, we have reason to believe that the actual absorption takes place in the form of the free acid, and is too slow to produce any noteworthy effect. This explanation is in harmony with the Overton-Mever theory of narcosis, according to which a substance must have a certain distribution coefficient between the two solvents water and fat (or lipoids) in order to exert hypnotic action. This of course applies strictly only to the synthetic hypnotics, none of which appear to exert any specific action upon the higher brain centers. By increasing the complexity of the dialkylbarbituric acids the solubility in water is reduced to a minimum beyond which absorption is too slow to result in the phenomenon of hypnosis, or if a strongly basic grouping has been introduced, the distribution coefficient becomes less than unity.

Summary

A number of ethyl dialkylmalonates have been prepared in which one alkyl is ethyl or isoamyl and the other n-propyl with substitution of a tertiary amino group on the γ -carbon. From these esters the corresponding barbituric acids have been prepared. The latter, when tested physiologically, failed to show the hypnotic effect characteristic of the simple dialkylbarbituric acids. This inactivity is attributed in some instances to insolubility and consequent failure of absorption, in others, to a reversal of the distribution coefficient.

METHYL AND ETHYL AMMONIUM-MERCURIC BROMIDES

By Raymond M. Hann

Received March 2, 1923

Woodward and Alsberg¹ have pointed out the fact that tertiary alkyl amines in $0.1\,N$ concentration are readily precipitated as tri-alkyl ammonium-mercuric iodides by the addition of Mayer's reagent (potassium mercuric iodide) and have used this fact as a basis for the separation of tertiary from the primary and secondary amines. As a sequel to this research, Jamieson and Wherry² have prepared and described a series of methyl and ethyl ammonium-mercuric iodides, and have further extended the method to the crystallographic identification of the addition products, a procedure now commonly used in this Bureau as a confirmatory analytical step in the separation of amines. Barker and Porter³ have also contributed to the subject by a description of a number of the higher homologous quaternary ammonium-mercuric iodides.

The present work was undertaken at the suggestion of Dr. Edgar T. Wherry, Crystallographer of the Bureau of Chemistry, in order to complete the series of alkyl ammonium-mercuric halides and to determine the feasibility of using the alkyl substituted bromides in place of the corresponding iodides for the separation and identification of alkyl amines.

Unfortunately, the extreme solubility of all the alkyl ammoniummercuric bromides in common solvents precludes their use in determining amines. While the iodides usually are formed by addition of 1 molecule of alkyl ammonium bromide to 1 of metal bromide, the bromides tend to combine in the ratio of 1 to 2.

Numerous experimental difficulties were encountered in making the substances described. Preliminary attempts to make them in alcohol-acetone solution from alkyl halide, metal bromide and amine hydrochloride resulted in indefinite mixtures of alkyl ammonium-mercuric chlorides and bromides.

The compounds were finally obtained by the use of the hydrobromide of the amine in alcoholic solution according to the following equation: $R_2NH.HBr + RBr + HgBr_2 \longrightarrow R_3NHBr.HgBr_2 + HBr$. Concentration of the alcoholic solution gave crystals which, in a few cases, were suitable for crystallographic measurement.⁴

Experimental Part

1,2-Dimethylammonium-mercuric Bromide, (CH₃)₂NH₂Br.2HgBr₂.—Thirty-five g. of mercuric bromide suspended in 300 cc. of absolute ethyl alcohol was treated with ab-

⁴ Reserved for publication by Dr. E. T. Wherry.

divided silver we found that it was possible to remove the chlorine from each of the 3 carbinol chlorides by allowing the substances to react for 20 minutes; only a trace of nuclear bromine was removed during this time. We did not succeed in isolating the resulting free radicals in a crystalline state, but their actual existence in their respective solutions was proved by the fact that oxygen was absorbed quantitatively in accordance with the equation, $(BrC_6H_4)R_2C-+O_2=(BrC_6H_4)R_2C-O-O-CR_2(C_6H_4Br)$; the resulting peroxides were isolated and analyzed. Iodine was absorbed by the solutions of the radicals, and the iodides of the general type, R_3CI , were produced.

It is now obvious that the removal of the nuclear bromine by the silver must occur subsequently to the removal of the carbinol chlorine; that is, the bromine is removed, not from the bromotriarylcarbinol chlorides themselves, but from the free radicals which have resulted from the initial action of the silver on the carbinol chlorides.

Such a mobility of bromine in the phenyl nucleus is especially remarkable in view of the fact that not even a trace of bromine is removed by silver from such compounds as $R_2(BrC_6H_4)C-X$, where X represents H, OH, OC_2H_5 or other similar groups. It is only when the valence, which is otherwise attached to X, becomes free that the bromine in the phenyl nucleus becomes labile toward metallic silver.

No rational explanation can be advanced for such a marked change in the stability of the nuclear bromine if the structure I is accepted for the radical p-bromotriphenylmethyl. However, if the existence of a dynamic equilibrium between a benzenoid and some quinonoid structure such as II, is assumed we then have a plausible explanation for the lability of the bromine. It is evident that the carbon atom C*, in II, must have different

$$R_2C = \underbrace{\hspace{1cm}}^{*} \underbrace{\hspace{1cm}}^{*} R_2 \underbrace{\hspace{1cm}}^{*} \underbrace{\hspace{1cm}}^{*} Br \underbrace{\hspace{1cm}}^{*} \underbrace{\hspace{1cm}}^{*} Br \underbrace{\hspace{1cm}}^{*} Br \underbrace{\hspace{1cm}}^{*} Br$$

properties from those which it possessed when it was part of a benzenoid nucleus; it should now function, to some extent, as though it were an aliphatic rather than an aromatic carbon atom and the bromine which is attached to it should, therefore, be removable by silver.

The problem, however, assumes greater complexity when the mobility of nuclear halogen in the brominated free radicals is studied quantitatively. It had been previously found⁴ that even under the most favorable conditions only $^{1}/_{2}$ of the total amount of nuclear bromine is removed from p-bromotriphenylcarbinol chloride. We have now established a similar behavior for the other two p-brominated carbinol chlorides previously mentioned; presumably this phenomenon is characteristic for all triarylmethyls that contain a bromine atom in the para position to the methane

carbon atom. It seems to us that without the aid of the quinonoid hypothesis it would be impossible to explain why only a fraction, and moreover, a very definite fraction of the total bromine is removed from the bromotriarylmethyls.

When a radical of the type under discussion is produced, the following factors must be taken into consideration: in addition to the dynamic equilibrium, existing between the unimolecular forms I, II and III, there is undoubtedly a state of equilibrium operating between these unimolecular and various bimolecular forms; there is no valid reason for assuming that the ordinary hexa-arylethane is the only bimolecular form possible. On the contrary, it is only rational to assume that union, with the formation of a bimolecular radical, may take place between I and I, or between any two of the unimolecular tautomers, 6 forms of R_6C_2 being possible.

Now it is evident that a bimolecular form, resulting from the union of I and I, III and III or I and III would not contain mobile bromine atoms; in a combination of II and II both bromine atoms would be equally labile and, therefore, both would be removable by silver. It is only when combination has taken place between I and II or II and III that one of the two bromine atoms in the resulting compound is linked to a quinonoid nucleus and is, therefore, labile while the second bromine remains attached to a true benzenoid ring. Consequently, if either one of these latter two bimolecular forms is present, in the complex system of tautomers which may result when a p-bromotriarylmethyl is formed, it then becomes possible to account for the very remarkable fact that $^{1}/_{2}$, and no more than $^{1}/_{2}$, of the total bromine is removed by the molecular silver.

If it is assumed, for example, that the principal component in solution, with respect to reactivity toward molecular silver, is IV (that is, I + II) the result of the interaction with silver would be as follows:

$$\begin{bmatrix} R_2C & & B_r & R_2C & & B_r & B_$$

Removal of the labile bromine, by metal, from IV leads to the formation of V which contains a trivalent carbon atom in the nucleus, thus making this compound analogous to II; since II is in tautomeric equilibrium with I, in a similar way V must be in equilibrium with VI. The latter substance (VI) may be designated as a free radical of "the second order," $R_8C-C_6H_4-CR_2$, while I represents a free radical of "the first order," R_3C .

When a mole of p-bromotriphenylcarbinol chloride, in solution, is converted into the radical of the first order, the solution, in accordance with the equation previously given, should absorb an amount of oxygen in agreement with the following ratio; 1 mole of oxygen for each 2 moles of the brominated triarylcarbinol chloride. When, however, prolonged reaction with the metal has resulted in the formation of the radical of the second order (VI), then only $^{1}/_{2}$ of that amount of oxygen which has been required by Radical I is necessary for the formation of the peroxide (VII) which corresponds to Radical VI.

Experiments have conclusively established the validity of this assumption. It was found that when chlorine alone was removed from the triarylcarbinol chloride the subsequent absorption of oxygen was, as anticipated, 1 mole of oxygen for 2 moles of R₃C-Cl; but when, in addition

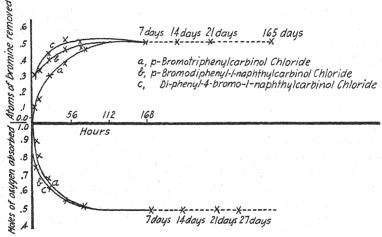

Fig. 1.—The relation between increase of nuclear bromine removed and the corresponding decrease of the amount of oxygen absorbed by the radicals

to the chlorine, the full $^1/_2$ of the nuclear bromine was eliminated the subsequent absorption of oxygen was found to be only $^1/_2$ mole for 2 moles of R₃C–Cl. Finally, when only a part of the total possible $^1/_2$ gram atom of bromine was removed, the amount of oxygen absorbed was also a corresponding fraction between 1 mole and $^1/_2$ mole.

The curves of Fig. 1, which have been constructed from data in Tables I, II and III given in the experimental part of this paper, show the concordance between these two phenomena; increase in the quantity of nuclear bromine removed is paralleled by a decrease in the amount of oxygen which the reaction product was capable of absorbing.

In further confirmation of the above hypothesis concerning the mechanism of the reaction, we have isolated the peroxides, corresponding to the radicals of the second order, in the case of each of the 3 p-bromotriarylmethylcarbinol chlorides. All our attempts to isolate the free radicals themselves in crystalline condition proved unsuccessful; these radicals appear to be extremely sensitive to various influences, and upon concentration of their respective solutions they were either polymerized or decomposed into inert substances.

Another phenomenon, namely, a change in color, indicates a change of the free radical of the first order into the radical of the second order. With the elimination of chlorine from *p*-bromodiphenyl-1-naphthylcarbinol chloride there was formed a blue-violet solution, resembling an aqueous solution of potassium permanganate; upon the removal of nuclear bromine the color gradually changed into an intense blue.

It seems to us that the results we have obtained leave no alternative to the conclusion that the p-bromotriarylmethyls exist, not only in a benzenoid state but also in a quinonoid modification; union of the two types gives rise to a bimolecular combination, the constitution of which is tautomeric with the ordinary, bimolecular hexa-arylethane.

If the phenomenon of quinoidation is accepted for the *p*-bromotriarylmethyls, must it not be equally operative in the case of other, halogen-free radicals of the triarylmethyl type?

Salt-like Derivatives.—In discussing the salt-like derivatives of the triarylcarbinols it must be remembered that only combinations between the carbinols and certain acids produce colored compounds; with hydrochloric and hydrobromic acids, colorless chlorides and bromides are produced; combinations with the organic acids, studied so far, are devoid of color. On the other hand, the carbinol sulfates, sulfites, nitrates, perchlorates and phosphates all possess color, some of these derivatives being as intensely colored as the triphenylmethane dyes themselves.

It has been shown that the nuclear halogen is not removed from the colorless, salt-like derivatives, even to the slightest extent, by contact with silver salts. However, in the case of the *colored*, *para*-halogenated triarylcarbinol derivatives, such as the sulfates, the halogen in the aromatic nucleus is readily removed by silver sulfate. Here, again, the mobility of the nuclear halogen finds its best explanation in the assumption of a quinonoid chromophore in the molecule.

Silver sulfate removes 1 atom of chlorine and, subsequently, 1 whole atom of bromine from 1 molecule of p-bromotriphenylcarbinol chloride.⁶ The mechanism of this reaction can be formulated as follows: first, the carbinol chlorine is removed, resulting in the formation of the colorless carbinol sulfate (VIII); this tautomerizes instantly into the colored sulfate (IX). The bromine, being now attached to a carbon atom (C*),

⁵ Hantzsch, Ber., 54, 2577 (1921).

⁶ Gomberg, ibid., 40, 1852 (1907).

essentially aliphatic in nature, becomes reactive toward silver sulfate, and there results a colored, para-quinonoid sulfate (X).

This interpretation of the experimental results according to the quinon-oid hypothesis was, at one time, challenged by v. Baeyer⁷ who stated that the formation of silver bromide did not necessarily indicate that the compound X had been formed; according to him the silver halide might have been produced during a disruption of the triarylmethyl nucleus. We have now been able to prove, in a very decisive manner, that v. Baeyer's criticism is not valid. We have shown that in the case of each of the 3 bromocarbinol sulfates the bromine is actually removed by the silver sulfate, approximately 1 whole atom of bromine from each R₃C-X. Moreover, the reaction mixture, on hydrolysis, yields the corresponding p-hydroxytriarylcarbinol XI and XII, and this has been identified in both the benzenoid and the quinonoid state. It is, therefore, evident that, both subsequent as well as prior to the removal of the para bromine, the triarylmethyl nucleus remains intact.

Thus, just as in the case of the colored triarylmethyls, the mobility of nuclear halogen in the colored salts also is logically explained by the assumption of a quinonoid constitution. The inference is fully justified that the colored triarylcarbinol sulfates, in general, regardless of whether or not they contain nuclear halogen, must be quinonoid.

Experimental Part

Preparation of Materials

para-Bromotriphenylcarbinol Chloride

The Carbinol, $(Br_{\theta}CH_{4})(C_{\theta}H_{5})_{2}C$ —OH.—This carbinol was prepared by the action of phenylmagnesium bromide on p-bromobenzophenone^{3a} and also by the interaction of phenylmagnesium bromide and the methyl ester of p-bromobenzoic acid.^{3b}

Since the resulting crude carbinol was an oil and consequently difficult to purify, it was converted by means of hydrogen chloride into the corresponding crystalline chloride. From the pure chloride the carbinol was readily obtained by the following process. Three g. of the chloride, 8 cc. of acetone, 1.2 cc. of dimethyl aniline and 2 cc. of water were refluxed for $^{1}/_{2}$ hour. The acetone was removed on a steam-bath and the viscous residue was freed from dimethylaniline hydrochloride by washing with water. When the product was stirred with a small amount of carbon disulfide the material quickly be-

⁷ Baeyer, Ber., 40, 3085 (1907).

came crystalline. After recrystallization from glacial acetic acid the carbinol was found to melt at $102-103^{\circ}$; this temperature is 30° higher than that recorded in the literature. Recrystallization from other solvents such as petroleum ether did not change the melting point. The compound dissolves very readily in benzene, in ether, in acetone and in carbon disulfide; with coned. sulfuric acid an orange-red solution is formed.

The Chloride.—The pure carbinol was dissolved in the smallest possible amount of absolute ether and the solution was then saturated with hydrogen chloride. The carbinol chloride soon precipitated; after several hours, the chloride was collected and then thoroughly dried over soda lime and sulfuric acid in a vacuum desiccator. The chloride melted at 112-114°, as recorded in the literature.

para-Bromodiphenyl-1-naphthylcarbinol Chloride

The Carbinol, $(BrC_6H_4)(C_6H_5)(C_{10}H_7)C$ —OH.—A solution of 1-naphthylmagnesium bromide was prepared from 4.0 g. of magnesium turnings, which had been etched with a small amount of iodine, 125 cc. of absolute ether and 25 cc. of 1-naphthyl bromide. Forty g. of p-bromobenzophenone, dissolved in 50 cc. of warm benzene, was added to this solution and the mixture was then heated for 5 hours in a bath. When the magnesium addition product settled out it was collected on a filter, thoroughly washed with benzene and then decomposed with ice and a small amount of acid in the usual manner. The carbinol was then obtained at once quite pure. When the magnesium addition product failed to precipitate, the reaction mixture, after treatment with ice and acid, was distilled with steam in order to remove the solvent and any unchanged ketone. The crude carbinol was then recrystallized from carbon disulfide. The yield, based on the ketone, was 80%. The carbinol melts at $132-133^\circ$. It dissolves readily in ether, benzene and warm alcohol and is colored an intense green by concd. sulfuric or perchloric acid.

Analysis. Calc. for C23H17OBr: Br, 20.55. Found: 20.72.

The Chloride.—A warm, concentrated solution of the carbinol in benzene was saturated with hydrogen chloride. After 36 hours most of the chloride had precipitated. The hydrochloric acid, produced from the water formed during the reaction and the excess of hydrogen chloride, was removed by means of a pipet and the carbinol chloride was quickly filtered on a Büchner funnel. The material was washed several times with absolute ether and finally suspended in ether to remove the last traces of acid. After 24 hours the chloride was filtered and dried in a vacuum desiccator over sulfuric acid and soda lime; m. p., 182–183°.

The carbinol chloride combines with the chlorides of such metals as zinc, tin, iron, mercury and aluminum, forming intensely colored, green addition products.

Analyses. Calc. for $C_{23}H_{16}ClBr$: C, 67.75; H, 3.93; Cl, 8.70; Br, 19.62. Found: C, 67.53; H, 4.02; Cl, 8.84; Br, 19.83.

p-Bromophenyl-chrysofluorene.—The carbinol, as well as the corresponding chloride, when heated with glacial acetic and coned. sulfuric acids, loses 1 molecule of water or 1 molecule of hydrogen chloride and is converted into a fluorene.

That the latter has Constitution XIII, rather than XIV or XV, was proved by carrying out the reactions indicated below.

Fifty cc. of boiling glacial acetic acid was mixed with 10 g. of the carbinol and the mixture was heated until the carbinol had completely dissolved. Two cc. of concd. sulfuric acid was then added and the solution was vigorously stirred; the latter became deep green and the fluorene precipitated almost instantly. After the mixture had cooled, water was added and the material was filtered and washed; yield, 6.1 g. The compound, recrystallized from xylene, melts at 233–235°. The fluorene is only slightly soluble in the ordinary organic solvents and is not colored by concd. sulfuric acid.

Analysis. Calc. for C23H15Br: Br, 21.54. Found: 21.60.

A mixture of 1.9 g. of fluorene, 50 cc. of glacial acetic acid and 12 g. of sodium dichromate was refluxed for $2^1/_2$ hours, and then poured into 200 cc. of hot water, whereupon 0.9 g. of a yellow substance, the quinone XVII, was precipitated. The material was filtered and from the filtrate there was deposited, after 36 hours, 0.2 g. of the colorless, crystalline 4'-bromobenzoyl-2-benzoic acid (XVIII) which melted at $167-168^{\circ}$. The melting point given in the literature⁸ is 169° .

The crystalline quinone, after several recrystallizations from glacial acetic acid, melted at 172–173°. It was found to be quite soluble in benzene, acetone or carbon disulfide; it dissolved in coned. sulfuric acid with the formation of a blood-red solution.

Analyses. Calc. for $C_{23}H_{13}O_{2}Br$: C, 66.19; H, 3.14; Br, 19.17. Found: C, 66.22; H, 3.21; Br, 19.02.

In conformity with its constitution as a quinone, the compound liberates iodine when treated with a mixture of potassium iodide, alcohol and hydrochloric acid.9

That the quinone is an intermediate product in the oxidation of the fluorene to the benzoyl-benzoic acid is proved by the fact that oxidation converts it almost quantitatively into the above-mentioned acid. To a boiling solution of 0.3 g. of the yellow material in 30 cc. of glacial acetic acid 1 g. of chromic anhydride was added during the course of an hour. The reaction mixture was then poured into 50 cc. of water and the mixture filtered. The filtrate was partly neutralized with sodium hydroxide and then extracted a number of times with ether. The ether extracts yielded 0.17 g. of the crystalline bromobenzoyl-benzoic acid.

Diphenyl-4-bromo-1-naphthylcarbinol Chloride

4-Bromo-1-cyanonaphthalene.—This substance, required for the preparation of the carbinol, was prepared as follows: 1-aminonaphthalene was acetylated¹⁰ and the resulting 1-acetylaminonaphthalene was brominated.¹¹ The 4-bromo-1-acetylaminonaphthalene thus prepared was boiled with alcohol and hydrochloric acid and thereby hy-

⁸ Ger. pat., 148,110.

⁹ Valeur, Compt. rend., 129, 522 (1899).

¹¹ Rother, Ber., 4, 850 (1871).

drolyzed into 4-bromo-1-aminonaphthalene. Upon recrystallization from gasoline this substance was obtained in the form of colorless crystals which melt at 102°,12

Twenty-two g. of the bromo-amine was added to glacial acetic acid which contained hydrogen chloride somewhat in excess of that required theoretically to convert the amine into the hydrochloride; the amine hydrochloride settled, with the liberation of heat, in the form of a paste. The latter was thoroughly stirred and the warm mixture then cooled to 15°. Eighteen cc. of amyl nitrite was added, all in one portion, the mixture being vigorously stirred and the temperature kept below 25°. After a short time all of the material had dissolved and only a very small amount of nitrogen was evolved. The clear acetic acid solution of the diazonium chloride was poured, a little at a time, with constant stirring, into 300 cc. of absolute ether which had previously been cooled to 0°. The diazonium chloride separated as an oil which quickly solidified to a light yellow, crystalline product. The liquid was decanted, the precipitate washed with cold ether and then filtered and quickly air-dried. The diazonium salt, which weighed about 20 g., was dissolved at once in 400 cc. of ice water.

The conversion of the dissolved material into the cyanide was effected by adding it slowly, well below the surface, to a clear solution of cuprous cyanide, prepared from 75 g. of copper sulfate in 300 cc. of water and 81 g. of potassium cyanide in 180 cc. of water. During this addition, carried out in a 3-neck, 2-liter round-bottom flask, the mixture was vigorously stirred mechanically and the temperature held at 80°. After all of the diazonium solution had been added the stirring was continued for 1/2 hour. When the mixture had cooled the liquid was decanted from the brown, crystalline material and the latter was then washed with water and dried. The cyanide was extracted from the crude reaction product with glacial acetic acid, the extracts were concentrated and the cyanide was precipitated by the addition of water. The yield was 18 g., or 80%. It was found unnecessary to purify the cyanide further in order to convert it into the corresponding carboxylic acid. The pure cyanide is soluble in benzene and in warm alcohol, and melts at $102-103^\circ$.

4-Bromo-1-naphthalenecarboxylic Acid.—The crude cyanide was refluxed for 12 hours with a mixture consisting of equal parts of water, glacial acetic acid and coned. sulfuric acid. The reaction mixture was then poured into water and the acid was separated from unchanged cyanide by extraction of the precipitated material with dil. sodium carbonate solution. The clear, alkaline solution was then acidified with hydrochloric acid and the bromonaphthoic acid obtained in the form of colorless crystals. The acid is soluble in alcohol and acetic acid; m. p., 13 217–220°.

Analyses. Calc. for C₁₁H₇O₂Br: C, 52.61; H, 2.81; Br, 31.85. Found: C, 52.46; H, 2.80; Br, 31.19.

Ethyl Ester of 4-Bromo-1-naphthalenecarboxylic Acid.—Fifty g. of the acid was dissolved in 600 cc. of absolute alcohol and the solution then partly saturated with hydrogen chloride; the mixture was refluxed for 16 hours. After removal of about $^2/_3$ of the alcohol under reduced pressure the residue was poured into 3.5 liters of ice water; the resulting oil soon solidified. The ester was washed with dilute aqueous sodium carbonate and then air-dried. Since it is extremely soluble in the usual organic solvents the ester could not be recrystallized; it was purified by dissolving it in low-boiling petroleum ether, filtering and then allowing the solvent to evaporate spontaneously. The yield was 56 g., or 90%; m. p., $42-43^\circ$.

¹² Morawski and Gläser, *Monatsh.*, 9, 293 (1888).

¹³ This compound has been recorded in the literature, since the completion of this work, by Mayer and Sieglitz, *Ber.*, 55, 1841 (1922). The method used by these investigators is not, however, a preparative one. The melting point is given as 212°.

Diphenyl-4-bromo-1-naphthyl Carbinol, $(C_6H_5)_2(BrC_{10}H_6)C$ —OH.—A solution of phenylmagnesium bromide was prepared from 10.2 g. of magnesium turnings, 45 cc. of bromobenzene and 100 cc. of ether. The ether was removed under diminished pressure and 35 cc. of dry toluene was then poured on the sirupy phenylmagnesium bromide; 15 g. of the ethyl 4-bromo-1-naphthalate dissolved in 50 cc. of dry toluene was added and the mixture gently refluxed for 4 hours. The reaction mixture was decomposed, the toluene layer separated and the toluene removed by steam distillation. The solid, slightly yellow carbinol thus obtained was dissolved in alcohol-free ether and converted directly into the carbinol chloride as described below. The yield of crude carbinol, based on the ester, was 60%.

The pure carbinol was obtained from the carbinol chloride by refluxing, for 45 minutes, a mixture of 8.2 g. of the pure chloride, 2.6 g. of dimethyl aniline, 50 cc. of acetone and 8 cc. of water. The reaction mixture was then freed from acetone and dimethylaniline hydrochloride. The carbinol was recrystallized from ether with the addition of a small amount of petroleum ether. It was obtained in the form of colorless crystals; m. p., 130°.

Analyses. Calc. for C₂₃H₁₇OBr: C, 70.95; H, 4.40; Br, 20.55. Found: C, 71.14; H, 4.37; Br, 19.71.

The Chloride.—A concentrated solution of the carbinol in absolute ether was saturated with hydrogen chloride, whereupon the carbinol chloride began to precipitate. After 24 hours the liquid was decanted from the crystals, the latter transferred to a Büchner funnel, washed with a small amount of absolute ether and then dried in a vacuum desiccator over sulfuric acid and soda lime. The chloride was further purified by recrystallization from benzene with the addition of an equal volume of low-boiling petroleum ether; m. p., 160–161°; it dissolves in concd. sulfuric acid, forming a deep green solution.

Analysis. Hydrolyzable Cl, Calc.: 8.7%. Found: 8.4%.

Reaction between Molecular Silver and the Carbinol Chlorides

The Radicals from p-Bromotriphenylcarbinol Chloride.—A number of tubes, each containing $1.000~\rm g$. of pure carbinol chloride, $3.0~\rm g$. of 20-mesh, molecular silver and $30~\rm cc$. of xylene, were rotated at room temperature for various periods of time.

A second series of tubes was prepared, identical with those described above with the exception that bromobenzene was used as a solvent instead of xylene, the latter having been used because of its comparatively low vapor pressure. After rotation for a definite period of time a tube from the first series was opened and the amount of silver halides was determined; a tube from the second series, rotated for an equal period of time, was placed in an apparatus designed for the measurement of absorbed oxygen.¹⁴

As the following table shows, the radical of the first order was formed quantitatively, after rotation for 20 minutes, and the solution of the radical absorbed approximately the calculated amount of oxygen. Upon further reaction of the silver the nuclear bromine was slowly removed with the gradual formation of the radical of the second order; the amount of oxygen, which the tubes were then capable of absorbing, gradually

¹⁴ Gomberg and Schoepfle, This Journal, 39, 1661 (1917).

decreased until a fairly constant value—1/2 of the amount found for the first radical—was obtained.

p-Bromotriphenylmethyl Peroxide, $[(C_6H_4Br)(C_6H_5)_2C]_2O_2$.—After the reaction mixture had rotated for 20 minutes, in absolute ether as a solvent and with exposure to the air, the peroxide was formed. It melted at 167° and was identical with the peroxide which is formed by the simultaneous action of silver and air on a solution of the carbinol chloride. 15

The Carbinol Iodide.—A mixture of 1.000 g. of the carbinol chloride, 2.6 g. of silver and 30 cc. of benzene was rotated for 20 minutes. The mixture was then filtered, in an atmosphere of carbon dioxide, and titrated with a 0.1 N benzene solution of iodine. An equilibrium was established when 64% of the theoretical amount of iodine necessary to form the carbinol iodide had been added. A similar equilibrium has been found in the case of other triarylcarbinol iodides. That p-bromotriphenylcarbinol iodide had actually been formed was proved by the conversion of the reaction product into the chloride. Dry silver chloride was added and the mixture was shaken for several hours; p-bromotriphenylcarbinol chloride was isolated from the solution. $R_2C-I + AgCI = R_3C-CI + AgI$.

Although a number of attempts were made to isolate the radical of the first and that of the second order in a crystalline state none of the experiments led to the desired result. Both radicals seemed to be characterized by great solubility in all solvents except low-boiling petroleum ether; from the latter solvent, however, products were obtained that absorbed oxygen to only a small extent.

The Radicals from p-Bromodiphenyl-1-naphthylcarbinol Chloride.— In this set of experiments absolute ether was used as a solvent instead of

xylene and the tubes containing carbinol chloride, silver and solvent were treated as previously described.

The radical of the first order formed a deep violet solution, while that of the second order was an indigo color.

Peroxide of the Radical of the First Order; p-Bromodiphenyl-1-naphthylmethyl Peroxide, $[(Br_6CH_4)(C_6H_5)(C_{10}H_7)C]_2O_2$.—The deep violet solution of the radical, obtained by rotating 1.00 g. of the carbinol chloride, 3 g. of 20 mesh silver and absolute ether for 20 minutes, was quickly decolorized upon exposure to air. The yields of peroxide from two experiments were 0.87 g. and 0.84 g., or 91% and 88%, respectively. The peroxide, which is crystalline, is only slightly soluble in organic solvents and is colored deep green by coned. sulfuric acid. It melts with decomposition at 146°.

Analyses. Calc. for $C_{46}H_{32}O_2Br_2$: C, 71.15; H, 3.93; Br, 20.60. Found: C, 71.32; H, 4.02; Br, 19.77.

Peroxide of the Radical of the Second Order, $[(BrC_6H_4)(C_{10}H_7)(C_6H_5)C-C_6H_4-C(C_6H_5)(C_{10}H_7)]_2O_2$.—For the preparation of this substance a tube containing 1.00 g. of the carbinol chloride, 3 g. of 40-mesh silver and dry carbon disulfide was rotated for 60 hours. Upon exposure of the indigo-colored solution to the air it turned red and finally orange and, after the solvent had evaporated spontaneously, a yellow, resinous material remained. For purification, the peroxide was redissolved in a small amount of carbon disulfide and precipitated by the addition of a small amount of low-boiling petroleum ether; in this way a cream-colored, flocculent substance was obtained. It was found impossible to obtain the compound in crystalline condition. The peroxide, when heated, undergoes a gradual decomposition which begins at about 120°. It dissolves in carbon tetrachloride and benzene and is insoluble in alcohol, acetone or ethyl acetate.

Analysis. 16 Calc. C₉₂H₆₄O₂Br₂: C, 81.16; H, 4.74. Found: C, 80.96; H, 5.92.

Attempts to Isolate the Radicals.—The intensely colored solution, known to contain only the free radical of the first order, was siphoned into the apparatus designed for use in the isolation of free radicals.¹⁷ The solvent was removed at a low temperature under reduced pressure, and a gummy, indigo-blue residue was obtained. No spontaneous production of crystals could be obtained from a saturated solution of the radical; precipitating reagents likewise yielded only amorphous material. A solution of the amorphous substance absorbed a small amount of oxygen but complete decolorization did not take place.

Similar negative results were obtained in our attempts to isolate the radical of the second order.

The Radicals from Diphenyl-4-bromo-1-naphthylcarbinol Chloride.—A number of tubes, each containing 1.000 g. of the carbinol chloride, silver and solvent, were treated as previously described. In the tubes, used for the measurement of absorbed oxygen, bromobenzene was used, as before, for a solvent; for the silver halide determinations the carbinol chloride was dissolved in absolute ether.

¹⁶ The analytical results for bromine, obtained by the Carius method, were somewhat lower than those demanded by the above formula.

Peroxide of the Radical of the First Order, $[(C_6H_5)_2(BrC_{10}H_6)C]_2O_2$.—The ether solution of the radical was brown-red with a tinge of green. Exposure of the solution to the air resulted in an instant decolorization, accompanied by peroxide formation. The yield of peroxide obtained from 1 g. of the carbinol chloride was 0.82 g. or 86%. The peroxide is insoluble in cold benzene and when heated darkens at about 148° and melts with decomposition at 153–154°.

Analysis. Calc. for C46H32O2Br2: Br, 20.60. Found: 20.13

Peroxide of the Radical of the Second Order, $[(BrC_{10}H_7)(C_6H_5)_2C-C_{10}H_6-C-(C_6H_5)_2]_2O_2$.—The violet solution of the radical, obtained by rotating an ether solution of the carbinol chloride with silver for 48 hours, was decolorized at once upon exposure to air. The corresponding peroxide, which is quite soluble in ether, was precipitated to only a small extent; the bulk of the peroxide was obtained by allowing the solvent to evaporate spontaneously. This substance is a cream-colored, amorphous material and the color is changed to deep green by cone, sulfuric acid. In order to purify the substance for analysis it was dissolved in absolute ether and precipitated by the addition of low-boiling petroleum ether.

Analyses. Calc. for C₉:H₆₄O₂Br₂: C, 81.16; H, 4.74. Found: C, 80.81; H, 5.25.

When heated, the compound turned black at about 135° and gradually melted with decomposition.

Reaction between Silver Salts and the Carbinol Chlorides

p-Bromo-triphenylcarbinol Chloride and Silver Sulfate.—A number of sealed tubes, each containing 1.000 g. of the carbinol chloride, 3 g. of finely divided, thoroughly dried silver sulfate and 25 cc. of dry, acid-free nitrobenzene were prepared. Upon mixing the components a red solution was instantly formed. The tubes were rotated continuously, for a number of days, at a temperature of 50°.

After a definite period of reaction a tube was opened, the nitrobenzene solution filtered from the silver salts, and the amount of silver chloride and bromide in the latter was then estimated. The results of the silver halide analyses indicated to what extent the quinonoid sulfate (X) had been formed.

The highly colored, nitrobenzene solution was shaken with small amounts of 3% sodium hydroxide solution until the red color, due to the presence of the sulfate, had disappeared. Upon careful acidification of the alkaline extracts with acetic acid phydroxytriphenylcarbinol was obtained. The latter, after recrystallization from acetic acid, was isolated in the quinonoid modification.¹⁸

For further identification the colored carbinol was converted into the colorless, benzenoid form which was found to melt at 158–159°, as reported in the literature.

¹⁸ Gomberg, This Journal, **35**, 1036 (1913).

Finally, the benzyl derivative, prepared from the carbinol, was found to be identical with the benzyl compound previously described.¹⁹

In one experiment an analysis of the silver halides showed that, in addition to all of the carbinol chlorine, 74% of the nuclear bromine had been removed; the yield of phydroxytriphenylcarbinol obtained in this instance was 70%.

It was found inadvisable to allow the reaction between the silver and the brominated carbinol chloride to proceed to completion. When the mixture was rotated long enough to remove all of the nuclear bromine, a red, alkali-soluble oil resulted; this consisted, in part, of decomposition products of the sulfate; p-hydroxytriphenylcarbinol could not be isolated from the mixture. This latter fact is not surprising since even the pure, crystalline p-hydroxytriphenylcarbinol, in the quinonoid modification, decomposes through auto-oxidation when kept for some time in a stoppered bottle.

p-Bromodiphenyl-1-naphthylcarbinol Chloride and Silver Sulfate.—A mixture of 1.000 g. of the carbinol chloride, 3 g. of silver sulfate and 15 cc. of nitrobenzene was rotated, at 50°, for 3 days. The red-brown solution was then filtered and the nitrobenzene removed by distillation with steam. The red residue was dried, dissolved in a small amount of benzene and precipitated by the addition of petroleum ether. The precipitate was washed with low-boiling petroleum ether and finally recrystallized from alcohol. The yellow crystals which were obtained melted at $168-170^{\circ}$. This compound proved to be phenyl-1-naphthylquino-methane, 20 (C_6H_6)($C_{10}H_7$):C: C_6H_4 :O.

Diphenyl-4-bromo-1-naphthylcarbinol Chloride and Silver Sulfate.—Upon mixing 1.000 g. of the carbinol chloride, 3 g. of silver sulfate and 15 cc. of nitrobenzene a very deep green solution was instantly obtained. After rotation for 65 hours, at 50°, the solution had turned deep violet in color. The mixture was filtered and the solvent was removed by distillation with steam. The deep red, solid residue was shaken for 12 hours with a solution of 1.5 g. of sodium hydroxide in 50 cc. of 50% alcohol. After filtration the filtrate was acidified with acetic acid. The precipitated material was extracted with chloroform and the latter was then allowed to evaporate spontaneously. Upon treatment of the resulting residue with a small amount of acetic acid an orange-yellow, crystalline material was obtained. This compound melted at $178-179^\circ$ and was p-naphthofuchsone, $(C_6H_5)_2:C:C_10H_6:O$. When mixed with material prepared according to the literature, 21 the mixture melted at 179° .

In other series of experiments p-bromotriphenylcarbinol chloride in nitrobenzene solution was mixed with other silver salts, such as silver sulfite and silver nitrate. In each case intensely colored solutions resulted. Using silver sulfite a 68% yield of p-hydroxytriphenylcarbinol was obtained, thus proving that a quinonoid sulfite, entirely analogous to the sulfate, was formed as an intermediate product.

When silver nitrate was used, in the hope of obtaining a solution of the quinonoid nitrate, spontaneous decomposition of the resulting product took place, and only picric acid could be isolated.

This investigation was made with the assistance of The National Aniline and Chemical Company Fellowship. We wish to acknowledge our appreciation of the generous aid which has been given us.

Summary

- 1. p Bromodiphenyl 1 naphthylcarbinol, diphenyl 4 bromo 1 naphthylcarbinol and the corresponding chlorides have been synthesized and described.
 - 19 Gomberg and Buchler, This Journal, 45, 211 (1923).
 - ²⁰ Gomberg and Lang, *ibid.*, **42**, 1882 (1920).
 - ²¹ Gomberg and Sullivan, *ibid.*, 42, 1867 (1920).

p-Bromophenyl-chrysofluorene has been prepared and its constitution proved.

- 2. It has been shown that prolonged reaction between p-bromotriaryl-carbinol chlorides and excess of molecular silver, at ordinary temperature, results, in the first stage, in the removal of 1 atom of chlorine (carbinol chlorine); in the second stage, in the additional removal of $^{1}/_{2}$, and only $^{1}/_{2}$, of an atom of bromine (nuclear bromine). A formulation of the reaction has been given in this paper which explains not only the mobility of the nuclear bromine, but also gives a rational explanation of the removal of exactly $^{1}/_{2}$ of an atom, but no more, of the ring halogen. The explanation is based on the idea that the free radicals exist in 2 tautomeric modifications, benzenoid and quinonoid. According to this hypothesis, during the first stage of the reaction the radical of the "first order," R_3C \longrightarrow $R_2C = \bigcirc$ \longrightarrow H, results; during the second stage, a radical of the "second order," R_3C — C_6H_4 — CR_2 , is produced.
- 3. It was shown that the absorption of oxygen by the compound, formed by the removal of the carbinol chlorine alone, is equal in amount to that calculated for a free radical R_3C —. Furthermore, it has been demonstrated that the substance which results from the elimination of both the carbinol chlorine and $^{1}/_{2}$ of an atom of bromine absorbs only $^{1}/_{2}$ of the above quantity of oxygen, that is a quantity of oxygen demanded by the more complex radical of the "second order."

The peroxides corresponding to the two types of radicals have been isolated and analyzed.

- 4. Prolonged reaction between any of the 3 carbinol chlorides and silver sulfate results, likewise, in the removal of both carbinol and nuclear halogen. In this instance 1 atom, and not $^{1}/_{2}$ of an atom, of ring halogen was eliminated from 1 molecule of the triarylcarbinol chloride. This fact, also, is in complete harmony with the assumption that the bromine is a part of a quinonoid nucleus.
- 5. The general conclusion is that in the colored triarylmethyls, as well as in the colored, salt-like derivatives of the triarylcarbinols, color and quinoidation are concomitant phenomena.

REACTIONS OF STRONGLY ELECTROPOSITIVE METALS WITH
ORGANIC SUBSTANCES IN LIQUID AMMONIA SOLUTION. III.
THE REDUCTION OF NITROBENZENE BY SODIUM IN LIQUID
AMMONIA

By George F. White and Kenneth H. Knight Received March 3, 1923

It has been pointed out by Kraus and White¹ that organic compounds of very diverse function react with the alkali metals in liquid ammonia. The field offered for investigation is very extensive, since at present insufficient data are at hand to explain the mechanism of many new reactions and to predict the character of the products which might be formed. The selection of the reduction of nitrobenzene as a basis for the present study seemed very desirable in view of the general interest in the reduction of nitro compounds and, further, in view of the progress which would probably be made for the future investigation of the behavior under similar conditions of compounds of closely related function.

Both nitrobenzene and sodium are soluble in liquid ammonia, so that conditions in such a system are ideal for the rapid reduction of the nitro compound by the electrons of the highly ionized metal. Reduction in fact takes place extremely readily, and it is important to compare the process with the more familiar reductions in heterogeneous systems.

The reduction of nitrobenzene by sodium in non-aqueous media has to a certain extent been investigated. Hofmann and Geyger² found that sodium readily reacts with an ethereal solution of chloronitro-benzene and of chloronitro-toluene with the production of compounds in which sodium has entered the nitro group. They were unsuccessful in reducing nitrobenzene under similar conditions. Schmidt,³ however, was able to reduce nitrobenzene slowly in ethereal solution at ordinary temperature and rapidly in boiling toluene, that is, in the latter case, above the melting point of metallic sodium. He obtained a sodium compound to which he assigned the formula, $C_6H_5N(Na)ONa$, since it yielded β -phenylhydroxylamine when treated with acid. Schmidt also suggested the possibility that the disodium compound has the constitution $C_6H_5N(=O)Na_2$, and that it should thereby yield the hypothetical aniline oxide $C_6H_5N(=O)H_2$ with acids, aniline oxide then immediately rearranging to phenylhydroxylamine.

We have found that the same disodium derivative of phenylhydroxylamine as Schmidt obtained in toluene or ether solution is produced in

¹ (a) Kraus and White, This Journal, **45**, 768 (1923). See also (b) White, *ibid.*, **45**, 779 (1923).

² Hofmann and Geyger, Ber., 5, 915 (1872).

³ Schmidt, *ibid.*, **32**, 2911 (1899).

liquid ammonia by the reduction of nitrobenzene. The compound is rather insoluble in liquid ammonia, being precipitated as a red crystalline solid. Either sodium oxide is formed as a by-product and then is more or less completely ammonolyzed,4 or ammonia enters into the primary reaction with the formation of sodium amide and sodium hydroxide in equimolecular amounts. The reaction may then be expressed by the equation, $C_6H_5NO_2 + 4Na + NH_3 = C_6H_5N(Na)ONa + NaNH_2 +$ NaOH. By the addition of water to the reaction mixture azobenzene and azoxybenzene were isolated. However, these were substances produced by the secondary reactions of phenylhydroxylamine in hot alkaline aqueous solution. By the use of ammonium chloride in liquid ammonia the disodium salt was converted into its corresponding ammono acid in the absence of water. $C_6H_5N(Na)ONa + 2NH_4C1 = C_6H_5N(H)OH +$ $2\text{NaCl} + 2\text{NH}_3$. β -phenylhydroxylamine was extracted from the mixture with anhydrous solvents. In liquid ammonia, then, reduction of nitrobenzene proceeds as in all other solvents, phenylhydroxylamine being the first product to be isolated (or the sodium derivative of it), while nitrosobenzene may be assumed to be an intermediate product since indirect methods have indicated its formation in aqueous solutions. Azo bodies are not formed primarily but may result from secondary reactions in aqueous alkaline solution.

That disodium phenylhydroxylamine has the constitution, C₆H₅N(Na)-ONa, is very probable, since sodium would more readily add to oxygen than to nitrogen. Further, the compound reacts with alkyl halides in liquid ammonia, but no dialkylaniline oxide could be isolated from such reaction mixtures. It is of interest to note that preliminary experiments indicate that an excess of methyl iodide reacts with the sodium compound in liquid ammonia with the formation of an unstable oil. This oil has certain of the characteristics of the primary product which Bamberger and Tschirner⁵ obtained by the action of methyl iodide on dimethylaniline oxide and which they considered to be phenyldimethyl-methoxyammonium iodide, but which they found was too unstable to isolate. Such a compound could result from the disodium derivative of phenylhydroxylamine in liquid ammonia according to the following series: C₆H₅N(Na)ONa -> $C_6H_5N(CH_3)OCH_3 \longrightarrow C_6H_5N(I)(CH_3)_2OCH_3$. We have further shown that potassium amide reacts with phenylhydroxylamine in liquid ammonia. A red crystalline precipitate is produced which has the same physical properties as the sodium or potassium compound resulting from the reduction of nitro or nitrosobenzene. To test these views on the structure of the

⁴ Unpublished observations of E. F. Whyte in this Laboratory have proved that sodium oxide in liquid ammonia is rapidly ammonolyzed to sodium amide and sodium hydroxide.

⁵ Bamberger and Tschirner, Ber., 32, 1882 (1899).

disodium compound, a study of the formation of the alkyl derivatives of phenylhydroxylamine in liquid ammonia will be made.

Disodium phenylhydroxylamine is readily prepared by the reduction of nitrosobenzene in liquid ammonia: $C_6H_5NO + 2Na = C_6H_5N(Na)ONa$. As no by-products are formed, the reaction offers an especially good opportunity for further study of the structure of the sodium compound.

By the action of an excess of sodium in liquid ammonia, nitrobenzene is readily reduced to disodium anilide, which yields aniline by the action of ammonium chloride or water: $C_6H_5N(Na)ONa + 2Na + NH_3 = C_6H_5-NNa_2 + NaOH + NaNH_2$. Phenylhydroxylamine itself is reduced in liquid ammonia directly to aniline: $C_6H_5NHOH + 2Na + NH_3 = C_6H_5-NH_2 + NaOH + NaNH_2$.

A study of the reduction of azoxybenzene, azobenzene and hydrazobenzene in liquid ammonia has revealed the facts cited below.

Azoxybenzene is rapidly reduced to azobenzene: C_6H_5 —N—N— C_6H_5 +

 $2Na + NH_3 = C_6H_5 - N = N - C_6H_5 + NaNH_2 + NaOH$. By the further action of sodium on azobenzene, sodium atoms add directly to the azo group in the azobenzene molecule, whereby a disodium ammono salt of hydrazobenzene results: $C_6H_5 - N = N - C_6H_5 + 2Na = C_6H_5N(Na) - N(Na) - C_6H_5$. From this ammono salt hydrazobenzene may be obtained by the addition of ammonium salts of mineral acids or by the addition of water: $C_6H_5 - N(Na) - N(Na) - C_6H_5 + 2H_2O = C_6H_5 - N(H) - N(H) - C_6H_5 + 2NaOH$. The possible synthesis of quaternary hydrazines by the action of alkyl and aryl halides on the sodium salt of hydrazobenzene will be investigated.

The sodium derivative of hydrazobenzene is reduced by an excess of sodium to disodium anilide, C_6H_5 —N(Na)—N(Na)— C_6H_5 + 2Na = $2C_6H_5NNa_2$, from which compound aniline is obtained by the addition of water.

It is important to note in connection with these reductions that sodium does not react with free hydrazobenzene in liquid ammonia with the formation of the disodium derivative and the evolution of hydrogen, but that the molecule splits, and monosodium anilide is formed: C_6H_5 -NHNHC₆H₅ + 2Na = 2C₆H₅NHNa. The reduction of hydrazobenzene and of azobenzene to the mono- and disodium anilides, respectively, proceeds rapidly, and this method for the preparation of these latter compounds in liquid ammonia offers many advantages over the method of direct interaction of sodium and aniline.⁶

Considering the small quantities of reagents employed in the various experiments, good yields of phenylhydroxylamine, azobenzene and hydrazo-

⁶ Ref. 1b, p. 784. See also Picon, Compt. rend., 175, 1213 (1922).

benzene were obtained by the reduction of nitrobenzene, azoxybenzene and azobenzene, respectively. The method may prove of practical application in the synthesis of more valuable reduction products of other nitro and azo compounds.

Experimental Part

Apparatus and Procedure.—The apparatus and the experimental method employed were essentially identical with those described in the second article of this series.⁷

Materials.—The nitrobenzene used was redistilled thrice and had only a faint tinge of yellow color. Azoxybenzene, azobenzene and hydrazobenzene were obtained by reduction of nitrobenzene in alkaline aqueous solution, and β -phenylhydroxylamine by reduction of nitrobenzene in neutral solution in the usual manner. Nitrosobenzene was prepared by oxidation of phenylhydroxylamine. These nitrobenzene reduction products were recrystallized until pure as evidenced by their melting points.

The Reduction of Nitrobenzene

General Observations.—Franklin and Kraus⁸ have observed that the aromatic nitrohydrocarbons are more or less soluble in liquid ammonia, solutions of nitrobenzene being very little colored, but those of the polynitro compounds often being highly colored. Solutions of nitrobenzene showed no electrical conducting power, while those of dinitrobenzene evidenced a conductance which increased up to a maximum with time. Solutions of trinitrotoluene were found to attain their final conductance values at once.

In conformity with the above we have noted that nitrobenzene, which is very soluble in liquid ammonia, is colored red to violet in ammonia solution when only partially purified by distillation. Distillation of the compound three or four times gave a product which was colorless in ammonia solution. The impurities in the colored solutions were very probably traces of polynitro compounds which would act as pseudo acids, exhibiting the phenomena of "slow neutralization" observed by Franklin and Kraus and yielding colored ammonium salts of their aci forms. These observations substantiate the conclusions drawn from the following experiments, that nitrobenzene exhibits no desmotropic character in liquid ammonia solution and that no metallic derivatives of it are formed in such solutions.

As sodium was added in successive portions to colorless solutions of nitrobenzene in liquid ammonia, the solutions became yellow, then orange, dark red and finally dark brown, while a precipitate which at first appeared to be white darkened as the reduction proceeded. The color phenomena varied somewhat in the different experiments because minute amounts of certain of the colored reduction products had a marked effect on the appearance of the others. The reaction of the metal solution with the

⁷ Ref. 1b, p. 780.

⁸ Franklin and Kraus, Am. Chem. J., 20, 382 (1898); 23, 277 (1900).

nitro compound was rapid but was characterized by no excessive violence when the sodium was added in small portions. In the presence of a large excess of sodium, however, the reaction was very violent and explosions were apt to occur. On partial reduction of nitrobenzene, if the ammonia was then evaporated before addition of water and the reaction products exposed to the air, violent explosions resulted, accompanied by flame and the deposition of carbon.⁹

No hydrogen was evolved in any of the reductions.

When nitrobenzene was treated with sodium in the proportion of 1 molecule of the former to 1, 2 or 3 atoms of the latter, there was only partial reduction of the nitrobenzene, some of this substance being recovered from the mixture of reaction products.

The Formation of Disodium Phenylhydroxylamine.—Four and a half g. of sodium was added to a liquid ammonia solution of 6 g. of nitrobenzene, which corresponds to a ratio of 4 atoms of sodium to 1 molecule of the nitro compound. Before the last small portion of sodium was added the mixture was bright red in color but became dark brown on addition of the remainder; 11 g. of ammonium chloride was then introduced into the reaction tube and the mixture thoroughly stirred. All sodium compounds were thereby decomposed with the formation of insoluble sodium chloride. The resulting mixture was light yellow. The ammonia was evaporated and the dry residue extracted thrice with hot anhydrous benzene. The mixture was filtered and the benzene extract treated with an equal volume of anhydrous petroleum ether. After the solution had cooled, 1.9 g. of colorless crystals of β -phenylhydroxylamine (m. p., $80-82^{\circ}$) was obtained; yield, 36%. These were soluble in water, and the aqueous solution readily reduced ammoniacal silver nitrate and Fehling solutions.

The precursor of phenylhydroxylamine in the above experiment might be its disodium derivative, $C_6H_5N(Na)ONa$, or the disodium derivative of aniline oxide, $C_6H_5N(=O)Na_2$. In the latter case, aniline oxide, the hypothetical tautomer of phenylhydroxylamine, would, after being set free by addition of ammonium chloride, instantaneously rearrange into the hydroxylamine. It was found that the sodium reduction product reacted with methyl iodide in liquid ammonia with great readiness, but all attempts to isolate dimethylaniline oxide, $C_6H_5N(=O)(CH_3)_2$, were unsuccessful. On the other hand the following experiment indicates the formation of a dimethyl derivative of phenylhydroxylamine.

Three and six-tenths g. of nitrobenzene was reduced by 2.7 g. of sodium in liquid ammonia, whereby the disodium compound was produced; 16.8 g. of methyl iodide was then added, or twice as much as was required to form a dimethyl derivative of phenylhydroxylamine. The mixture was at first red but soon changed to a yellow color, and on the addition of 4 g. of ammonium chloride a clear yellow oil was formed which coagulated to an amorphous precipitate. After evaporation of the ammonia and extraction of the residue with ether, from the ether extract a reddish oil was isolated which when warmed had the odors of dimethylaniline and formaldehyde. These latter substances were likewise found by Bamberger and Tschirner⁵ to be formed when the unstable

 $^{^9}$ Schmidt, Ref. 3, has noted the explosive properties of disodium phenylhydroxylamine.

product of the reaction between dimethylaniline oxide and methyl iodide spontaneously decomposed.

Dipotassium Phenylhydroxylamine.—Several experiments proved that potassium reacts with nitrobenzene in liquid ammonia just as does sodium. A red, crystalline precipitate was formed and from this phenylhydroxylamine was prepared.

The following experiment confirms the assumed structure of the metallic compounds: 1.02 g. of potassium was dissolved in liquid ammonia and was converted into potassium amide by the catalytic action of ferric oxide; 1.5 g. of phenylhydroxylamine was then added. The colorless solution immediately became deep red in color and a red crystalline precipitate slowly separated. The following tentative reaction may be written: $C_6H_5N(H)OH + 2KNH_2 = C_6H_5N(K)OK + 2NH_3$.

Disodium Anilide.—One g. of nitrobenzene was reduced by 1.1 g. of sodium, that is, in the ratio of 1 molecule of the nitro compound to 6 atoms of sodium. The complete reduction was rather slow, and the mixture was allowed to stand for 24 hours. A brownish-green solution was obtained to which water was added. An oil, separated from this mixture, proved to be aniline.

The Formation of Sodium Amide.—To test for the formation of sodium amide in the reduction of nitrobenzene, 3.6 g. of nitrobenzene in liquid ammonia, was reduced by 2 g. of sodium, and then 9 g. of α -bromonaphthalene was added. Vigorous boiling of the liquid ammonia indicated that a reaction ensued. Water was then added, the ammonia evaporated, and the aqueous mixture acidified with hydrochloric acid. This mixture was extracted with ether to remove azoxybenzene and any unchanged bromonaphthalene, and the aqueous solution was then made alkaline. A small amount of α -naphthylamine separated from the solution. The synthesis of this compound in liquid ammonia may then be formulated thus: α -C₁₀H₇Br + NaNH₂ = α -C₁₀H₇NH₂ + NaBr.

The metal amide formed in the reduction of nitrobenzene in liquid ammonia does not react with any excess of the nitro compound. This was proved by a test experiment in which nitrobenzene was treated with potassium amide. The nitrobenzene was recovered unchanged.

The Secondary Formation of Azoxybenzene and Azobenzene

These compounds may be obtained when water is added to the mixtures of partially reduced nitrobenzene and liquid ammonia, and result from the familiar reactions of phenylhydroxylamine in alkaline aqueous solution.

Two g. of sodium was added to an ammonia solution of 3.6 g. of nitrobenzene. The final mixture was reddish-yellow. Water was added, the ammonia was evaporated, and the cooled aqueous solution filtered. The yellow residue was recrystallized from methyl alcohol; 1.8 g. of azoxybenzene, m. p. 34–36°, was obtained.

Two and eight-tenths g. of sodium was added to an ammonia solution of 3.6 g. of nitrobenzene. Water was added, and the insoluble residue obtained was twice crystallized from alcohol; 0.9 g. of azobenzene, m. p. 68.5°, was obtained.

The Oxidation of Disodium Phenylhydroxylamine

Three and six-tenths g. of nitrobenzene was reduced by 2.7 g. of sodium in liquid ammonia. Air was blown through the liquid ammonia mixture for $^3/_4$ hour. The color became very dark red; 6.4 g. of ammonium chloride was then added and a dark tarry mass separated. The ammonia was evaporated and anhydrous ether was added. The ether solution was green which would indicate the possibility of the presence of

some nitrosobenzene, although none of the compound was isolated. The ether extract yielded considerable nitrobenzene, but no phenylhydroxylamine. The experiment proved that disodium phenylhydroxylamine is oxidized to nitrobenzene in liquid ammonia.

The Reduction of Nitrosobenzene

Nitrosobenzene is insoluble in liquid ammonia. It was found to react with either potassium or sodium with great rapidity. A dark red solution was formed at first, but after 2 equivalents of the alkali metal were added a red crystalline precipitate slowly formed. This would indicate that the metallic derivatives of phenylhydroxylamine are to a certain extent soluble in liquid ammonia. Phenylhydroxylamine was isolated by the same procedure as described above in connection with the reduction of nitrobenzene.

The Reduction of Phenylhydroxylamine

Phenylhydroxylamine is extremely easily soluble in liquid ammonia. To a solution of 2 g. of this compound was added 0.84 g. of sodium. A light yellow precipitate (sodium amide and sodium hydroxide) formed, but no hydrogen was evolved in the reduction. The mixture became blue on the addition of 0.7 g. of sodium over the above amount, so that 2 atoms of sodium reacted with 1 molecule of the phenylhydroxylamine. The ammonia was evaporated leaving an oily residue from which aniline was extracted.

The Reduction of Azoxybenzene

Azoxybenzene is difficultly soluble in liquid ammonia, the solution being colored yellow; 4.3 g. of the substance was reduced by 1 g. of the sodium (1 molecule of azoxybenzene to 2 atoms of sodium). The reaction was very rapid, fine yellow crystals of azobenzene separating out of solution. These were isolated and crystallized from alcohol; yield, 77%; m. p., 63-68°.

The Reduction of Azobenzene

Formation of Hydrazobenzene.—Azobenzene dissolves to a slight extent in liquid ammonia with the production of a yellow solution; 3.95 g. of azobenzene was treated with 1 g. of sodium in liquid ammonia (in the ratio of 1 molecule of azobenzene to 2 atoms of sodium). The action was rapid and a blood-red solution was formed containing no precipitate. On addition of water a faintly yellow precipitate resulted. After evaporation of the ammonia the aqueous solution was filtered and the residue crystallized from alcohol. White crystals of hydrazobenzene were obtained; m. p., 126–129°; yield, 75%. No aniline was formed in the reduction.

Formation of Disodium Anilide.—One g. of azobenzene was reduced with 0.5 g. of sodium in ammonia (1 molecule of azobenzene to 4 atoms of sodium). A red-brown opaque solution resulted. Water was added and aniline was isolated from the aqueous solution. To test for the formation of disodium anilide in this reduction in liquid ammonia, 5.0 g. of azobenzene was treated with 2.5 g. of sodium, and 17.0 g. of ethyl iodide was then added to the liquid-ammonia solution. Water was then added and an ether extract of the aqueous solution yielded an oil that boiled at $205-215^{\circ}$ and evidently consisted mainly of diethylaniline. This substance was formed in ammonia by a reaction expressed by the equation, $C_6H_5NNa_2 + 2C_2H_5I = C_6H_5N(C_2H_5)_2 + 2NaI$.

The Reduction of Hydrazobenzene

Formation of Aniline.—Hydrazobenzene is readily soluble in liquid ammonia, yielding a pale yellow solution. When sodium was added to such a solution in the proportion of 1 molecule of hydrazo compound to 1 atom of sodium, the solution became dark red and a white gelatinous precipitate consisting probably of monosodium anilide (see below) was precipitated. No hydrogen was evolved in the reduction. After the addition

of water at least $^{1}/_{2}$ of the original amount of hydrazobenzene was recovered and some aniline was also obtained. The test showed that there was insufficient sodium for complete reduction and that the hydrogen atoms of the hydrazine molecule were not replaced by sodium.

Two g. of hydrazobenzene was treated with 0.5 g. of sodium in liquid ammonia (1 molecule of hydrazobenzene to 2 atoms of sodium). After the addition of water, by the usual procedure an oil was isolated which gave a violet color with sodium hypochlorite solution and boiled at 184° and, therefore, was practically pure aniline. No hydrazobenzene was recovered from the reaction mixture.

Formation of Monosodium Anilide.—Four g. of hydrazobenzene was treated with 1 g. of sodium as in the preceding experiment. To the mixture was then added 6.8 g. of ethyl iodide. Water was added and an ether extract of this aqueous solution yielded an oil which gave on distillation 2 fractions, one boiling at 185° consisting of aniline, and a second boiling at 200–205° consisting of mono-ethylaniline. The latter compound was synthesized in liquid ammonia evidently according to the following equation: $C_6H_5NH-Na + C_2H_5I = C_6H_5NHC_2H_5 + NaI$.

Summary

Nitrobenzene and nitrosobenzene are readily reduced by sodium in liquid ammonia with the formation of a disodium derivative of β -phenylhydroxylamine, the structural formula of which is probably $C_6H_6N(Na)$ -ONa. Phenylhydroxylamine is liberated from this salt in ammonia by the action of ammonium chloride, and the free phenylhydroxylamine may be isolated by extraction with anhydrous solvents after evaporation of the ammonia. By the further reduction of the disodium derivative in liquid ammonia, disodium anilide is formed and aniline is obtained from this by the action of ammonium chloride or water. Phenylhydroxylamine itself is reduced directly to aniline in liquid ammonia.

The disodium derivative of phenylhydroxylamine is oxidized in liquid ammonia to nitrobenzene by air.

Azoxybenzene and azobenzene are not formed as direct reduction products of nitrobenzene in liquid ammonia, but may be isolated after treatment of the partially reduced mixture with water. They result from the secondary reactions of phenylhydroxylamine in alkaline aqueous solution.

Azoxybenzene is reduced by sodium to azobenzene. Azobenzene is reduced to a disodium derivative of hydrazobenzene from which the latter compound may be obtained after treatment with ammonium chloride or water. The disodium derivative of hydrazobenzene may be further reduced by sodium in ammonia to disodium anilide, while hydrazobenzene itself is reduced by sodium to monosodium anilide.

Mono- and dialkylanilines may be synthesized in liquid ammonia by the action of alkyl halides on mono- and disodium anilides, respectively.

THE QUANTITATIVE DETERMINATION OF TRYPTOPHAN

By George E. Holm and Geo. R. Greenbank

Received March 17, 1923

Many methods, chiefly colorimetric, have been used for the quantitative determination of the tryptophan content of proteins, but few have given results accurate and concordant enough to warrant their general use where absolutely quantitative results are desired.

The bromine absorption test, the Adamkiewicz reaction, the nitroso-indole reaction, and others have been used with little real success.

Voisenet's¹ test for tryptophan, using formaldehyde in the presence of potassium nitrite and concd. hydrochloric acid, was made the basis for its quantitative determination by Fürth² and his associates, and excellent results were obtained. Their data indicate that the reaction of tryptophan with formaldehyde in the presence of sodium nitrite is rapid and while the color reaches a quite constant maximum, it may permit an error of from 10 to 20%. They also found that the color produced was very sensitive to an excess of hydrochloric acid, to excess of sodium nitrite and formaldehyde concentrations, to reducing and oxidizing substances and to metals. Various methods were tried for dissolving the proteins but the results obtained with these solutions are all within experimental error of the method.

The observation of Rhode,³ that tryptophan gives a blue color with p-dimethylaminobenzaldehyde, has found the most general application and has been used by Herz-feld,⁴ Kurchin,⁵ Thomas,⁶ and by May and Rose,⁷ While the methods employing this aldehyde are capable of very accurate results, the most general error in the method used by these workers has been due to the fact that the reactions in the standard or the unknown protein solutions have not been brought to a maximum color intensity.

The work of Gortner and Holm⁸ proved that the "humin" formed upon the acid hydrolysis of proteins in the presence of aldehydes was due to the presence of tryptophan. In the presence of a definite optimum amount of a certain aldehyde, the amount of "humin" formed, as measured by the nitrogen content, is a fairly accurate estimate of the amount of tryptophan. When a protein is allowed to stand at room temperature in the presence of benzaldehyde or some other aromatic aldehyde and 20% hydrochloric acid, a color develops which is peculiar to the aldehyde used. At lower temperatures this color is quite stable, but as soon as the solution is heated a dark "humin" is formed. The use of aliphatic aldehydes produces a dark condensation product immediately. Further unpublished work showed that the dark "humin" product formed when indole derivatives are condensed with aldehydes probably consists of a condensation of 1 molecule of the indole derivative with 2 or more molecules of the aldehyde. When the reaction is

carried out in a molecular ratio of 1:1 the product is chiefly a soluble, deeply colored compound. These results indicate that if the reaction could be controlled, and if a reaction of a molecular ratio of 1:1 only could be obtained, the color produced would be a direct measure of the amount of an indole derivative present.

These observations emphasize the fact that in all cases where aldehydes are used care must be taken that conditions are such as to prevent the secondary reaction, as far as this can be done. The sensitiveness of the reaction used by Fürth and his associates is evident, since formaldehyde condenses very readily with tryptophan even at relatively low temperatures. The aldehyde used by Herzfeld, and by Thomas and more recently by May and Rose, p-dimethylaminobenzaldehyde, is very suitable, in that at lower temperatures very little or none of the secondary condensation products is formed. Herzfeld's error was evidently due to the fact that the reacting mixtures of either standards or unknowns were not allowed to

react long enough to produce a maximum color, and consequently his results are low in some cases. Thomas digested his proteins completely before applying the test and therefore his results are more nearly correct, although it is doubtful whether time enough was given for the development of maximum color. May and Rose used casein as a standard and calculated their results on the basis that the tryptophan content of casein is 1.50%, which is undoubtedly too

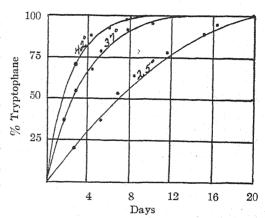

Fig. 1—Effect of temperature and time upon the rate of reaction of tryptophan with p-dimethylaminobenzaldehyde in 20% HCl

low. Figures given later will show that the time allowed for the completion of the reaction in their standards and the unknowns was too short.

Experimental Part

Herzfeld's method, slightly modified, has been used by the authors for some time, and has been found to be reliable when certain precautions are taken with regard to the conditions under which the determinations are made. It has also been applied to samples of proteins without previous digestion with enzymes, and reliable results have been obtained.

The effect of temperature and time upon the reactions involved when a pure sample of tryptophan is treated with p-dimethyl-aminobenzaldehyde in the presence of 20% hydrochloric acid is shown by the curves given in Fig 1.

At 25° the reaction is slow, but there is little danger of a great amount of the secondary condensation product forming at that temperature, as shown by the fact that in every case the reaction reaches completion though the time factor is very large. At 37° and 42° the reactions are much more rapid but do not show maximum color development until the sixth or eighth day in the case of the experiment at 42°, and not until the tenth or twelfth day in the case of the experiment at 37°. At 42° the color is not permanent for any length of time. Under these conditions, therefore, when working at about 37°, as did May and Rose, it is necessary to allow approximately 8 days for the standard to develop maximum color. Assuming that the color of their standard developed according to the curve in Fig. 1, it was approximately 70% developed. Inasmuch, however, as the color of the unknowns was proportionately developed, the results are good in most cases. As soon as maximum color has been developed in a standard or unknown, it is best maintained if the solution is kept at a temperature of 25° or lower and if, in addition, it is diluted. Under such conditions standards have been found to maintain their color for 8 or 10 days and in some cases even longer.

Some of the results obtained by applying the facts illustrated in Fig. 1 are shown in Table I.

Several 2 to 5 mg. samples of tryptophan were weighed out and each was placed in 100 cc. of 20% hydrochloric acid solution to which had been added an excess of the aldehyde. From time to time readings were made against standards by means of a Duboscq colorimeter, until the readings of the unknowns became constant.

Table I
RESULTS OBTAINED WITH PURE TRYPTOPHAN

	Expts.	Temperatures used ° C.	Calc. Mg.	ount of trypt Found Mg.	ophan——— Recovered
1.	(Av. of 5 detns.)	25, 37, one detn. at 42	5.00	4.985	99.7
2.	(Av. of 5 detns.)	25, 37, one detn. at 42	2.00	1.976	98.8
A		25	2.70	2.77	102.6
\mathbf{B}		25	1.20	1.17	97.5

A and B were samples of unknown concentration prepared by J. M. S.

The results obtained in these experiments indicate that pure tryptophane in solution can be accurately estimated by this method under the conditions given.

The effect of various concentrations of the aldehyde was determined and it was found that there was practically no difference in the rate of the reaction at 25° whether 1 mol. or 10 mols. of the aldehyde were used to each mol. of tryptophan. Two mols. seemed to give the best results.

For the determination of pure tryptophan in solution or in a mixture of amino acids the authors recommend the use of approximately 2 mols. of aldehyde to each mol. of tryptophan present. The reaction may be carried out at 25° or 37° . The latter is preferable.

The method has been tried upon proteins that have not been previously digested with enzymes. In these cases the method is dependent upon the rate of hydrolysis of the protein by the acid used, which is quite rapid in concd. acid solution and much slower in dil. acid. Inasmuch as the color is less stable in concd. than in dil. acid solution, it has been found that a 20% hydrochloric acid solution is most satisfactory. Sulfuric acid has not been tried.

Several samples of proteins were ground very fine and 0.10 g. of each was suspended in 100 cc. of 20% hydrochloric acid containing an excess of p-dimethyl-aminobenzaldehyde. Reactions were carried out at both 25° and 37°. Readings were made from time to time against standards containing 2 mg. and 5 mg. of pure tryptophan, using a Duboscq colorimeter, until the colors of the unknowns reached maximum intensity.

Results indicate that 37° is preferable to 25° in this experiment.

The results for casein, fibrin and Witte's peptone are embodied in Table II, which also gives results obtained by the same general method and by other methods. Some of the difficulties and errors of other authors who have used the same general method have been pointed out elsewhere in the paper.

^a By formaldehyde-nitrite method.

With some proteins a sharp maximum in color intensity was produced, which extended over but 1 day. It is doubtful, therefore, whether results with all proteins are reliable when this method is used. This sharp maximum would indicate that a secondary reaction takes place to some extent before the primary color-producing reaction has been completed. The difficulty of hydrolysis of some proteins in the medium used may be a factor concerned here. From the results obtained upon pure tryptophan it seems that in general the best results might be obtained with the use of samples of proteins previously digested by enzymes.

In this connection it is interesting to call attention to the tryptophan content of fibrin as determined by Gortner and Holm.⁸ The fibrin used in the determinations reported in this paper was taken from the same sample as that used in their work upon "humin." formation. They estimated that in the presence of an optimum amount of formaldehyde 95% of the tryptophan was removed as "humin." Their figures indicate that

⁹ By phenol regent method. Folin and Looney, J. Biol. Chem., 51, 421 (1922).

¹⁰ By direct isolation, Hopkins and Cole, J. Physiol., 27, 418 (1901-2).

the tryptophan content of this fibrin, calculated upon the basis of the humin nitrogen was 4.8%. The total tryptophan content would therefore be 5.05% which is in excellent agreement with the value obtained by the colorimetric method.

Summary

- 1. Some of the difficulties and errors in the methods used by various authors are pointed out.
- 2. The effect of temperature and time upon the reaction of p-dimethylaminobenzaldehyde in 20% hydrochloric acid has been studied. In this concentration of hydrochloric acid the reaction requires greater time for completion than is generally supposed. The higher the temperature, the greater the instability of the color produced.
- 3. Pure tryptophan in solution can be accurately determined by use of this method. The tryptophan content of proteins can also be accurately determined without previous hydrolysis of the protein, but from observations and from general considerations it seems that an enzyme-digested protein is better suited for this determination than is undigested protein.
- 4. There is excellent agreement between the figures for the tryptophan content of fibrin obtained by the "humin" formation method of Gortner and Holm⁸ and those obtained by the colorimetric method.

SOME NEW DERIVATIVES OF SYNTHETIC ADRENALINE (SUPRARENINE)

By Casimir Funk and Louis Freedman Received March 23, 1923

In the manufacture of synthetic adrenaline, and especially in its purification, we have observed the formation of certain derivatives which are of unusual chemical interest, and which may prove to have valuable pharmacological properties.

It has been found that the secondary alcohol group in the side chain

forms ethers of the type HO —CH(O—R)—CH₂NHCH₃, where R represents an alkyl radical. A derivative of adrenaline has been prepared by Mannich¹ in which the hydrogens of all 3 hydroxyl groups have been replaced by methyl groups, but so far as we are aware no derivatives have as yet been described in which only the secondary alcohol group has been converted into an ether.

We have succeeded in preparing the methyl and ethyl ethers of this type, but have failed so far to prepare the purified propyl and benzyl

¹ Mannich, Arch. Pharm., 248, 127, 154 (1910).

derivatives. Large amounts of tarry residue, from which it is difficult to obtain the pure products, are formed with the higher homologs.

These new ethereal compounds differ from adrenaline in that they form soluble and easily oxidizable bases and, therefore, have to be isolated and purified as the hydrochlorides. We have as yet been unable to reconvert these ethers into adrenaline by hydrolysis; vigorous hydrolysis cannot be used because of the ease with which these compounds decompose.

In the preparations of the ethyl compound, when the reaction to form the ether is made more vigorous, another new compound, which has also been isolated and purified, is formed. This compound is probably the dihydrochloride of the di-ether of adrenaline with the structure

of water from 2 molecules of adrenaline.

None of the above compound was formed as a by-product in the preparation of the methyl ether, even though the reaction was carried out under higher temperature and pressure. Further work on the preparation of these compounds, and their pharmacologic action, is now being carried out.

Experimental Part

Preparation of the Hydrochloride of the Ethyl Ether of r-Adrenaline, r-3,4-Dihydroxy-phenyl Ethyl-ethanol-methyl Amine Hydrochloride.—Racemic adrenaline (synthetic) was heated with absolute ethyl alcohol containing various amounts of dry hydrogen chloride for various periods of time. We will describe only those experiments that gave the best results.

A solution of 4.4 g. (0.02 mole) of adrenaline hydrochloride in 44 cc. of absolute ethyl alcohol containing 0.02 mole of dry hydrogen chloride was refluxed for 1 hour on a waterbath. It was then filtered, the filtrate evaporated to half volume and the residue allowed to stand over sulfuric acid. On the next day, a crop of crystals was obtained which when filtered and washed with absolute alcohol, and dried, gave 2.4 g. of a white crystalline compound melting at 163° (with decomposition). After recrystallization from absolute alcohol, the material weighed 2.0 g. and melted at $165-166^{\circ}$. After 4 recrystallizations from absolute alcohol it melted at 169° (corr.); r-adrenaline hydrochloride melts at 157° . This new compound is soluble in 2.5 parts of absolute alcohol. It is readily soluble in water and its aqueous solution, on addition of ammonia, yields a soluble base which oxidizes very quickly in the presence of an excess of ammonia. The highest yield of the ethyl ether was obtained by using 1.5 molecular equivalents of hydrogen chloride and refluxing for $^{1}/_{2}$ hour. Thus, from 22 g. of adrenaline hydrochloride, we obtained 16 g. (65%) yield) of the hydrochloride of the ether.

In its color reactions it resembles adrenaline. With ferric chloride, it gives a dark green which turns to a maroon-red on standing or on addition of ammonia. It also gives an orange-red to a bright red color on addition of mercuric chloride and sodium acetate to its aqueous solution. These color reactions prove that the phenolic groups

in the ring are free, and that the secondary alcohol group can still give the sublimate reaction, even though the alcohol group is converted to an ether. On treatment with sodium nitrite in hydrochloric acid solution, the compound gives a yellow oil which shows the characteristic Lieberman nitrosamine reaction, proving the presence of a secondary amine and precluding the possibility of the addition of the ethyl group on the nitrogen.

Analyses.² Subs., 0.2788: 11.5 cc. of 0.1 N HCl. Subs., 0.0971: Cl, 0.0138; CO₂, 0.1212; H₂O, 0.0642. Calc. for $C_{11}H_{15}O_{5}NCl$: C, 53.36; H, 7.32; N, 5.65; Cl, 14.35. Found: C, 53.60; H, 7.34; N, 5.73; Cl, 14.21.

The hydrogen chloride can also be titrated directly with standard alkali, the formation of the easily oxidizable base giving a red color in excess alkali, thus acting as an indicator.

Preparation of Di-adrenaline-ether Dihydrochloride.—A solution of 45 g. of racemic adrenaline hydrochloride in 450 cc. of absolute ethyl alcohol containing 36.5 g. of dry hydrogen chloride (4 molecular equivalents) was refluxed for 1 hour. The product failed to crystallize at first, but after it had stood over sulfuric acid for several days a crop of crystals weighing 20 g. was obtained. This substance did not melt sharply and appeared to be a mixture. The bulk of it was practically insoluble in absolute alcohol, but was recrystallized from 70% alcohol, the more soluble ethyl ether hydrochloride remaining in solution while the di-adrenaline-ether dihydrochloride crystallized in clusters of thin rectangular prisms. The compound melted at $166-174^{\circ}$ without decomposition, forming a yellow oil. It was triturated in a mortar with 95% alcohol, filtered and washed several times with 95% alcohol; m. p., $172-180^{\circ}$. On further recrystallizing and washing, the compound melted sharply at $180-183^{\circ}$. The final yield of the pure product was 3 g., the remaining material being the ethyl ether described in the previous experiments.

Color Reactions.—With ferric chloride it gives a deep green which passes to a reddishviolet and then to a violet on standing or on addition of ammonia. With mercuric chloride and sodium acetate, it gives a grayish-blue precipitate which darkens on standing. With ammonia alone it forms a gray precipitate which dissolves in an excess of ammonia, giving a purple solution. It is precipitated by phosphotungstic and phosphomolybdic acids, forming a grayish-white precipitate. The ethyl and methyl ethers are not precipitated by these reagents.

Analyses. Subs., 0.2779: 13.8 cc. of 0.1 N HCl. Subs., 0.1185: CO₂, 0.2243; H₂O, 0.0678; Cl, 0.0199. Calc. for $C_{15}H_{26}O_{5}N_{2}Cl_{2}$: C, 51.29; H, 6.22; N, 6.68; Cl, 16.83. Found: C, 51.67; H, 6.35; N, 6.8; Cl, 16.87.

Preparation of the Hydrochloride of Methyl Ether of Racemic Adrenaline. (r-3,4-Dihydroxy-phenyl-methyl-ethanol-methylamine Hydrochloride.)—A solution of 11 g. of racemic adrenaline hydrochloride in 110 cc. of absolute methyl alcohol containing 7.3 g. (4 molecular equivalents) of dry hydrogen chloride was refluxed for 1 hour. The methyl ether crystallized immediately as the reaction mixture cooled, forming thin rectangular prisms. The crude compound melts at 172–173° with effervescence. It is very soluble in absolute methyl alcohol but less soluble in absolute ethyl alcohol. On recrystallization from 5 parts of absolute ethyl alcohol, it separated in white rectangular prisms similar to the ethyl derivative; m. p., 175° (corr.); yield, 3 g. or about 26%. This methyl ether gives the same color reactions as does the ethyl derivative.

Analyses. Subs., 0.2536: 10.7 cc. of 0.1 N HCl. Subs., 0.0978: CO₂, 0.1863; $\rm H_2O$, 0.0630; Cl, 0.0150. Calc. for $\rm C_{10}H_{16}O_2NCl$: C, 51.37; H, 6.90; N, 5.99; Cl, 15.18. Found: C, 51.94; H, 7.15; N, 5.95; Cl, 15.33.

An attempt to form the di-adrenaline ether by means of this reaction, even by heating at higher temperatures in a sealed tube, failed. Only the methyl ether was obtained.

² All combustions were made by the Dennstedt method.

Summary

Racemic adrenaline hydrochloride is readily converted into ethers in which the hydrogen of the secondary alcohol group is replaced by an alkyl group, by treating it with the corresponding absolute alcohol containing dry hydrogen chloride. The methyl and ethyl ethers have thus far been obtained and described. In the formation of the ethyl ether we have isolated as a by-product what appears to be di-adrenaline ether, formed by the condensation of 2 molecules of adrenaline with the elimination of 1 molecule of water from the 2 secondary alcohol groups.

THE ACTION OF SELENIUM OXYCHLORIDE UPON ETHYLENE, PROPYLENE, BUTYLENE AND AMYLENE¹

By Carl, E. Frick Received April 20, 1923

Preliminary experiments by Lenher² have shown that the oxychloride of selenium reacts with saturated paraffin hydrocarbons only very slowly at high temperatures, while with the unsaturated hydrocarbons of the aliphatic series, it unites directly, frequently with great evolution of heat. Mueller³ has reported that selenium oxychloride reacts with unsaturated hydrocarbons and ketones, producing substances that are very unstable in light and air. He gave no analytical results, however, nor any properties of the substances produced. The object of this investigation has been to make a quantitative study of the reactions taking place between selenium oxychloride and the olefins, ethylene, propylene, butylene and amylene; and to compare these reactions with those of selenium monochloride and the same olefins.

When selenium oxychloride reacts with ethylene, the dichloride of bis $(\beta$ -chloro-ethyl)selenide is always produced, regardless of whether the ethylene or the oxychloride is in excess during the course of the reaction. With selenium monochloride and ethylene, Boord and Cope⁴ have pointed out that this reaction takes place in two stages and that bis $(\beta$ -chloro-ethyl)selenide is produced when the ethylene is in excess, while the dichloride of bis $(\beta$ -chloro-ethyl)selenide is always formed when the monochloride is in excess.

⁴ Boord and Cope, This Journal, 44, 395 (1922).

Preparation of Materials

Selenium Oxychloride.—The method of Lenher⁵ was used, which consists in the union of selenium tetrachloride and selenium dioxide in a medium of carbon tetrachloride. The oxychloride was freed from carbon tetrachloride by fractionation and purified further by two distillations under reduced pressure.

The Olefins.—Ethylene and propylene were made by the method of Newth, 6 which consists in the dehydration of the corresponding alcohols with glacial phosphoric acid. isoPropyl alcohol was used in the preparation of the propylene. The best yields were obtained when the phosphoric acid was kept at a temperature of 210° in the case of the preparation of ethylene and at 360° in the case of the preparation of propylene. β -Butylene was prepared from N-butyl alcohol by the contact method of King. The catalyst used was pumice stone impregnated with glacial phosphoric acid. Temperatures from 280–400° gave practically the same yields of β -butylene. The γ -butylene was removed by bubbling the gaseous product through 60% sulfuric acid. The amylene was a commercial sample and was purified by the method improved and successfully used in connection with the course in Organic Chemical Manufacturing at the University of Illinois. This method worked very well and gave practically pure trimethylethylene, boiling at 36–38°. The yield was about 350 cc. per liter of crude amylene.

Experimental Part

In order to find out whether the same products were obtained in the interaction of selenium oxychloride and the olefins when the selenium oxychloride was added in excess, and when the olefin was in excess, two general procedures were used.

- 1. The olefin was passed into pure selenium oxychloride or a solution of it in an inert solvent, usually chloroform, until absorption of the olefin was completed. The reaction proceeded with evolution of heat and sometimes required cooling. When no more olefin was absorbed, the solvent was evaporated under diminished pressure, and the crude material was purified by crystallization from a suitable solvent. When a liquid product was obtained that could not be crystallized it was purified by fractional distillation under diminished pressure.
- 2. The selenium oxychloride in an inert solvent, usually chloroform, was dropped into an atmosphere of the olefin, in such a way that the latter was always maintained in excess throughout the course of the experiment. A 3-liter, Pyrex flask served as the reaction chamber and was fitted with a mercury-sealed glass stirrer, a dropping funnel, and an inlet and outlet tube for the olefin. The olefin was passed in until the air was displaced and the solvent saturated. The selenium oxychloride solution was then permitted to drop from the funnel at such a rate that the olefin was always maintained in excess. The reaction took place slowly, the walls of the flask becoming coated with selenium dioxide. After the

addition of a measured quantity of the oxychloride solution, the agitation was continued for a few minutes in the presence of the olefin and the operation interrupted. The reaction mixture was filtered rapidly by suction and the solvent evaporated under reduced pressure. The crude, oily product was purified by crystallizations from a suitable solvent or by fractional distillation under diminished pressure, as the nature of the product required.

Bis(β -chloro-ethyl)selenide Dichloride.—(1) Dry ethylene was passed into a solution of 83 g. (1 /2 mole) of selenium oxychloride dissolved in 200 cc. of anhydrous chloroform, until no more was absorbed. The ethylene was rapidly absorbed with evolution of heat, and a white, crystalline substance separated, clogging the inlet tube from time to time. The solution remained practically colorless; no reduction to selenium monochloride took place. (2) Two hundred cc. of a solution of selenium oxychloride in anhydrous chloroform, containing 85 g. of pure selenium oxychloride, was dropped slowly into an atmosphere of ethylene. A white, crystalline substance separated but more slowly than when the oxychloride was in excess.

The reaction mixtures were freed from the solvents by evaporation, the crude products purified by repeated crystallizations from chloroform or carbon tetrachloride, and dried at room temperature. Bis(β -chloro-ethyl)selenide dichloride was obtained in both cases, as long, white, prismatic crystals; m. p., 121.5°.

The product was analyzed for selenium by fusion of $0.2~\rm g$. of substance with 8–10 g. of a 1:1 mixture of anhydrous sodium carbonate and sodium peroxide. After fusion, the melt was dissolved with water, the solution acidified with hydrochloric acid and filtered. An excess of hydrochloric acid, sufficient to bring the concentration of the solution to $15~\rm to~20\%$ of hydrochloric acid, was added and the selenium precipitated from the hot solution by $25~\rm cc.$ of a saturated solution of sulfur dioxide. Chlorine was determined either by fusion in a similar manner, acidifying with nitric acid and titrating by the Volhard method, or by Stepanoff's³ absolute alcohol-sodium method.

Analyses. Calc. for $C_4H_8Cl_4Se$: C, 17.33; H, 2.91; Cl, 51.05; Se, 28.58. Found: C, 17.08, 16.97, 17.13; H, 2.91, 3.07, 3.30; Cl, 51.22, 51.49, 51.05; Se, 28.80, 28.45, 28.50.

When the crystals were dissolved in cold water it was found that partial hydrolysis had taken place. When a little nitric acid was added and the chlorine precipitated in the cold by silver nitrate, exactly $\frac{1}{2}$ of the total chlorine was precipitated.

Analysis. Total chlorine: 51.15. After hydrolysis in cold water only: 25.56.

This compound was first described by Heath and Semon, 10 who obtained it by passing ethylene into a solution of selenium monochloride. Their sample melted at 118° , and after they had made several analyses they came to the conclusion that it was symmetrical tetrachloro-diethyl selenide. About the same time, Bauser, Gibson and Pope, 11 making use of the same reaction, obtained a white, crystalline compound, slightly hygroscopic, melting at 122.5° . They showed by analysis that the compound was β - β '-dichloro-diethyl selenide dichloride, and that upon reducing this substance in water solution with sulfur dioxide, they obtained β - β '-dichloro-diethyl selenide as a colorless oil that solidified when cooled.

Because of this apparent disagreement in the results of these different workers, selenium monochloride was prepared by the method of Divers and Shimose, 12 and the reaction with ethylene duplicated. When ethylene was passed into the solution of

selenium monochloride in benzene, red selenium separated and a white substance crystallized. After purification by crystallization from benzene, the product was shown by analysis as well as by its melting point to be identical with the product obtained from ethylene and selenium oxychloride, which has been shown to be $bis(\beta$ -chloro-ethyl)-selenide dichloride.

Bis $(\beta$ -chloropropyl) selenide Dichloride.—(1) Dry propylene gas was passed into a solution of 85 g. of pure selenium oxychloride until absorption was completed. The propylene was rapidly absorbed with evolution of heat. A white, crystalline substance separated at once. (2) A solution of about 40 g. of selenium oxychloride in 183 cc. of anhydrous chloroform was allowed to drop slowly into an atmosphere of propylene. A white, crystalline solid settled in this case also.

The reaction mixtures were freed from the solvents by evaporation, the solid products purified by repeated crystallizations from petroleum ether, and dried at room temperature. Bis(β -chloropropyl)selenide dichloride was obtained in both cases as white, plate-like crystals resembling naphthalene, melting at 80°.

Analyses. Calc. for $C_6H_{12}Cl_4Se$: C, 23.60; H, 3.96; Cl, 46.48; Se, 25.95. Found: C, 23.43; H, 3.98; Cl, 46.43; Se, 25.67.

This compound has been prepared by Boord and Cope⁴ by passing propylene gas into an excess of selenium monochloride dissolved in benzene. They describe it as a white, crystalline compound melting at 81°.

Bis $(\beta$ -chlorobutyl) selenide Dichloride.—In an attempt to isolate bis $(\beta$ -chlorobutyl)-selenide dichloride, (1) dry β -butylene was passed into 85 g. of pure selenium oxychloride until absorption was completed. The butylene was rapidly absorbed with evolution of heat. A yellowish, viscous mass was obtained which was stable as long as the mixture was kept cooled in ice water. When the product was allowed to come to room temperature, red selenium separated and a dark, oily product remained. (2) A solution of 42 g. of selenium oxychloride in 183 cc. of anhydrous chloroform was dropped slowly into an atmosphere of β -butylene. A white, crystalline substance separated slowly (identified as selenium dioxide), and the solution became reddish-yellow. The chloroform was evaporated under reduced pressure and an oily substance remained. This crude product could not be induced to crystallize. It was decomposed by distillation even under strongly reduced pressure.

In several experiments, a small, dark red fraction was obtained, boiling at 104-108° under 68 mm. pressure.

Analyses. Calc. for $C_8H_{16}Cl_4Se$: Cl, 42.57; Se, 23.74. Calc. for $C_8H_{16}Cl_3Se$: Cl, 35.86; Se, 26.69. Found: Cl, 37.00, 37.08; Se, 26.70, 26.46.

The selenium content of this small fraction is near that required for the unsymmetrical β - β '-dichlorobutyl- β '-chlorobutyl selenide. It is improbable that this compound is one of the main products of the reaction; rather, it is present only in small amounts among the decomposition products. It is believed from observations made throughout the course of the reaction, that the dichloride of bis(β -chlorobutyl)selenide was formed whenever the temperature of the reaction mixture was kept below 10°. The formation of the same by-product, selenium dioxide, showed that the reaction proceeded in a manner similar to that of the reactions of ethylene and propylene with selenium oxychloride.

Boord and Cope⁴ were also unable to obtain the dichloride of $bis(\beta-chlorobutyl)$ selenide when using selenium monochloride and butylene.

Bis(β -chloro-amyl)selenide Dichloride.—In an attempt to prepare bis(β -chloro-amyl)selenide dichloride, (1) 35 g. (0.5 mole) of amylene dissolved in 200 cc. of anhydrous chloroform was added gradually to 83 g. (0.5 mole) of selenium oxychloride dissolved in 200 cc. of anhydrous chloroform. As soon as the two solutions were brought

together, selenium dioxide separated. After the reaction mixture had stood for 24 hours in a refrigerator, it was filtered and the chloroform evaporated under diminished pressure. (2) A solution of 83 g. (0.5 mole) of selenium oxychloride in one series of experiments, and 41.5 g. (0.25 mole) of selenium oxychloride in another series of experiments, each dissolved in 150 cc. of anhydrous chloroform, was allowed to drop slowly into 35 g. (0.5 mole) of amylene dissolved in 200 cc. of anhydrous chloroform and cooled to 0° in an ice-bath. Selenium dioxide separated at once, and after all of the selenium oxychloride solution had been added the selenium dioxide was separated and the chloroform evaporated under reduced pressure.

The crude products in each case did not crystallize, but underwent decomposition even under greatly reduced pressure. Selenium monochloride was identified as one of the liquid fractions, and there was obtained a small quantity of a pale yellow, almost colorless liquid; b. p., $85-100^{\circ}$ (atm.). The product was doubtless a mixture of amyl chlorides. Pure tertiary amyl chloride boils at 86° .

Analyses. Calc. for $C_{10}H_{20}Cl_4Se$: Cl, 39.29; Se, 21.92. Calc. for $C_5H_{11}Cl$: Cl, 33.28. Found: Cl, 33.40, 33.19; Se, none.

It is believed that the reaction proceeded in a manner similar to that of ethylene and propylene with selenium oxychloride, and that the dichloride of bis(β -chloro-amyl)-selenide was formed whenever the reaction mixture was kept below 10°. Selenium dioxide was identified as a by-product.

Boord and Cope⁴ were also unable to obtain the dichloride of $bis(\beta$ -chloro-amyl)-selenide, when using selenium monochloride and amylene.

Discussion of Results

These results show clearly that when selenium oxychloride reacts with the olefin hydrocarbons, the dichlorides of the corresponding alkyl selenides, are always produced regardless of whether the olefin or the oxychloride are in excess during the course of the reaction. Selenium dioxide has been identified as the by-product in every case, and since no selenium monochloride or selenium is produced, the reaction may be expressed as follows: $2C_nH_{2n} + 2Cl_2SeO = (Cl C_nH_{2n})_2Se Cl_2 + SeO_2$.

It is interesting to compare the above equation with the one given by Boord and Cope⁴ for the interaction of selenium monochloride and the oelfins when the selenium monochloride is in excess: $2 C_n H_{2n} + 2 Cl_2 Se = Se = (ClC_n H_{2n})_2 SeCl_2 + 3 Se$. Boord and Cope give the mechanism of this latter reaction as evidence in favor of the unsymmetrical structure for selenium monochloride. The similarity of the two preceding equations as written, and the results obtained in the syntheses described in this paper, are offered as still further evidence of the correctness of the unsymmetrical formula for selenium monochloride. Boord and Cope have given the credit for the suggestion of this formula to Konek-Norwall¹³ but it appears that Divers and Shimose, ¹⁴ nearly 30 years earlier, gave its formula as $Se = SeCl_2$, and to them, therefore, should be given the credit for suggesting this unsymmetrical structure.

¹³ Konek-Norwall, Oesterr. Chem. Ztg., 16, 288 (1913).

¹⁴ Ref. 12, p. 194.

The author wishes to express his appreciation to Professor Victor Lenher, at whose suggestion and under whose direction this work was carried out.

Summary

- 1. The reactions between selenium oxychloride and ethylene, propylene, butylene and amylene have been studied.
- 2. The mechanism of the reaction between selenium oxychloride and the olefins has been formulated and has been compared with that of selenium monochloride and the olefins.
- 3. It has been shown that with selenium oxychloride and the olefins, the dichlorides of the corresponding alkyl selenides are always formed regardless of whether the oxychloride or the olefin is in excess during the course of the reaction.
- 4. It has been shown that the final reaction products of selenium monochloride and the olefins are identical with those formed by the interaction of selenium oxychloride and the olefins.
- 5. The results obtained in these syntheses have been offered as further evidence in favor of the unsymmetrical structure for selenium monochloride.

THE ACTION OF SELENIUM OXYCHLORIDE ON PURE RUBBER 1

By CARL E. FRICK Received April 20, 1923

In the studies on the oxychloride of selenium which have been in progress in this Laboratory, Lenher² has shown that pure rubber, vulcanized rubber and vulcanite react chemically with selenium oxychloride. It seemed advisable to undertake a quantitative study of this reaction, if possible, as any information would be interesting in view of our incomplete knowledge of the nature of the rubber hydrocarbon. The products obtained by the action of selenium oxychloride on 2 wild, and 2 plantation rubbers, and a synthetic rubber prepared from isoprene, were investigated.

Preparation of Materials

Selenium Oxychloride.—The method of Lenher³ was used.

Pure Rubber Hydrocarbon.—Samples4 of crude, unworked rubber were washed

¹ This paper is constructed from a part of a thesis submitted by the author to the Graduate School of the University of Wisconsin in partial fulfilment of the requirements for the degree of Doctor of Philosophy, January, 1923.

² Lenher, This Journal, 43, 29 (1921).

³ Lenher, ibid., 42, 2498 (1920).

⁴ These samples were kindly furnished by Dr. W. C. Geer of the B. F. Goodrich Co. and Prof. H. E. Simmons of the University of Akron.

in frequent changes of water until dirt and soluble impurities were removed, dried, and freed from resins by extraction with boiling acetone for 24 hours. The residue was freed from acetone and the rubber hydrocarbon dissolved in pure carbon tetrachloride. The undissolved protein was filtered off and the rubber precipitated by absolute alcohol. The sample was freed from alcohol, redissolved in carbon tetrachloride, reprecipitated by alcohol 7 times, and finally redissolved and kept in pure carbon tetrachloride. The following natural rubbers were used in this study: Upriver, fine, hard Para; first latex Pale Crepe; Upper Caucho Ball; and ribbed Smoked Sheet.

Synthetic "Isoprene Rubber."—This was prepared from pure isoprene by the well-known method discovered practically simultaneously by Mathews⁵ in England and Harries⁶ in Germany, using metallic sodium to effect the polymerization. The rubbery mass was washed with acetone, dissolved in carbon tetrachloride, reprecipitated by alcohol, redissolved and reprecipitated several times, and thus purified in exactly the same manner as the natural rubbers. The sample was finally redissolved and kept in pure carbon tetrachloride.

Isoprene.—The isoprene was prepared from dl-limonene (dipentene) by passing the vapors over an electrically-heated platinum wire, using the principle of Harries' isoprene lamp. The limonene was obtained from washed orange oil, which was over 96% pure limonene. The crude isoprene was freed from any contained amylene by allowing it to stand for several days in contact with barium dioxide, dried with fused calcium chloride and distilled, then dried with metallic sodium and redistilled, using a Vigreaux fractionation column. Ostromuislinskii's method of purification by forming the tetrabromide and then removing the bromine by treatment with zinc dust at 0° in absolute alcohol solution was found to be impractical when it was desirable to prepare a liter or more of pure isoprene. The material was colorless; b. p., 33.2–33.8° (742 mm.).

Solvents.—Acetone was freshly distilled over anhydrous potassium carbonate, and the fraction boiling at 56-57° used. Carbon tetrachloride was purified by treatment with saturated chlorine water for several days in diffused sunlight. It was then washed thoroughly with distilled water, dried over fused calcium chloride and distilled.

Experimental Part

When crude rubber, vulcanized rubber or even vulcanite is placed in selenium oxychloride a vigorous reaction sets in and the rubber is dissolved with evolution of heat. The solution becomes reddish brown in color and contains selenium monochloride and selenium, in addition to the decomposition products of the rubber. In order to study this reaction, it became evident at once that the reaction would have to be more carefully controlled and further that the results would be the easier to interpret, the purer the samples of rubber used. The reactions of selenium oxychloride on the purified rubber hydrocarbon in solution in carbon tetrachloride, were carried out in all cases as follows.

To a known quantity of a 5% solution by weight of pure rubber in dry carbon tetrachloride, cooled to 0° , was added slowly, with vigorous stirring, an excess of a 5% solution of selenium oxychloride in dry carbon tetrachloride, also cooled to 0° . The selenium oxychloride was added in slight

excess as otherwise the solution could not be filtered because the excess of rubber clogs the filter. A yellowish-white, amorphous substance immediately settled. The solution was filtered quickly through a Büchner funnel, the precipitated material transferred to a beaker containing cold carbon tetrachloride and agitated in order to free the material from the slight excess of selenium oxychloride. This operation was repeated several times using fresh portions of cold, dry carbon tetrachloride. The precipitated material was finally brought onto the filter paper and the carbon tetrachloride replaced by ethyl ether. The ether was quickly evaporated, the dry, amorphous powder transferred to a glass-stoppered weighing bottle and this container kept at 0°. Due to its instability at ordinary room temperatures and the consequent evolution of hydrogen chloride, the material had to be handled in this way. This instability also prevented further purification of the material by any of the usual methods.

Table I shows the comparative results based on the averages of all of the complete analyses of the various reaction products of selenium oxychloride with the natural rubbers and the synthetic isoprene rubber

Table I

Average Analyses⁹ of the Products of the Reaction between Rubber and Selenium Oxychloride

	SeOCl ₂ reaction products with	C %	н %	Se %	C1 %	(Diff.) %	Ratio C: H
	"Isoprene Rubber"	23.72	4.67	22.57	23.79	25.25	10:23.3
	Pale Crepe	23.75	4.37	22.81	24.23	24.84	10:22.3
	Smoked Sheet	21.60	4.66	27.04	24.69	22.01	10:26.0
	Para	23.85	4.42	26.74	26.03	18.96	10:22.1
	Caucho Ball	24.49	4.37	26.09	25.35	19.70	10:21.1

Discussion

Attention is called to several points brought out in this table. (1) It will be noted that the average content of carbon in the various reaction products of either synthetic rubber from isoprene, or the natural rubbers, varies less than 1%, except in the case of the product from Smoked Sheet, which is about 2% lower. (2) The average contents of hydrogen in the various reaction products vary less than 0.4 of 1%. (3) The average content of selenium in the synthetic isoprene-rubber product is practically the same as in the plantation Pale Crepe product. The amount of selenium in reaction products of the other 3 natural rubbers, varies only within 1%, but all are 4 to 5% higher than in the case of the Pale Crepe or the synthetic isoprene rubber. It will be noted, however, that the products from all 3 of the natural rubbers in which the latex was coagulated by smoke have a selenium content of 26 to 27%. The Smoked Sheet comes from

⁹ The "average analyses" are the means of the results of 10 to 12 determinations on different samples of the same material handled under as nearly the same conditions as possible. The average analysis for each constituent is accurate to at least 1%.

exactly the same source as the Pale Crepe (cultivated *Hevea brasiliensis*), but the latex of Pale Crepe is coagulated by acetic acid, while the latex of Smoked Sheet is only partially coagulated by acetic acid and is then smoked to complete the process. Possibly this difference in the selenium content of the 2 reaction products can be attributed to the method of coagulation. (4) The average content of chlorine in the various reaction products from either the synthetic or the natural rubber varies about 2.2%. (5) The ratio of carbon to hydrogen has changed from C₁₀H₁₆ in the pure rubber, up to C₁₀H₂₆ in the reaction products. (6) Parallel with the chemical changes in the various kinds of rubber upon treatment with selenium oxychloride, there is a great change in their physical properties. The products are all amorphous powders, having lost their elasticity and swelling power, and are insoluble in the ordinary rubber solvents, such as benzene, carbon tetrachloride, chloroform and ether. (7) The two most important conclusions that can be drawn from the comparative data on these reaction products are: (a) the pure rubber hydrocarbon from natural, *Hevea* rubbers, shows a slightly different behavior in its reaction with selenium oxychloride, depending upon the source of the rubber and its method of coagulation; (b) judging by the behavior towards selenium oxychloride, there is no difference in empirical composition between the pure rubber from a typical natural rubber, such as Pale Crepe, and a synthetic rubber, made by the polymerization of isoprene by metallic sodium. This statement is in contradiction to the recent article of Kirchof. 10 Kirchof has compared the ultimate analyses that have been made on the rubber hydrocarbon from different sources and also the analyses of the various derivatives that have been reported. He concluded that synthetic rubber is a true polymer of the corresponding hydrocarbon, C₅H₈, but that the hydrocarbon of Para rubber has the empirical composition C₁₀H₁₇ and cannot be formed from the hydrocarbon C5H8 through polymerization, as Harries supposed. According to Kirchof, neither the empirical composition nor the structure of synthetic rubber is identical with that of Para rubber.

The present work tends to support the conclusion that Harries reached after a study of the hydrolysis products of the ozonides of various kinds of natural and synthetic rubbers, namely, that there is no essential difference in constitution between natural rubber and the polymerized isoprene.

The author wishes to express his appreciation to Professor Victor Lenher, at whose suggestion and under whose direction this work was carried out; also to Professor Homer Adkins for helpful suggestions.

Summary

1. The reactions between selenium oxychloride and the natural, *Hevea* rubbers, Pale Crepe, Smoked Sheet, Para and Caucho Ball, have been studied.

¹⁰ Kirchof, Kolloidchem. Beihefte, 16, 47 (1922).

- 2. The reaction between selenium oxychloride and a synthetic rubber made by polymerizing isoprene has been studied.
- 3. It has been found that when the various rubbers are treated with selenium oxychloride their physical properties are changed. The products are all amorphous powders, having lost their elasticity and swelling power, and are insoluble in the ordinary solvents for rubber.
- 4. It has been shown that the pure rubber hydrocarbon from natural, *Hevea* rubbers, shows a slightly different behavior in its reaction with selenium oxychloride, depending upon the source of the rubber and its method of coagulation.
- 5. It has been shown definitely that, judging by their respective behaviors towards selenium oxychloride, there is no difference in empirical composition between the pure rubber hydrocarbon from the Hevea tree and the synthetic rubber made by polymerizing isoprene with metallic sodium.

DIPROPARGYL METHYLENE ETHER

By Herbert H. Guest Received April 21, 1923

The statement has been made by Delange¹ that "as a rule, acetylenic linkages produce unpleasant odors.* * * *An exception is methylheptine carboxylate." Apparently, the acetylenic linkage adjacent to an alcoholic group forms another exception of Delange's generalization. For example,³ octin-2-ol-1 has a much pleasanter and more intense odor than octanol. Also,⁴ 2-methylhexin-3-ol-2 has a very pleasant, flower-like odor. Finally, it is well known that propargyl alcohol itself possesses a pleasant odor.

It seemed of interest, therefore, to prepare a number of alcohols having the triple bond in the α position to the hydroxyl group and compare their odors with those of the corresponding saturated alcohols.

The only method so far available for the preparation of these alcohols is that of Moureu and Desmots³ which depends upon the action of trioxymethylene on the sodium derivative of acetylene hydrocarbons. Unfortunately, the latter are not easily obtainable and, moreover, the yield of alcohol is very poor.

This paper describes the attempt to prepare these alcohols by the alkylation of the metallic derivatives of the methylal of propargyl alcohol.

³ Moureu and Desmots, ibid., [3] 27, 361 (1901).

⁴ Dupont, Compt. rend., 148, 1524 (1909).

This acetal was readily obtained by a method that parallels that of Claisen⁵ for the preparation of propargyl-aldehyde acetals, such as CH: C.CH- $(OCH_3)_2$. The starting point is β -dibromohydrin⁶ which was readily converted into the corresponding acetal. The latter loses 2 molecules of hydrobromic acid on treatment with alcoholic potash to form the acetal of propargyl alcohol: $CH_2Br.CHBr.CH_2OH \longrightarrow (CH_2Br.CHBr.CH_2O)_2-CH_2 \longrightarrow (CH: C.CH_2O)_2CH_2$.

It was hoped that the magnesium-bromide compound, $(MgBrC: C-CH_2O)_2CH_2$, would react with alkyl bromides in a manner analogous to that observed by Grignard⁷ in the preparation of phenylethyl alcohol from phenylmagnesium bromide and glycol chlorohydrin. The action of ethylmagnesium bromide on the acetylenic acetal proceeded normally with a steady evolution of ethane. After some hours or when the ethereal solution was warmed to complete the reaction, a product was formed which was insoluble in ether or benzene. This resinous material has not been identified and is probably the inter-reaction product of 2 or more molecules, in the manner observed by Tschitschibabin and Jelgasin⁸ who found that acetals are acted upon by Grignard reagents to form ethers. When the reaction was stopped before this insoluble substance was produced and alkyl bromide added to the cold mixture, alkylation did not take place.

The silver compound (AgC: C.CH₂O)₂CH₂ was readily obtained but proved to be exceedingly inert. For example, prolonged boiling with excess of butyl bromide failed to give the desired butyl acetal. This result is in harmony with the observation of Reitzenstein⁹ as to the inertness of the silver derivative of the acetal of propargyl aldehyde, AgC: C.CH(OCH₃)₂.

Metallic sodium did not react readily with the acetal of propargyl alcohol and when it was heated for a long time with sodium in toluene suspension a yellow solid was obtained which was not the normal reaction product of acetylenes and sodium.

Experimental Part

Bis(2,3-dibromopropyl)methylene Ether, (CH₂Br.CHBr.CH₂O)₂.CH₂.—Into 342 g. of dibromohydrin dry hydrogen chloride¹⁰ was led until the weight of the mixture had increased 3.5 g.; 135 g. of paraformaldehyde was added and the mixture was allowed to stand at room temperature for 6 days. Ether was added and the excess of paraformaldehyde removed by filtration. The ethereal solution was dried over sodium carbonate. On distillation at 10 mm. pressure, a fraction boiling at 118° to 170° was collected, weighing 76 g., which consisted mostly of unaltered dibromohydrin, and a second fraction boiling at 170–235° which on redistillation gave 195 g. boiling at 220° under 7 mm. pressure. This yield of acetal corresponds to 55%.

Analysis. Subs., 0.3715: AgBr, 0.6218. Calc. for C₇H₁₂O₂Br₄: Br, 71.43. Found: 71.23.

This acetal was also prepared by the catalytic action of ferric chloride, 11 as follows: 75 g. of dibromohydrin, 25 g. of trioxymethylene and 3.5 g. of sublimed ferric chloride were mixed and heated at $125-150^{\circ}$ for 2 hours. When the product was treated as in the previous case, 18 g. of unaltered dibromohydrin and 42 g. of acetal were obtained, duplicating the percentage yield. Finally, the same results were obtained by the use of dry calcium chloride as catalyst to the extent of 20% of the weight of dibromohydrin taken.

This acetal is a viscous oil, insoluble in alcohol but soluble in ether or benzene.

 $Bis(\alpha\text{-bromo-allyl})$ methylene Ether, $(CH_2: CBrCH_2O)_2CH_2$.—This compound was obtained from the dibrompropyl acetal by the action of a slight excess of finely powdered potassium hydroxide in ether suspension, at a temperature below 25°. The reaction product was treated with water, the oil in ethereal solution dried over calcium chloride and distilled at 10 mm. pressure. On repeated redistillation an oil was obtained, b. p., $135-140^{\circ}$ at 10 mm. pressure, which was soluble in organic solvents.

Analysis. Subs., 0.2773: AgBr, 0.3680. Calc. for $C_7H_{10}O_2Br_2$: Br, 55.9. Found: 56.48.

Dipropargyl Methylene Ether, (CH: $C.CH_2O)_2CH_2$.—To 4 molecular proportions of potassium hydroxide dissolved in 4 times the weight of 95% alcohol and cooled to $25-30^\circ$, one molecular equivalent of the dibromopropyl acetal was gradually added and the mixture kept cold. After $^1/_2$ hour at room temperature, this was heated under a reflux condenser on the steam-bath for 2 to 3 hours. The salt was separated on a filter by suction, the alcoholic filtrate made neutral with acetic acid and then the alcohol removed by distillation under diminished pressure at a low temperature. The residue was poured into water and the oil (400 g.) dissolved in ether, dried over sodium carbonate and distilled at 10 mm. pressure. Fraction 1, b. p. 70–100°, amounted to 98 g.; Fraction 2, b. p. 100–140°, weighed 57 g. and the residue weighed 5 g.

Fraction 1 was redistilled at 10 mm. pressure and the high-boiling portion added to Fraction 2. The united high-boiling fractions were then treated with alcoholic potassium hydroxide as before. On final distillation 56 g. of an oil was obtained which boiled at $75-80^{\circ}$ under 10 mm. pressure and at 162° under 760 mm. pressure; yield, 50%. This oil was free from halogen.

Analyses. Subs., 0.2325: H₂O, 0.1340; CO₂, 0.5730. Calc. for C₇H₈O₂: C, 67.74; H, 6.45. Found: C, 67.22; H, 6.45.

SILVER SALT (AgC: C.CH₂O)₂CH₂.—To a solution of 2 molecular proportions of silver nitrate in a small amount of water and much alcohol, ammonium hydroxide was added by drops until the precipitate that first formed redissolved. One molecular equivalent of acetal dissolved in alcohol was then added, and a white granular precipitate formed at once. This was separated by filtration with suction and washed with alcohol and ether. When dried at 60°, it turned brown; it exploded at 110°. It is insoluble in ammonium hydroxide, alcohol, ether or water.

Analysis. Subs., 0.1825: AgCl, 0.1545. Calc. for C₇H₆O₂Ag₂: Ag, 63.9. Found: 63.71.

This silver salt, while still moist, was added to an ethereal solution of a large excess of butyl bromide. The mixture was heated for 5 to 6 hours under a reflux condenser. As the appearance of the insoluble material did not change, the ether was removed, more butyl bromide added and the whole heated for 5 hours longer. The insoluble material

¹¹ Trillat and Cambier, Bull. soc. chim., [3] 11, 757 (1894).

¹² Compare Adkins and Nissen, This Journal, 44, 2749 (1922).

was removed by filtration and the filtrate distilled. The latter proved to be unaltered butyl bromide.

Action of Grignard Reagent on Acetal.—To a Grignard solution made from 50 g. of ethyl bromide was added gradually at 5–10° an ethereal solution of dipropargyl methylene ether. Ethane was evolved steadily and was collected and tested. After 24 hours outdoors, two layers formed in the liquid. To this mixture was then added 50 g. of butyl bromide, and the whole heated for 3 hours under a reflux condenser; dry toluene was then added and the ether removed. The heating was continued for 1 hour longer. No magnesium bromide separated. The reaction mixture was then treated with dil. sulfuric acid, and the upper layer dried and distilled. After removal of the solvent, no oil was obtained. The residue, which was insoluble in solvents, could not be resolved into any individual product.

This experiment was repeated several times under various conditions, but so far unsuccessfully.

Summary

- 1. Dipropargyl methylene ether was prepared from the acetal of β -dibromohydrin.
- 2. It was found that the silver derivative of dipropargyl methylene ether did not react with alkyl halides under the conditions indicated.
- 3. Dipropargyl methylene ether reacts with ethylmagnesium bromide but the resulting reaction product did not aid in the synthesis of the higher homologs of propargyl alcohol.

OBSERVATIONS ON THE PROPERTIES OF ARSPHENAMINE¹

By Walter G. Christiansen Received April 26, 1923

The Relation of Arsphenamine to Some Methyl Ketones

In connection with an investigation of the ease of solution of arsphenamine in water, samples were precipitated from methyl alcohol solution by acetone instead of ether. Analytical data on material precipitated in this way confirm the conclusion of Fargher and Pyman² that the product contains 1 molecule of acetone in addition to the usual 2 molecules of water.

Calc. for $C_{12}H_{14}O_2N_2Cl_2As_2.2H_1O.(CH_3)_2CO$: As, 28.2; Cl, 13.3. Found: As, 28.1; Cl, 13.1.

Prolonged drying in a vacuum removes the 2 molecules of water but the acetone remains unchanged;² when the material is dried to constant

¹ This is the twelfth of a series of studies on the properties contributing to the toxicity of arsphenamine being made under a grant from the United States Interdepartmental Social Hygiene Board to the Harvard Medical School; the work is under the general direction of Dr. Reid Hunt.

² Fargher and Pyman, J. Chem. Soc., 117, 372 (1920).

weight at about 98° in a slow stream of dry carbon dioxide the loss is that calculated for 2 molecules of water and the dried product gives a strong qualitative test for acetone.

Calc. for 2 H₂O: H₂O, 6.7. Loss at 98°: 6.1.

Moreover, when arsphenamine containing a molecule of acetone is dissolved in absolute methyl alcohol and reprecipitated with ether, the dried product still gives a very positive test for acetone. Since neither drying or reprecipitation from acetone-free solvents removes the acetone, the latter must be bound very firmly to the arsphenamine molecule and is not retained mechanically. In view of this strong union, one would expect that if a small amount (0.5 cc.) of acetone be added to a methyl alcohol solution of arsphenamine (1 g. in 8 cc. of methyl alcohol) before the latter is poured into ether, the product, after it is washed and dried, would contain acetone; this has been found to be true. In similar experiments using methylethyl, methyl-n-propyl, methyl-n-butyl, and methylisobutyl ketone, instead of acetone, the products always give positive tests for methyl ketone.

From the work described above it is evident that arsphenamine possesses a strong affinity for methyl ketones. The tests for ketones were made by testing with alkali and iodine the first portions of the distillate of a 5% aqueous solution of the arsphenamine.

The Conversion of Arsphenamine Into a Polyarsenide

The reduction of a mixture of 2 different aryl arsonic acids or the digestion of a mixture of 2 symmetrical aryl arseno compounds always results in the formation of 1 unsymmetrical arseno compound. Also, when an arsonic acid is reduced in the presence of an inorganic arsenical, an organic polyarsenide, such as Ar₂As₄, is formed instead of a mixture of ArAs = AsAr and metallic arsenic. It has now been found that an arseno compound in the presence of nascent arsenic changes to a polyarsenide.

A solution of 0.2 g. of arsphenamine in 3.2 cc. of water is treated with 2.4 cc. of 50% hypophosphorous acid, 0.4 cc. of hydrochloric acid (d., 1.19) and 3.2 cc. of an aqueous solution of sodium arsenite (1 g. of NaAsO₂ in 16 cc. of solution). The pale yellow solution, in a stoppered cylinder, is allowed to st and at room temperature in the dark; it becomes orange colored, and then red; turbidity sets in and finally a precipitate forms. When the material stands long enough, the solution becomes colorless and the orange-colored precipitate becomes covered by a black layer of metallic arsenic. Before this stage is reached, the mixture of orange-colored solid and solution is poured into 2 volumes of 1 to 1 cold hydrochloric acid and the solid is washed with acid and dried in a vacuum over sodium hydroxide. From 1.3 g. of arsphenamine, 1.7 g. of a red polyarsenide of arsphenamine is obtained.

Analysis. Calc. for C₁₂H₁₄O₂N₂Cl₂As₄: As, 50.9. Found: 52.5.

When a mixture of 3-amino-4-hydroxyphenyl-arsenious oxide and sodium arsenite in aqueous solution containing hydrochloric acid, is reduced with hypophosphorous acid and the polyarsenide isolated as described above, a red solid is obtained which contained 53.7% of arsenic and dissolves in water to give a red solution.

The rate of polyarsenide formation as determined by the color change and appearance of turbidity varies greatly depending upon the method of preparation of the arsphenamine. The following methods are arranged in the order in which resulting arsphenamine undergoes polyarsenide formation with decreasing speed: (1) reduction of 3-nitro- or 3-amino-4-hydroxyphenylarsonic acid with pure hydrosulfite; (2) reduction of the nitro acid to toxic arsphenamine with commercial hydrosulfite; (3) reduction of the amino acid or the nitro acid to relatively non-toxic arsphenamine with commercial hydrosulfite; (4) reduction of the amino acid with hypophosphorous acid followed by precipitation with hydrochloric acid.

When a sample which gives the polyarsenide reaction quite rapidly is allowed to stand in aqueous solution with a small amount of hydrochloric acid, the viscosity of the solution increases and the rate at which it is converted into a polyarsenide decreases. Also, when a specimen of arsphenamine base which gives a polyarsenide fairly rapidly is converted into the dihydrochloride the latter gives a polyarsenide less rapidly than the original base. It seems that the rate at which this reaction takes place is closely connected with the degree of polymerization³ of the arsphenamine.

The Precipitation of Dilute Aqueous Solutions of Arsphenamine with Hydrochloric Acid

During the investigation of the reduction of 3-nitro-4-hydroxyphenylarsonic acid to arsphenamine base with commercial hydrosulfite, it was
shown that the conditions under which the nitro group is reduced exert a
great influence on the toxicity of the product; and two sets of conditions
were developed, one of which favored the formation of toxic products
whereas the other enabled one to obtain products of low toxicity. In
both procedures the quantities of reagents are identical. Mr. George, of
this Laboratory, has examined the action of precipitants on dilute aqueous
solutions of a number of samples of arsphenamine and finds that the amount
of hydrochloric acid required to precipitate a solution of a specimen prepared under the conditions most favorable to the development of low toxicity is nearly twice as great as that required for the toxic specimen prepared under the other procedure.

Two-tenths cc. of a 2% solution of alkalinized arsphenamine, that is, one containing the disodium salt of arsphenamine, is diluted with 1 cc. of water in a 7 cc. test-tube which is then placed in a water-bath at 37°. Hydrochloric acid (1:1) is added from a small buret until a permanent precipitate is secured. All specimens prepared under the most favorable conditions require 1.95 cc. of acid and those prepared under the least favorable conditions require only 1.12 cc.

When marked changes are made in the preparation of the arsphenamine, such as changes in the acidity of the reduction mixture, the hydrochloric

³ Sherndal, J. Lab. Clin. Med., 7, No. 12 (1922).

acid titration fluctuates greatly from the values given above. Since the amount of hydrochloric acid is constant only when every detail of the preparation of the arsphenamine is exactly duplicated each time, this titration is a rapid way to detect variations in the routine preparation of this material, and specimens giving a low precipitation value should be carefully examined toxicologically.

The precipitation of arsphenamine from aqueous solutions with hydrochloric acid is a salting-out process and involves the coagulation of the finely divided arsphenamine particles in the original solution. Since the less toxic specimens require more acid than the relatively toxic ones, the arsphenamine is in a more finely divided state in the less toxic solutions. This difference in the state of division may account for some of the unfavorable results encountered in the more toxic material.

The Importance of the Quantity of Hydrochloric Acid Used in Converting Arsphenamine Base into the Hydrochloride

In the common method of converting arsphenamine base into the hydrochloride the base is dissolved in methyl alcoholic hydrochloric acid and this solution is mixed with a large amount of ether to precipitate the arsphenamine. The quantity of hydrochloric acid used in this process has considerable bearing on the physical properties of the resulting arsphenamine. If only 1 molecule of acid per molecule of base is used, the alcohol solution is dark colored; in extreme cases, as when the nitro acid has been reduced improperly, the color may be reddish-brown. As more acid is added, the color changes gradually to a clear yellow. The dark colored solution of the monohydrochloride, poured into ether, gives a gummy and dark colored precipitate; part of the solid remains suspended in the ether and cannot be filtered out easily. When more methyl alcoholic hydrochloric acid is added to the ether suspension, the precipitate coagulates and settles at once. When a solution of the base in methyl alcohol containing 2 or a fraction more molecules of hydrochloric acid is poured into ether, the yellow precipitate coagulates at once and the supernatant liquor is perfectly clear. In order to secure the desired yellow color and to obtain a precipitate that can be manipulated easily it is advisable to use a slight excess of acid over that necessary to form the dihydrochloride.

The amount of acid used in preparing the hydrochloride has very little bearing upon the toxicity and sulfur content of the product. It has been noted, however, that material made with less than 2 molecules of acid produces death more quickly than material prepared with an excess of acid, when administered in fatal doses to rats.

I wish to thank Dr. Reid Hunt for his interest in this work, and Mr. Arthur Norton for preparing the higher methyl ketones.

Summary

Arsphenamine forms additive compounds with methyl ketones in which the ketone is bound very firmly. Neither drying at room temperature or at 98°, nor reprecipitation from ketone-free methyl alcohol with ether removes the ketone. When an aqueous solution of arsphenamine and sodium arsenite is treated with hydrochloric and hypophosphorous acids. the yellow color gradually changes to red and a polyarsenide of arsphenamine is formed. The rate at which this reaction takes place depends upon the method used in preparing the arsphenamine and seems to be related to the physical properties of the latter. The quantity of 1 to 1 hydrochloric acid necessary to precipitate a dil. aqueous solution of arsphenamine is constant when one method of preparation is strictly followed, but slight variations in certain steps in the synthesis cause fluctuations in the amount of acid required. Therefore, this titration has been found useful in determining the closeness with which the routine method of preparation has been followed. The physical properties of arsphenamine are affected materially by the amount of hydrochloric acid used in converting the base into the hydrochloride; it is advantageous to use a slight excess over the two molecules needed to secure the dihydrochloride.

Boston 17, Massachusetts

[Contribution from the Department of Chemical Research, Parke, Davis and Company, No. 18]

5,5-DIARYLBARBITURIC ACIDS

By Arthur W. Dox and Adrian Thomas Received April 30, 1923

Considering the great importance of veronal (diethylbarbituric acid) and luminal (phenylethylbarbituric acid) as therapeutic agents, and the large number of homologs that have been prepared by substituting other alkyl groups, it is surprising that no attempts to prepare 5,5-diarylbarbituric acids are on record. Luminal, in which one of the ethyl groups of veronal has been replaced by phenyl, is said to be 2.5 times as powerful in its physiological action as veronal, and is widely used in the treatment of epilepsy. The introduction of a second phenyl group might be expected to increase the physiological activity still further, provided the resulting derivatives possessed certain essential physical properties. The isomeric 1,3-diphenylbarbituric acid has been prepared by Whiteley¹ from malonyl chloride and carbanilide. No statement is made regarding its physiological properties, but from analogy with other N-substituted barbituric acids, we should hardly expect this substance to be of medicinal value.

The substitution of one or more aryl groups on the 5-carbon atom of Whiteley, J. Chem. Soc., 91, 1330 (1907).

barbituric acid is much more difficult than the substitution of alkyl groups. Some of the more reactive alkyl halides, such as allyl bromide² and benzyl chloride,³ react directly with barbituric acid or a mono-alkyl substituted barbituric acid. Other alkyls, as ethyl and its homologs, must be introduced in a previous step of the synthesis, as in the alkylation of an alkyl malonate before condensation with urea. An aryl halide, on the other hand, cannot be made to react with an alkyl malonate. The aryl group, in luminal, for example, is added in a still earlier step of the synthesis. The addition of a second aryl would naturally be attended by further complications.

The most satisfactory method for the preparation of 5,5-dialkylbarbituric acids is the condensation of an ester of the corresponding dialkylmalonic acid with urea.⁴ An ester of a diarylmalonic acid might, therefore, be expected to condense with urea in the same manner. The simplest derivative of this type, methyl diphenylmalonate, was prepared by Staudinger, Göhring and Schöller,⁵ from the acid chloride obtained by treatment of diphenylketene with oxalyl chloride. Obviously, this method is too costly to be of practical importance.

Several alkyl diarylmalonates have been prepared by Guyot and Esteva⁶ by condensing aromatic hydrocarbons with alkyl oxomalonates in the presence of concd. sulfuric acid. In this reaction water is split out and 2 products are formed, an alkyl aryltartronate and an alkyl diarylmalonate, the amount of the latter depending upon the temperature and time of reaction. Guyot and Esteva describe the methyl and ethyl esters of ditolyl- and di-o-xylylmalonic acids. The lower homolog, diphenylmalonic ester, they evidently did not succeed in obtaining, although the methyl and ethyl esters of phenyltartronic acid are mentioned.

By the method of Guyot and Esteva the writers succeeded in preparing ethyl diphenylmalonate, but all attempts to condense this with urea were unsuccessful. The substance appears to lack the stability of the dialkylmalonic esters, and when treated with sodium ethylate and urea it readily loses a carboxyl group. No evidence of the formation of a diphenylbarbituric acid was obtained; the only products identified were diphenylacetamide and diphenylacetic acid. Likewise, ethyl di-ptolylmalonate, prepared by the same method, gave only the corresponding acetamide and the substituted acid. However, the diphenylmalonic esters are apparently more stable when an hydroxyl is present on the benzene nucleus. Thus, from ethyl di-(p-hydroxyphenyl)malonate we obtained by the usual method, di-(p-hydroxyphenyl)barbituric acid.

³ Dox and Yoder, This Journal, 44, 1144 (1922).

⁴ Fischer and Dilthey, Ann., 335, 334 (1904).

⁵ Staudinger, Göhring and Schöller, Ber., 47, 43 (1914).

Guyot and Esteva, Compt. rend., 148, 564 (1909).

This is the first diarylbarbituric acid containing 2 aromatic hydrocarbon radicals attached directly to the 5-carbon atom. It is isomeric with 5,5-diphenoxybarbituric acid in which the aryl groups are joined to the pyrimidine nucleus through oxygen.

Experimental Part

Ethyl Diphenylmalonate.—Ethyl oxomalonate was prepared by oxidation of ethyl malonate with nitrous anhydride. Thirty g. of this product was dissolved in 90 g. of anhydrous benzene, and 60 g. of concd. sulfuric acid added. The sulfuric acid layer became purplish-blue and some heat was developed. The flask was then immersed in an oil-bath at 70° and the mixture mechanically stirred for 7 hours, after which it was poured on cracked ice and the sulfuric acid removed by agitation with several lots of water. The excess of benzene was removed by distillation, and the residue distilled in a vacuum. The main product consisted of 17.5 g. of a thick, yellow oil; b. p., 180–200° (9 mm.). After several days a few crystals appeared in this oil and when it was then stirred with a glass rod the entire mass solidified. It was purified by drying on a porous plate and recrystallizing from alcohol in which it is readily soluble. The product consisted of small white prisms; m. p., 58–59°.

Analyses. Subs., 0.1961: H_2O , 0.1110; CO_2 , 0.5281. Calc. for $C_{19}H_{20}O_4$: H, 6.41; C, 73.08. Found: H, 6.29; C, 73.45.

From the mother liquor a small amount of a product melting at $27-28^{\circ}$ was obtained. This corresponds to Guyot and Esteva's ethyl phenyltartronate.

Condensation of Ethyl Diphenylmalonate with Urea.—In our first experiment Fischer and Dilthey's veronal method was employed. A mixture consisting of 5.0 g. of ethyl diphenylmalonate, 1.5 g. of urea, and 1.5 g. of sodium dissolved in 25 cc. of absolute alcohol was heated in an autoclave at 106–108° for 7 hours. The product was neutralized with hydrochloric acid, filtered, diluted with water and evaporated; 2.5 g. of colorless crystals was thus obtained. Treatment with cold dil. alkali dissolved 1.0 g. and this was again recovered by acidifying the solution. The substance consisted of white needles; m. p., 145°. A qualitative test for nitrogen was negative. In making this test the characteristic orange odor of diphenylmethane was noted. This substance would result from simple loss of carbon dioxide from diphenylacetic acid. The neutralization constant of the acid was 222; calc. for C₁₄H₁₂O₂, 212. The substance was undoubtedly diphenylacetic acid.

The portion of the reaction product insoluble in dil. alkali was recrystallized from alcohol; m. p., $169-170^{\circ}$. The nitrogen content was 6.80%; calc. for $C_{14}H_{13}NO$, 6.63%. This identified the substance as diphenylacetamide.

Ethyl diphenylmalonate, in its instability toward sodium ethylate, is in striking contrast to the diethylmalonate which is saponified only with difficulty. In their preliminary paper, Guyot and Esteva⁸ state that the free diarylmalonic acids could not be obtained, since treatment of the esters with alcoholic potash split out carbon dioxide and gave the corresponding diarylacetic acids. We attempted, therefore, the condensation with urea under less drastic treatment, using a lower temperature and 1 mole of sodium instead of 3. Nevertheless, the same products resulted, and in about the same proportions. No barbituric acid derivative could be isolated.

Condensation of Ethyl Di-p-tolylmalonate with Urea.—Ethyl di-p-tolylmalonate was prepared in a similar manner from ethyl oxomalonate, toluene and sulfuric acid; m. p., 91-92°; Guyot and Esteva report a melting point of 93.5°. When heated with

⁷ Curtiss, Am. Chem. J., 35, 478 (1906).

⁸ Guyot and Esteva, Bull. soc. chim., [4] 3, 803 (1908).

urea in the presence of sodium ethylate it gave two products which were readily separated by treatment with cold dil. alkali. The acid product contained no nitrogen and melted at 140–141°; the recorded melting point of di-p-tolylacetic acid is 144°.

Di-p-tolylacetamide.—The alkali-insoluble product from the condensation described above was recrystallized from dil. alcohol and obtained in white needles melting at 190°. The substance is almost insoluble in water, but is readily soluble in alcohol.

Analyses. Subs., 0.2, 0.2: cc. of 0.1 N NH₃, 8.2, 8.2. Calc. for $C_{16}H_{17}NO$: N, 5.81. Found: 5.74, 5.74.

Again no barbituric acid derivative was obtained.

Ethyl Di(p-hydroxyphenyl)malonate.—Ten g. of phenol was dissolved in 10 g. of ethyl oxomalonate. A considerable lowering of temperature resulted. Dry hydrogen chloride was passed in, and the solution was finally immersed in a freezing mixture and saturated with the gas. A viscous oil was obtained, which crystallized after several days at 0°. The crystals were dried on a porous plate and recrystallized from a large volume of hot water. Flat lustrous needles were obtained; m. p., 133–134°. The substance was difficultly soluble in water, readily soluble in alcohol and in dil. aqueous alkali. It gave a blue color with ferric chloride.

Analyses. Subs., 0.2022, 0.2016: H_2O , 0.1026, 0.1024; CO_2 , 0.4828, 0.4782. Calc. for $C_{21}H_{24}O_6$: H, 5.86; C, 66.24. Found: H, 5.69, 5.71; C, 65.12, 64.88.

5,5-Di(p-hydroxyphenyl)barbituric Acid.—The ester described above was autoclaved in the usual manner with urea and sodium ethylate. The reaction mixture was acidified, diluted with water and evaporated. The product separated first as an oil which soon solidified. Recrystallization from hot water gave small slender needles; m. p., 288–290°. The substance is moderately soluble in hot water, readily soluble in dil. alkali and in alcohol. From 7.5 g. of the ester 3.0 g. of the barbituric acid was obtained. This substance also gives the ferric chloride reaction.

Analyses. Subs., 0.2, 0.2: 12.4, 12.5, cc. of 0.1 N NH₃. Calc. for $C_{16}H_{12}N_2O_6$: N, 8.97. Found: 8.68, 8.75.

Ethyl Diphenoxymalonate.—Ten g. of sodium was dissolved in 200 cc. of absolute alcohol, the solution cooled in ice water and 40 g. of phenol added. To the cold sodium phenylate 75 g. of ethyl dibromomalonate was gradually added with stirring. The mixture was refluxed for 1 hour and then found to be neutral to litmus. The alcohol was distilled in a vacuum and the remaining oil washed with water and dried with calcium chloride. Distillation under diminished pressure gave 45 g. of an oil; b. p., 195–204° (6 mm.).

Analyses. Subs., 0.2518, 0.2502: H_2O , 0.1254, 0.1298; CO_2 , 0.5996, 0.5962. Calc. for $C_{21}H_{24}O_6$; H, 5.86; C, 66.24. Found: H, 5.58, 5.81; C, 64.94, 64.98.

5,5-Diphenoxybarbituric Acid.—The ester described above was heated in an autoclave with urea and sodium ethylate. The barbituric acid was isolated by the usual procedure and recrystallized from a mixture of benzene and alcohol. From 11.5 g. of the ester we obtained 6.5 g. of the barbituric acid in very fine white needles melting at 192°. The substance is nearly insoluble in water, difficultly soluble in benzene and readily soluble in alcohol; it is intensely bitter. It is isomeric with the di(p-hydroxyphenyl)-barbituric acid described above.

Analyses. Subs., 0.2, 0.2: ec. of 0.1 N NH₃, 12.6, 12.5. Calc. for C₁₆H₁₂N₂O₅: N, 8.97. Found: 8.82, 8.75.

Ethyl Di-(4-hydroxy-3-methylphenyl)-malonate.—A solution of 14 g. of o-cresol in 12 g. of ethyl oxomalonate was saturated at 0° with dry hydrogen chloride. After 4

⁹ Fritsch and Feldmann, Ann., 306, 81 (1899).

days the mass had solidified. The crystals were dried by suction and washed with water. Two recrystallizations from dil. alcohol gave 16 g. of short white prisms; m. p., 107–108°. From alcoholic solution water precipitated the substance as an oil which gradually solidified. A blue color is obtained with ferric chloride.

Analyses. Subs., 0.2504, 0.2514: H₂O, 0.1406, 0.1394; CO₂, 0.6158, 0.6220. Calc. for C₂₃H₂₈O₆: H, 6.49; C, 67.77. Found: H, 6.29, 6.22; C, 67.07, 67.47.

5,5-Di-(4-hydroxy-3-methylphenyl)-barbituric Acid.—Five g. of the ester obtained as described above, 2 g. of urea and 1.4 g. sodium dissolved in 25 cc. of absolute alcohol were heated in an autoclave for 7 hours at 107–109°. The usual treatment then gave an oil with a strong odor of cresol. The product was obtained in crystalline form by dissolving the oil in a small amount of absolute alcohol and adding petroleum ether. Recrystallization from dil. alcohol gave 1 g. of white prisms melting at 217–219°. The substance is insoluble in water, readily soluble in alcohol, odorless and tasteless, and in dil. alcoholic solution gives a blue color with ferric chloride.

Physiological Tests

The two isomers, $\operatorname{di}(p\text{-hydroxyphenyl})$ barbituric acid and diphenoxy-barbituric acid, were tested physiologically. A 3% solution, prepared by dissolving the substance in a minimum amount of dil. alkali, was injected intraperitoneally into white mice in the proportion of 0.02 cc. per g. of body weight. This corresponds to twice the effective dose of veronal. The mice were kept under observation for several hours, but no symptoms of somnolence were observed or even muscular incoördination. Veronal, when administered in the same way in doses 1/2 as great, produces a profound state of coma within 15 minutes. We must conclude, therefore, that the two barbituric acid derivatives described above are physiologically inert, at least in moderate doses.

An examination of the structure of the synthetic hypnotics commonly used shows that practically all are aliphatic derivatives. Where an aromatic grouping is present, as in luminal and in phenylethyl-hydantoin, the aromatic group comprises a relatively small part of the molecule. On the other hand, aromatic derivatives for which hypnotic properties might be predicted, on the basis of their distribution coefficient and molecular stability, are generally inert. Acetophenone perhaps comes the nearest to being an aromatic hypnotic, but a further increase in the aromatic groupings, as in benzophenone and diphenylcarbinol, causes the hypnotic action to disappear. It is of interest to note that the 2 barbituric acids under discussion consist essentially of 2 benzene rings and 1 pyrimidine ring, that is, they are predominatingly aromatic. The hydantoins furnish a parallel case: phenylethyl-hydantoin, mainly aliphatic, is an hypnotic while diphenyl-hydantoin, mainly aromatic, is not. Further evidence is, of course, required to establish this point, but from the data at hand it would appear that a search for hypnotics among derivatives that are essentially aromatic is not very promising.

Summary

Ethyl diphenylmalonate and ethyl di-(p-tolyl)malonate when subjected to the usual treatment with urea and sodium ethylate for condensation into a barbituric acid undergo decomposition with loss of a carboxyl group. When, however, the phenyl groups carry an hydroxyl group, as in ethyl di(p-hydroxyphenyl)malonate and ethyl di-(3-methyl-4-hydroxyphenyl)malonate the condensation to a 5,5-diarylbarbituric acid is readily effected. Neither 5,5-di(p-hydroxyphenyl)barbituric acid nor its isomer, 5,5-diphenoxybarbituric acid, shows noticeable hypnotic properties. Attention is called to the fact that these derivatives differ from the great majority of synthetic hypnotics in that they are predominantly aromatic.

THE UREA DEARRANGEMENT. II

By Tenney L. Davis and Kenneth C. Blanchard Received May 8, 1923

Just as urea dearranges into ammonia and isocyanic acid, so substituted ureas, thio-urea and guanidine, and their substitution products dearrange in similar fashion. When urea is heated with aniline, the isocyanic acid which is formed combines with the aniline to form phenylurea. This substance dearranges in two modes to form on the one hand aniline and isocyanic acid, on the other phenylisocyanate and ammonia; the phenylisocyanate and aniline combine to produce sym-diphenylurea which can dearrange in only one fashion to regenerate the substances from which it was produced. In the first paper¹ of this series, experiments were described which elucidate the mechanism of these reactions. By heating the dry materials together at about 160° we were able to prepare a number of derivatives of various aromatic primary amines.

In continuing the study we now find that the reactions take place in boiling aqueous solution. If urea and aniline hydrochloride are boiled together in water solution under a reflux condenser, phenylurea is formed and remains in solution in the hot liquid. After the clear solution has boiled for some time, diphenylurea begins to precipitate. Diphenylurea may be filtered from the hot liquid, and monophenylurea may be obtained by cooling the filtrate. By suitable modifications of the process, by repeating the boiling and filtration, it is possible to obtain either or both of the products in excellent yield. We find also that phenylurea refluxed in water solution yields sym-diphenylurea just as it does when heated at 160° in the dry state. When its aqueous solution is distilled, aniline passes over.

¹ Davis and Underwood, This Journal, 44, 2595 (1922).

In the aliphatic series, we have prepared sym-dimethylurea, diethylurea, di-n-butylurea, di-n-amyl-, di-iso-amyl-, benzyl- and dibenzylurea, by heating the amine hydrochloride with urea at 160–170° or by boiling the amine or its hydrochloride with urea in aqueous solution under a reflux condenser. When the amine hydrochloride was heated with urea, the amount of ammonium chloride which was produced indicated that the reaction had proceeded nearly to completion, but the aliphatic ureas are troublesome to manipulate and the yields of actual product, while considerable, were not as good as in the aromatic series.

When a solution of urea was refluxed with methylaniline hydrochloride and with ethylaniline hydrochloride, the corresponding unsymmetrical disubstituted ureas were produced. The yields were poor, but there was no evidence of tetrasubstituted urea, a fact which accords with our belief that the unsymmetrical disubstituted ureas dearrange in only one fashion: $RR'N-CO-NH_2 \longrightarrow RR'NH + HNCO$. The poor yields may perhaps have been due to the hydrolytic action of the amine hydrochloride solution on the isocyanic acid leading to the formation of ammonia and carbon dioxide, a belief which is supported by the fact that an increasing amount of the free base precipitated out as the boiling was continued.

Striking evidence of the dearrangement of substituted ureas was found in the interaction of aniline with sym-diethylurea. Diethylurea dearranges in only one fashion: C_2H_5NH —CO— NHC_2H_5 \rightleftharpoons C_2H_5NCO + $C_2H_5NH_2$. When it is heated with aniline, ethyl amine escapes and the ethyl isocyanate combines with the aniline to form sym-ethylphenylurea. This substance now dearranges in two modes: $C_2H_5NH_2$ + C_6H_5NCO \rightleftharpoons C_2H_5 —NH—CO— NHC_6H_5 \rightleftharpoons $C_6H_5NH_2$ + C_2H_5NCO . When it is heated alone, the more volatile substances escape and the aniline and phenylisocyanate combine to form sym-diphenylurea. The same product is formed more quickly if sym-diethylurea or sym-ethylphenylurea is heated with an excess of aniline.

Discussion of Experiments

Phenylated Urea.—A solution of 190 g. of urea and 390 g. of aniline hydrochloride in a liter of water was boiled under a reflux condenser. At the end of an hour crystals of sym-diphenylurea suddenly separated from the liquid. The boiling was continued until the mixture bumped, the hot liquid was filtered at the pump, the diphenylurea was washed on the filter with hot water, and the filtrate on cooling deposited crystals of phenylurea. This material was separated, and the filtrate was again boiled under a reflux condenser until it bumped, again filtered hot, again cold, and again refluxed. After four such boilings the final filtrate was evaporated to half volume for another small crop of each of the products. The diphenylurea accumulated from the hot filtrations was practically pure, m. p., 235°, and weighed 80.3 g., a yield of 25.5%. It was obtained in splendid, colorless needles by recrystallization from alcohol, 1 liter of solvent for every 25 g. of the material. The phenylurea from the cold filtrates amounted to 218.5 g.; yield, 53.5%. It was freed from the small amount of diphenylurea which it contained

by dissolving it in hot water, filtering, allowing to cool slightly until a flocculent precipitate of diphenylurea had appeared, and again filtering quickly without warming, and obtained as colorless needles or flakes; m. p., 147°.

A solution of 60 g. of urea and 300 g. of aniline hydrochloride in a liter of water was boiled under a reflux condenser for about 2 hours until the mixture bumped. The precipitated diphenylurea was filtered from the hot liquid and rinsed with a little hot water, the filtrate was returned at once to the flask and refluxed again until bumping recommenced, again filtered, etc. After four boilings the accumulated diphenylurea amounted to 192 g.; yield, 90%. The melting point indicated that the product was practically pure, but its appearance was improved greatly by recrystallization from alcohol with a little animal charcoal.

One experiment in which aniline itself was refluxed with a water solution of urea gave a good yield of the two products. One in which aniline and urea were refluxed in alcohol solution and the alcohol and excess aniline were removed by distillation with steam, gave a very poor yield, the reaction evidently not taking place to any great extent in alcohol and the products being probably formed during the distillation.

The reaction does not take place at ordinary temperatures. A solution of 30 g. of urea and 64.5 g. of aniline hydrochloride in 100 cc. of water was allowed to stand for 4 months in a stoppered flask. It was then extracted thoroughly with ether. The extract on evaporation yielded a residue too small in amount for a melting-point determination.

When a clear solution of 5 g. of phenylurea in 50 cc. of distilled water was boiled under a reflux condenser, it soon became turbid from the separation of small crystals. The crystals filtered from the hot liquid after 3 hours' boiling weighed 0.9 g. and were found to be pure diphenylurea; m. p., 235°. Further evidence of the dearrangement of phenylurea is found in the fact that its aqueous solution yields aniline on distillation. Six g. of phenylurea was dissolved in 250 cc. of water and the solution was distilled, more water being added, until a liter of distillate had been collected. An excess of bromine water was added to the distillate, and the mixture was extracted with chloroform. The chloroform on evaporation yielded 3.6 grams of residue which, recrystallized from chloroform, gave needles, m. p. 121°, identified as tribromo-aniline by mixed melting point with a known sample.

Methylated Urea.—A mixture of 13.5 g. of methylamine hydrochloride and 6 g. of urea was heated for 1 hour at 160-170°. The mass was extracted with boiling absolute alcohol and filtered for the removal of undissolved ammonium chloride. The alcohol solution was evaporated in a vacuum nearly to dryness. More ammonium chloride separated. This was removed by filtration and rinsed with ice cold absolute alcohol. Crystallization of the liquors yielded 6.9 g. of sym-dimethylurea, as colorless flakes, m. p., 99.5-100°; yield, 78.4%.

Ethylated Urea.—A mixture of 30 g. of ethylamine hydrochloride and 11.1 g. of urea was heated for 2 hours at 160-170°. Extraction of the product with absolute ether left a residue of 18.1 g. of ammonium chloride (90% yield) which indicated that the reaction had proceeded nearly to completion. The ether on evaporation yielded a pasty mass which, worked up from alcohol, gave 9.2 g. of sym-diethylurea as colorless needles; m. p., 112°; yield, 43%. The residue from the crystallization was a viscous, heavy, colorless sirup from which nothing further could be obtained.

Replacement of Ethyl by Phenyl.—A mixture of 4 g. of sym-diethylurea and 3.1 g. of aniline was heated at 160-170°. The material melted completely, ethylamine and ammonia were given off immediately, and after about 25 minutes needle crystals began to separate from the hot liquid. After an hour, the mixture was cooled and filtered with suction. The crystals, washed with alcohol and recrystallized from the same solvent, yielded sym-diphenylurea; m. p., 235°. The filtrate was kept in a vacuum until the

aniline had evaporated. The residue, recrystallized from a mixture of water and alcohol, yielded 0.2 g. of fine white needles, m. p., 98–99°, identified as sym-ethylphenylurea by a mixed melting point with a sample prepared by the interaction of phenylisocyanate with ethylamine in toluene solution.

Two g. of sym-ethylphenylurea was heated for $1^1/2$ hours at $160-170^\circ$. Ethylamine was evolved. The residue taken up in hot alcohol yielded on cooling 1.3 g. of sym-phenylurea as needle crystals; yield, 80%.

Butylated Urea.—A solution of 8 g. of *n*-butylamine and 3.3 g. of urea in 50 cc. of water was refluxed for $2^{1}/_{2}$ hours. The solution was evaporated to dryness, and the residue, dried in the steam oven and recrystallized from benzene, yielded 6.5 g. of symdi-*n*-butylurea, as white flakes, sparingly soluble in water; m. p., 70.5– 71.0° ; yield, 70%.

Analysis. Calc. for C9H20ON2: N, 16.28. Found: 16.15.

An experiment with the hydrochloride gave a similar result; 21 g. of *n*-butylamine was converted to the hydrochloride by treatment with hydrochloric acid and evaporated to dryness. When the resulting material was refluxed for 3 hours with 8.3 g. of urea in 150 cc. of water, the solution evaporated to dryness, and the residue extracted with ether for the separation of the product from ammonium chloride, the product recrystallized from benzene amounted to 17.3 g. of di-*n*-butylurea; yield, 71.7%.

Sym-di-n-butylurea heated with aniline at 160–170° yielded sym-diphenylurea, as expected. A small quantity of another substance was isolated as white flakes, m. p., 65°, which was possibly sym-n-butylphenylurea, but not enough was obtained for analysis.

We have not been able to prepare *unsym*-di-n-butylurea by boiling the secondary amine or its hydrochloride with a water solution of urea under a reflux condenser or by heating the hydrochloride with urea at 160-170°.

n-Amyl and iso-Amyl Urea.—Three and three-tenths g. of n-amylamine, b. p., 99-108°, prepared by the reduction of n-butyl cyanide, was converted to the hydrochloride, and the resulting dry product was heated with 1.1 g. of urea for 2 hours at 160-170°. The product was broken up under hot alcohol and filtered. Water was added to the filtrate until a turbidity began to appear. The crystals collected from the cold liquid amounted to 0.8 g. of crude product; m. p., 84-85°. By recrystallization from hot water, pure sym-di-n-amylurea was obtained as white flakes; m. p., 92.8°.

Analysis. Calc. for C₁₁H₂₄ON₂: N, 13.99. Found: 13.93.

A mixture of 5 g. of *iso*-amylamine hydrochloride and 1.2 g. of urea was heated for 3 hours at 160–170°. When the melt was treated with water, a light yellow oil separated. This was extracted with ether, and the ether solution, dried with fused sodium sulfate and allowed to evaporate, deposited an oil. When this oil was distilled in a vacuum, the first portion had an odor of isonitrile and did not crystallize, while the later portion crystallized in part to a pasty mass. After this had been spread on a porous tile, it yielded a product which could be recrystallized from alcohol and gave transparent plates; m. p., 37.5°.

Benzylated Urea.—Sym-dibenzylurea, m. p. 167°, was obtained in 69.2% yield by heating 2 equivalents of benzylamine with 1 equivalent of urea for 2 hours at 160–170°, and working up the product from alcohol.

Monobenzylurea, m. p., 146.6° , was produced along with dibenzylurea when urea and benzylamine were heated at $160-170^{\circ}$ in molecular proportions. Two g. of benzylurea heated at $160-170^{\circ}$ for 3 hours gave off ammonia, and 0.6 g. of pure dibenzyl was obtained from the product.

When urea was refluxed with benzylamine in aqueous solution, benzylurea was formed (95.8% yield, calculated from urea), but no dibenzylurea was produced even when a large excess of the amine was present. Unlike phenylurea, benzylurea is not

converted into dibenzylurea by boiling in water. Even long-continued boiling alone and in the presence of benzylamine and of dil. sulfuric acid were without effect, except that in the latter case an odor of isonitrile was noticed.

Reactions with Secondary Amines.—When urea was refluxed in aqueous solution with methylaniline, no ammonia was given off and no new substance was isolated from the mixture. No product was isolated from the mixture which resulted from the heating together of dibutylamine hydrochloride and urea. The 1,1-disubstituted ureas have been obtained (in poor yield) by boiling urea with aqueous solutions of the hydrochlorides of methylaniline and ethylaniline.

A mixture of 15.3 g. of ethylaniline hydrochloride and 6 g. of urea was refluxed in 50 cc. of water for 5 hours. Considerable oil separated. The material was extracted with ether and the extract was shaken with dil. hydrochloric acid for the removal of amine. Some of the substituted urea was also evidently removed, for the ether solution, dried and evaporated, yielded only about 0.1 g. of oil which crystallized after long standing. Recrystallized from ligroin this yielded pure unsym-ethylphenylurea, as white, lustrous, thin plates, m. p., 62°, identified by mixed melting point with a sample prepared from potassium cyanate and ethylaniline hydrochloride.

A mixture of 7.4 g. of methylaniline hydrochloride and 2 g. of urea in 20 cc. of water was refluxed for 9 hours. Considerable oil separated. The ether extract, when dried and allowed to evaporate, yielded about 1 g. of crystals, which when recrystallized from ligroin gave thin plates, m. p. 150°, that were identified as *unsym*-methylphenylurea by mixed melting point with a synthetic sample.

Summary

Urea may be used for the preparation of mono-substituted ureas from primary amines, by heating at 160° or by boiling in aqueous solution. The monosubstituted ureas, in the same way, are equivalent to the isocyanate for purposes of synthesis and yield *sym*-disubstituted ureas. The syntheses have been studied with the phenyl compounds and with a number of substances in the aliphatic series.

Certain secondary amines react with the nascent isocyanic acid from urea to form *unsym*-disubstituted ureas, but the yields are poor.

Unsymmetrical disubstituted ureas and symmetrical disubstituted ureas in which the groups are alike, dearrange in only one fashion. Symmetrical disubstituted ureas in which the substituent groups are different dearrange in two modes. Striking evidence is found in the fact that unsymethylphenylurea yields carbanilide when heated.

A NEW METALLO-ORGANIC COMPOUND: DIPLUMBIC HEXA-ETHYL¹

By Thomas Midgley, Jr., Carroll A. Hochwalt and George Calingaert Received May 10, 1923

Introduction

Two ethyl lead compounds are reported in the literature.

Tetra-ethyl lead was prepared by P. Pfeiffer by the action of lead chloride on ethylmagnesium iodide, according to the equation: $4C_2H_5MgI + 2PbCl_2 \longrightarrow Pb + Pb-(C_2H_5)_4 + 2MgI_2 + 2MgCl_2$. Löwig reported the preparation of "hexa-ethyl lead" by interaction of sodium-lead alloys and ethyl iodide. However, the formulas given by Löwig are antiquated, as they refer to water as HO. Löwig also considered lead as having an atomic weight of 103, and it is impossible to ascertain whether he assumed the formula for his compound to be PbEt3 or Pb2Et6. At any rate, his statement is not confirmed either by a molecular-weight determination or by an analysis for lead. Moreover, a more recent experimenter duplicated Löwig's work, and showed that the product obtained by Löwig was actually impure tetra-ethyl lead, the same as had been obtained in the meanwhile by Buckton by interaction of lead chloride and zinc ethyl, according to the equation, $2PbCl_2 + 2ZnEt_2 = Pb + PbEt_4 + 2ZnCl_2$. To quote Ghira, "I think it is not too much to presume that at the present time no lead compounds of the type PbX_3 or Pb_2X_5 have ever been reported, studied or isolated."

An exhaustive study of organic compounds of tetravalent lead has been made during the past few years by E. Krause and his co-workers. Krause prepared all his lead alkyls by Pfeiffer's method, and reported⁶ the following constants for Pb(C₂H₅)₄: b. p., 83° (14 mm.); d¹⁸, 1.6591.

The method used by Krause, namely, the decomposition of an alkyl or aryl magnesium halide by lead chloride, always yields a tetra-alkyl lead compound when an alkyl halide is used. However, using aryl halides and an insufficient amount of lead chloride, Krause was able to prepare a series of compounds of the type, PbX₃ or Pb₂X₆, which he considers as corresponding to trivalent lead.⁷

Experimental Part

In the work done by the authors of this paper, 65 g. of triethyl lead chloride, covered with 100 cc. of distilled water, was stirred with 40 cc. of 5 N sodium hydroxide solution until all had dissolved. The triethyl lead hydroxide formed was precipitated from this solution by the addition of 200 cc. of 5 N sodium hydroxide solution, and was separated; 60 g. of this hydroxide was dissolved in 200 cc. of 95% ethyl alcohol and electrolyzed with lead electrodes, using a current density of 0.01 amperes per sq.

cm. An oil was formed at the cathode, and much gas evolved at the anode. This oil was heavy and insoluble in alcohol, so that it collected at the bottom of the cell. The reaction is expressed by the following equations: $Pb(C_2H_5)_3OH = Pb(C_2H_5)_3^+ + (OH)^-$; $2Pb(C_2H_5)_3^+ + 2\Theta = Pb_2(C_2H_5)_6$.

Properties of the Oil.—The oil so obtained is yellowish and easily decomposed by air, giving a yellowish powder that darkens rapidly; d., 1.94. It distilled with steam without decomposition, but very slowly, in the ratio of 1 cc. of diplumbic hexa-ethyl, $Pb_2(C_2H_5)_6$, to 25–30 cc. of water. It could not be distilled directly without decomposition, but under 2mm. pressure it boiled at about 100°. It did not freeze at —80°.

Analysis.—A sample of the oil was analyzed for lead by the method of Krause.⁸ Subs., 0.235: PbBr₂, 0.291. Calc. for C₁₂H₃₀Pb₂: Pb, 70.4; calc. for C₈H₂₀Pb: Pb, 64.1. Found: 69.8.

The molecular weight was determined by the freezing-point lowering of benzene, using 5.10° as the cryoscopic constant for benzene, this being the value used by Krause for all lead compounds.

Subs., 0.6285, 0.0482, 0.0212, 0.0182: benzene, 9.184, 13.35, 11.48, 14.44; Δt , 0.600, 0.040, 0.032, 0.022. Calc. for $Pb_2(C_2H_\delta)_6$: mol. wt., 588; calc. for $Pb(C_2H_\delta)_7$; 294. Found: 582, 460, 294, 292.

Thus, diplumbic hexa-ethyl, like the corresponding aryl compounds⁷ is dissociated in 2 PbX₃ groups in dilute solutions, but exists as Pb₂X₆ at higher concentrations.

This shows one more similarity between organic lead and tin compounds, as it was usually considered that the last one only is able to give organic compounds containing a chain of 2 atoms of the metal. However, the easy dissociation shown by these compounds is very different from what is observed with carbon chains, and leaves but little hope as to the possibility of preparing longer chains of lead atoms.

An attempt was made to prepare the chlorine derivative of this compound. Since tetra-ethyl lead reacts with hydrochloric acid to form ethane and triethyl lead chloride, it was hoped that the hexa-ethyl compound might react similarly to give a substance, $Pb_2(C_2H_5)_5Cl$. Such is not the case; instead, the Pb-Pb linkage is apparently broken, giving as the main products of the reaction lead triethyl chloride $Pb(C_2H_5)_3Cl$, and lead chloride, while gas is given off. The reaction may probably be written as follows: $Pb_2(C_2H_5)_6 + 3HCl = Pb(C_2H_5)_3Cl + PbCl_2 + 3C_2H_6$.

Summary

Inasmuch as all organic lead compounds of the type PbX₄ are able to yield derivatives of the general formulas PbX₃Cl and PbX₃OH, a method has been developed by which the corresponding Pb₂X₆ compounds can be obtained readily.

⁸ Krause, Ber., 49, 1130 (1916).

It has been shown that such compounds are represented by the formula Pb_2X_6 in pure state or in concentrated solutions, and by PbX_3 in very dilute benzene solutions.

THE SUGAR CONTAINED IN TUBERCULINIC ACID, THE NUCLEIC ACID OF TUBERCLE BACILLI

By Elmer B. Brown and Treat B. Johnson¹ Received May 11, 1923

In previous papers by the authors² a description has been given of the method used for separating tuberculinic acid from tubercle bacilli, and also the nature of the pyrimidines which function in this acid. On the basis of new data obtained in our research we concluded that tuberculinic acid containing the pyrimidines, thymine and cytosine, but no uracil, resembles in its chemical characteristics a nucleic acid of animal origin, thereby establishing the natural group to which the tubercle bacillus is to be assigned. It is also known that the carbohydrates contained in plant and animal nucleic acids are characteristic of each group and differ in the two acids, hexose occurring in the acid of animal origin and pentose in the plant variety. Hence, an accurate knowledge of the sugar contained in tuberculinic acid would serve as a check on the above classification of the tubercle bacillus which is based on the results of a pyrimidine analysis.

The literature of the chemistry of tubercle bacillus reveals the fact that the carbohydrate phase of the work has received little attention at the hands of previous investigators, notwithstanding the fact that one of the first of them, Hammerschlag³ recognized its importance. He was able to detect a reducing sugar in defatted bacilli, but thought he was dealing with cellulose. De Schweinitz and Dorset⁴ were of the same opinion in regard to the nature of the carbohydrate contained in this material. Levene⁵ isolated a carbohydrate of a glycogen-like nature as an impurity of the nucleic acid from tubercle bacilli, but did not further investigate it beyond the point of ascertaining that it formed a soluble copper salt which permitted its separation from the insoluble copper nucleate.

Bendix⁶ was the first investigator to report the finding of a sugar complex in the nucleoprotein obtained from the tubercle bacillus. He characterized his product as a pentose, but gave no details as to the method employed in its isolation, nor any characteristic chemical tests in support of his conclusion. The only other investigator, so far

¹ This work was done with the aid of a grant from the Committee on Medical Research of the National Tuberculosis Association. The tubercle bacilli used in this research were furnished gratuitously to the writers by Parke, Davis and Co. and the Mulford Co. We take this opportunity to express appreciation of their coöperation and interest in our research.

as the writers are aware, to report the finding of a sugar in the nucleoprotein from the tubercle bacillus was Goris⁷ who claims to have found a hexose. The nucleoprotein was obtained from the defatted bacilli by extraction with water and precipitation with alcohol. Chemical data supporting this conclusion are also lacking.

Two other investigators working on tubercle bacilli have found sugars in the extracts of different solvents used on this material. Kozniewski⁸ found that acetone extracted a substance from tubercle bacilli which, when treated with dil. mineral acids was decomposed with the formation of an inactive reducing sugar. Agulhon and Frouin⁹ by the use of alcohol were able to extract a substance that yielded dextrose. These findings are of interest in showing the different parts of the bacillus from which the presence of sugars has been reported.

It is readily seen that the previous work on the carbohydrates of the tubercle bacillus gives very little accurate information in regard to the nature of the sugar functioning in this organism. Beyond the fact that a few investigators were able to find evidence of the presence of reducing sugars in different fractions of the tubercle bacillus, no conclusive results on the nature of these products have been obtained. Since the methods used for the identification of the different products were of a general nature and the material very complex, naturally the results obtained by the different investigators were incomplete and contradictory.

As a part of their investigation of the "Chemistry of the Tubercle Bacillus," which has been in progress in this Laboratory during the past 2 years. the writers have now been able to investigate the nature of the sugar contained in tuberculinic acid. After subjecting this nucleic acid to all the purification processes commonly used for the purification of other nucleic acids, a product was finally obtained which showed a constant content of nitrogen and phosphorus. Small portions of this material were used to ascertain qualitatively the nature of the decomposition products of the sugar, when subjected to acid hydrolysis. These tests showed that relatively large amounts of both formic and levulinic acids were produced and only very small amounts of furfuraldehyde. With this information in hand, greater amounts of tuberculinic acid were employed and the above products isolated and identified. Since hexose sugars yield on acid hydrolysis the above decomposition products and the pentoses under the same conditions yield only furfuraldehyde, the sugar functioning in tuberculinic acid is therefore definitely shown to be a hexose. The new data obtained by us are in complete accord with the results of our former work in which we found that thymine and cytosine were the only pyrimidines contained in tuberculinic acid, and show conclusively that the decomposition products of this nucleic acid are identical with those of known acids of animal origin, and different from those of the plant type in both their pyrimidine and sugar content.

In the experimental part of this paper is given a complete description of the behavior of tuberculinic acid when subjected to hydrolysis, and a report of our examination of the hydrolysis products produced by the decomposition of the sugar.

Experimental Part

The Purification of Tuberculinic Acid.—The nucleic acid used in this work was separated from tubercle bacilli by the application of our method, described in our previous publications² to a large amount of human and bovine tubercle bacilli which had previously been defatted with toluene.

The crude tuberculinic acid, 8.4 g. obtained from 810 g. of dry tubercle bacilli, was further purified by solution in 1% sodium hydroxide solution, addition of acetic acid until the solution was neutral, then picric acid as long as a precipitate was formed and finally acetic acid until the mixture was distinctly acid to litmus. To the filtered solution hydrochloric acid was then added until a faint turbidity was produced and the nucleic acid precipitated from the solution by the addition of twice its volume of 95% alcohol. The precipitate was separated from the solution by a high-speed centrifuge, washed with 50% alcohol containing hydrochloric acid and finally with 95% alcohol, absolute alcohol and with anhydrous ether. The dry product was a light gray powder and contained 8.11% of phosphorus and 11.3% of nitrogen. This material was then dissolved in dil. potassium hydroxide solution, the solution poured into 6 times its volume of absolute ethyl alcohol, and the precipitated potassium salt separated by means of the centrifuge. This was then washed with absolute alcohol and dried with ether. A granular powder, slightly yellow in color, was obtained. The salt was again dissolved in water and converted into the copper salt by acidification with acetic acid, filtration, addition of hydrochloric acid until an opalescence was produced and, finally, addition of 10% copper chloride solution. The copper salt was purified and converted into the free nucleic acid according to the directions of Levene, 10 using 5% hydrochloric acid. Analysis showed that the percentages of nitrogen and phosphorus had not changed and that we had a product which further treatment did not alter.

The Decomposition Products of the Sugar Produced on Hydrolysis of Tuberculinic Acid with Hydrochloric Acid.—One g. of tuberculinic acid was placed in a 500cc. distilling flask with 250 cc. of hydrochloric acid (d., 1.06) and the mixture distilled from an oil-bath at 150°. At intervals, when 25 cc. of distillate had passed over, an equal volume of hydrochloric acid (d., 1.06) was added maintaining approximately the same strength of solution. The distillation was continued for 7 hours, during which about a liter of distillate was collected. The solution did not boil smoothly, but occasionally foamed and super-heated, and on one occasion boiled over, a few drops reaching the bulk of the distillate before the receiver could be changed.

To the distillate an excess of phloroglucine dissolved in hydrochloric acid was added and the mixture heated at 80° to 85° for 2 hours and then allowed to stand overnight. The phloroglucide precipitate was collected on an asbestos mat in a Gooch crucible that had been previously dried to constant weight at 98°, washed with water and again dried to constant weight at the same temperature. This weighed 0.024 g. Since Osborn and Harris¹¹ under the same conditions obtained 0.252 g. of this product from 1 g. of triticonucleic acid from wheat, it is readily seen that the 2 acids differ markedly from each other in the amount of furfuraldehyde produced on hydrolysis. Steudel, 12 working

¹⁰ Levene, J. Biol. Chem., 48, 177 (1921).

¹² Steudel, *ibid.*, **56**, 212 (1908).

with thymus nucleic acid, also obtained furfuraldehyde, but in amounts somewhat smaller than the quantity produced from tuberculinic acid. The results obtained in the case of tuberculinic acid agree very closely with the results obtained by other investigators working with animal nucleic acids and differ materially from the results obtained when the plant acids were examined.

The solution remaining from the preceding experiment was utilized to ascertain whether levulinic acid was produced as a hydrolytic product of tuberculinic acid. The distillation was continued to dryness and the residue exhaustively extracted with ether, the ether extract poured through a dry filter paper and the ether then expelled by distillation. The gummy residue was heated on the hot plate for 2 hours to expel any hydrochloric or formic acids that it might contain, dissolved in 25 cc. of water and finally filtered from a small amount of insoluble material. Preliminary tests on 1cc. portions of this solution showed that it gave a strong iodoform reaction, as well as a deep red color when sodium nitroprusside and a few drops of sodium hydroxide solution were added, the color changing to violet after the addition of an excess of acetic acid. These tests, especially the latter, are characteristic of levulinic acid. The remainder of the solution was digested for 1 hour with an excess of zinc oxide according to the directions of Wehmer and Tollens¹³ in order to prepare the zinc salt. After decolorization with animal charcoal the filtered solution was evaporated to a small volume, when a precipitate began to separate; as the solution cooled, more was obtained. This precipitate was crystalline, showing 6-sided crystals when viewed under the microscope, and was identical in appearance with the zinc salt prepared from levulinic acid. The solution was evaporated to dryness, the residue washed with a mixture of equal parts of absolute alcohol and ether, dissolved in water and silver nitrate solution was added. A precipitate was obtained but in too small amount for a silver determination. These tests show conclusively that levulinic acid is produced on acid hydrolysis of tuberculinic acid.

The Isolation of Levulinic Acid from Tuberculinic Acid.—To 3.8 g. of tuberculinic acid in a 300cc. round-bottom Pyrex flask, 30 cc. of water and 10 cc. of concd. sulfuric acid were added and the mixture was heated in an oil-bath at 125° for 25 hours under a return condenser. At the end of this time 50 cc. of water was added and the solution distilled until 50 cc. had passed over. This distillate, which contained formic acid was saved, as described below.

The solution remaining in the hydrolysis flask was exhaustively extracted with ether, the ether extract poured through a dry filter and the ether distilled on a water-bath. The residue was allowed to remain on the steam-bath to dispel traces of water and formic acid. A viscous sirup was obtained, weighing 0.5 g. and composed chiefly of levulinic acid. This amount figured in terms of its hexose equivalent corresponds to 37.5% of the weight of tuberculinic acid used. The crude residue was dissolved in water, exactly neutralized with sodium hydroxide solution, and silver nitrate solution added in excess. A beautiful precipitate of the silver salt of levulinic acid was obtained. This was recrystallized once from water and dried at 100°.

Analysis. Subs., 0.1923: Ag, 0.094. Calc. for C₈H₇O₃Ag: Ag, 48.43. Found: 48.88. In other words, it was established that this compound was identical in every respect with the silver salt prepared from levulinic acid.

The Identification of Formic Acid.—The distillate obtained as described above was strongly acid to litmus, and when a few cubic centimeters was warmed with silver nitrate solution a silver mirror was obtained. A black deposit of mercury was immediately obtained when a crystal of mercurous nitrate was added and the solution warmed. A portion of the solution when neutralized with sodium hydroxide and treated with ferric chloride solution gave the characteristic red color when boiled, showing the formation

¹³ Wehmer and Tollens, Ann., 243, 314 (1887).

of ferric formate. When 30 cc. of the distillate was neutralized with sodium hydroxide the solution, then made acid to litmus with hydrochloric acid, and a solution of mercuric chloride added and the mixture digested on the water-bath, a white precipitate soon began to form. A large amount of calomel was obtained, covering the entire bottom of the beaker. These results show conclusively that the acid contained in the distillate was formic acid.

The Quantitative Determination of the Pyrimidines.—The solution remaining from the ether extraction was worked for the pyrimidines according to the directions given in one of our previous papers.² After the removal of sulfuric acid with barium hydroxide, and the purines with silver sulfate in acid solution, the pyrimidines were precipitated in the usual manner as silver salts. These salts were decomposed with hydrogen sulfide and the cytosine removed as the phosphotungstate. After decomposition of this salt with barium hydroxide the cytosine was isolated as the base; 0.37 g. was obtained, corresponding to 9.7% of the weight of nucleic acid used.

The filtrate left from the phosphotungstate precipitation was freed from this reagent with barium hydroxide, the barium removed in the usual way and the solution evaporated to dryness. The residue was taken up in water and filtered from a small amount of insoluble material and the solution again evaporated to dryness and weighed. The crude thymine weighed $0.45~\rm g.$, corresponding to 11.8% of the weight of the nucleic acid used. All of our solutions failed to respond to tests for uracil.

Summary

- 1. It has been shown that the sugar functioning in tuberculinic acid is a hexose. This was proven by identification of levulinic and formic acids as products of its hydrolysis.
- 2. A new analysis for pyrimidines in tuberculinic acid has been made and results have been obtained which are identical with those reported in our previous publication.²

THE ACTION OF ULTRAVIOLET LIGHT UPON DIKETONES

By C. W. PORTER, H. C. RAMSPERGER AND CAROLYN STEEL

Received May 16, 1923

In aqueous solution benzil is converted into benzilic acid by warming it with an alkali. The reaction is rapid and practically quantitative. It has been reported that the same rearrangement occurs slowly in the absence of alkali when benzil, in moist ether, is exposed to sunlight. Under similar treatment benzil in alcohol yields benzoic acid and benzoin.²

This investigation was undertaken to determine the action of radiant energy of short wave lengths upon aqueous and alcoholic solutions of benzil and the corresponding aliphatic diketone, diacetyl.

Preliminary tests were made with saturated aqueous solutions of benzil. The solutions were placed in open beakers with the liquid surfaces 18 cm. below a 110-volt quartz mercury-vapor lamp. Samples were withdrawn

² Ciamician and Silber, Ber., 36, 1575 (1903).

every 3 hours and titrated with sodium hydroxide solution. There was a gradual development of acid but an exposure of at least 30 hours was required to secure enough of the product for identification. Benzoic acid was the principal product.

Because of the slight solubility of benzil in water (0.33 g. per liter at 20°) mixtures of alcohol and water were used in the later experiments, and since ethyl alcohol is oxidized by the oxygen of the air under the influence of the ultraviolet light, blank determinations with the solvent alone were made under the same conditions. The acetic acid which developed in the blank tests (100cc. portions) amounted to approximately 1.2×10^{-6} moles per hour. Within 12 hours the benzil in 66% alcohol was completely converted into other products. The solvent was then removed by evaporation. By repeated extractions with hot water we obtained from the yellow tarry residue a mixture of colorless crystals. Approximately 80% of this crystalline part of the product was benzoic acid. The remainder was salicylic acid.

The mechanism for the production of these acids from benzil has been determined. The first step is hydrolysis of the diketone resulting in the production of benzoic acid and benzaldehyde. Atmospheric oxidation of benzaldehyde to benzoic acid is catalyzed by ultraviolet light and salicylic acid is formed from benzoic acid under the same conditions. A qualitative test for salicylic acid can be obtained when an alcoholic solution of benzoic acid is exposed to the ultraviolet light for less than an hour. When air was excluded by making the exposures in quartz flasks in an atmosphere of nitrogen no salicylic acid was formed. Under these conditions the oxidation of benzaldehyde was prevented, also, and the aldehyde appeared as one of the final products. Benzoin was produced in considerable quantities in the oxygen-free samples but we have not yet determined whether the production of benzoin is due entirely to reduction of benzil by alcohol or is due in part to a condensation of benzaldehyde.

In order to determine whether benzilic acid could be an intermediate product we exposed both water and alcohol solutions of pure benzilic acid. The solutions became cloudy in the first half hour of exposure. Two products were isolated. One was benzopinacol, $(C_6H_5)_2$. COH. COH. $(C_6H_5)_2$, and the other benzophenone. These products were never obtained from benzil.

Experimental Part

Benzil in Dry Benzene.—Several 50cc. portions of a 1% solution of benzil in dry, oxygen-free benzene were placed in quartz flasks, boiled to

³ The test for benzil was made by boiling the solution with an alkali, evaporating to dryness, and treating the residue with concd. sulfuric acid. Under this treatment, a mere trace of benzil yields benzilic acid in sufficient quantity to impart a red color to the sulfuric acid.

expel air from the solution, and the air of the flasks was replaced by pure nitrogen. Mercury seals were placed about the necks of the flasks. The solutions were exposed for 1 to 7 hours at a distance of 20 cm. from a 220-volt mercury arc. They acquired a light straw color as does pure benzene alone. When the solution was evaporated to dryness the benzil was recovered unchanged.

Benzil Vapor Exposed.—When exposed at a temperature of 200° in an evacuated flask for 6 hours, 0.2755 g. of benzil yielded 18 cc. of carbon monoxide (0°, 760 mm.) and a corresponding quantity of benzophenone. A flask containing benzil protected from the light by tin foil was kept in the same thermostat during the same interval of time. There was no thermal decomposition of the benzil.

Benzil in Water.—Several 50cc. portions of an aqueous solution of benzil (0.3 g. per liter) were exposed in quartz flasks in the presence of air. The increase in acidity during 30 hours is indicated in the following table.

TABLE I

Increase in Acidity of an Aqueous Solution of Benzil upon Exposure to Ultraviolet Light

Benzil in Alcohol and Water.—A stock solution was prepared by dissolving 2 g. of benzil per liter in 66% ethyl alcohol; 100cc. portions of this solution were exposed in quartz flasks. At the same time 100cc. portions of the pure solvent were exposed. At each interval indicated in the following table a benzil solution and a blank were withdrawn and titrated. The amount of the base reported is the difference between the two titrations.

TABLE II

EXPOSURE OF BENZIL IN WATER AND ALCOHOL

Time, hours....... 1 2 3 4 5 6 7 8 9 10 0.062 N NaOH, ec... 4.28 6.30 8.70 10.72 13.35 15.40 16.50 17.20 17.82 18.06

Assuming that 2 mols. of acid are derived from each mol. of benzil, this represents only a little more than 50% conversion, but the benzil had completely disappeared. Approximately half of it was converted into a resinous product, which we have not identified, and half was converted into benzoic acid. Part of the benzoic acid was oxidized to salicylic acid. The crystalline product was usually 80% to 90% benzoic acid and 20% to 10% salicylic acid.

Exposures in the Absence of Air.—Solutions of benzil in aqueous alcohol were exposed to a 220-volt lamp for 8 hours in the absence of air. A white precipitate formed and was identified as benzoin (m. p., 132–134°). Benzoic acid was isolated as in previous cases, but no salicylic acid was produced. The pure solvent (66% alcohol) under nitrogen yielded no acetic acid. Some hydrogen was produced from both the pure solvent

and the benzil solution. This is due to the decomposition of the ethyl alcohol into acetaldehyde and hydrogen. Alcohol thus acts as a reducing agent producing benzoin from benzil.

Benzilic Acid Exposed.—Benzilic acid, when dissolved in 50% alcohol and exposed to ultraviolet light, is converted into benzopinacol. When air is present benzophenone is produced also; but in the absence of air benzophenone is reduced to benzopinacol so rapidly that it never appears as a final product of the reaction.

Diacetyl in Water.—A stock solution of diacetyl was prepared by dissolving 2 g. of the diketone in 1 liter of water; 100cc. portions of this solution were exposed at a distance of 14 cm. from a 220-volt lamp. The substance was converted into acetic acid and acetaldehyde. The rate of acid formation is indicated by the following measurements.

TABLE III

Exposure of Diacetyl in Water

Time, hours	1	2	3	4	5	6	7	8	9	10
0.01 N NaOH, cc	70	100	118	130	138	144	148	151	152	153

Diacetyl Vapor.—A quartz flask having a capacity of 125 cc. was filled with diacetyl vapor at 100° and 1 atmosphere pressure and exposed to ultraviolet light. Gas was evolved at the rate of 8 cc. per minute. The gas was collected over mercury and analyzed. It was found to be carbon monoxide (2 vols.) and ethane (1 vol.).

Summary

Under the influence of ultraviolet light, benzil in the vapor state is decomposed into carbon monoxide and benzophenone when the temperature is 200° or above.

In dil. alcohol, in the absence of air, it is partly hydrolyzed to benzoic acid and benzaldehyde, but a portion of it is reduced by the alcohol to benzoin.

In aqueous alcohol in contact with air it is converted into benzoic acid. Further oxidation of the benzoic acid gives some salicylic acid.

Benzilic acid is not formed in solutions of benzil. The decomposition products of benzilic acid, namely, benzopinacol in the absence of oxygen, and benzophenone and benzopinacol in the presence of oxygen, were never found in the exposed benzil solutions.

Under the influence of ultraviolet light, diacetyl vapor yields ethane and carbon monoxide.

An aqueous solution of diacetyl yields acetic acid and acetaldehyde.

DERIVATIVES OF ANTHRAQUINONE. REACTIONS OF ANTHRAQUINONE SULFONIC ACIDS WITH MERCAPTANS¹

By W. S. Hoffman and E. Emmet Reid Received May 16, 1923

In a recent paper by Reid, Mackall and Miller² it has been shown that sulfonic acid groups in the α -position in anthraquinone are readily replaced by mercaptan residues to form anthraquinone thio-ethers, thio-ether sulfonic acids, and dithio-ethers, $C_{14}H_7O_2.SR$, 1,5- and 1,8-RS. $C_{14}H_6O_2.SO_3Na$ and 1,5- and 1,8- $C_{14}H_6O_2(SR)_2$.

The present investigation was undertaken to determine the best conditions for this reaction and to extend it to other mercaptans, particularly those of other types.

The speed of the reaction depends on the concentration of the sodium salt of the mercaptan and, hence, on account of the weakness of mercaptans as acids, is increased by excess of alkali. Alkali, however, tends to salt out the sodium anthraquinone sulfonate. Practically the maximum yield is reached with 4 equivalents of alkali and 4 hours' heating.

Previous work had shown that the reaction takes place with primary aliphatic mercaptans but not with aromatic. Benzyl mercaptan has been tried and has been found to work well, yielding well-characterized derivatives. p-Nitrobenzyl mercaptan reacts rapidly but the products are complex, extremely insoluble and difficult to handle, and so were discarded.

No difficulty was found in obtaining good yields of characteristic reaction products with isopropyl mercaptan, but the corresponding sulfones are obtained in small yield, if at all, since the —SCH(CH₃)₂ group is readily oxidized to —SO₃H and the sulfonic acids are obtained quantitatively if the oxidation is vigorous. In the case of mixed dithio-ethers an isopropyl group is oxidized to the sulfonic acid while, with the other, oxidation stops at the sulfone: RS.C₁₄H₆O₂.SCH(CH₃)₂ \longrightarrow RSO₂.C₁₄H₆O₂.SO₃H. Small yields of sulfones may be obtained from the 1- and the 1,5-, but none from the 1,8-dithio-ethers containing an isopropyl group. Monothio-ethylene glycol has been found to react normally, its reaction rate being greater than those of the simple mercaptans on account of its solubility in water and low volatility. The resulting hydroxy-thio-ethers are slightly soluble in water and readily act with hydrosulfite.

Ethylene mercaptan was found to react rapidly but the products are complicated and could not be purified; the principal one from the monosulfonic acid seemed to be the disulfide, C₁₄H₇O₂.SC₂H₄S.SC₂H₄S.C₁₄H₇O₂.

¹ From a dissertation presented by W. S. Hoffman in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

² Reid, Mackall and Miller, This Journal, 43, 2104 (1921).

1.5-Anthraquinone-butyl-sulfone-sodium sulfonate, C4H9SO2C14H6O2.-SO₃Na, was prepared by the oxidation of the corresponding thio-ether with fuming nitric acid. It is quite soluble in water; it separates from hot water with half a molecule of water of crystallization and from cold with 1 molecule. As previously shown, the thio-ether anthraquinone sodium sulfonate reacts with mercaptans, but on account of its extremely slight solubility even in boiling water, the reaction is very slow. Possibly on account of its far greater solubility, possibly partly on acount of greater reactivity, the sulfone-sulfonate mentioned above reacts extremely rapidly with mercaptans in hot alkaline solution to give sulfone-thio-ethers, 1.5-C₄H₉SO₂.C₁₄H₆O₂.SR, which appear as precipitates the instant that the mercaptans are added to the mixture. The yields are practically quantitative. In fact the reaction may advantageously be used for the identification of mercaptans. The melting points of the butyl sulfone-alkylthio-ethers so formed are definite but it is better to oxidize with fuming nitric acid to the mixed disulfones. These are particularly easy to purify and have good melting points. A number of these are given in previous article.3 Satisfactory results may be obtained with very small quantities of the mercaptans.

The great reactivity of the butyl-sulfone-anthraquinone sodium sulfonate toward mercaptans suggested that it might react with some compounds with which the sodium-anthraquinone sulfonates do not react. This has proved to be true with thiophenol which reacts at a satisfactory rate to give a good yield of butyl-sulfone-anthraquinone-thiophenol ether, $C_4H_9SO_2$.- $C_{14}H_6O_2$.S C_6H_5 , but the reaction does not go as fast and the yield is not as good as with the aliphatic mercaptans. p-Nitrothiophenol was tried in a similar manner. No product separated from the alkaline solution, which may be explained by the probable formation of some sort of sodium salt. After 4 hours' boiling the mixture was acidified and gave a brown solid which proved difficult to purify and was discarded. The reaction evidently takes place, but not smoothly.

It was thought that perhaps alcohols might react to give oxygen ethers. Butyl alcohol was added to the boiling alkaline solution of butyl-sulfone-anthraquinone sodium sulfonate and boiled for some time, but there was no indication of a reaction.

Experimental Part

Preparation of Butyl-anthraquinone Thio-ether. The effect of time, dilution and quantity of alkali upon the preparation of this substance as described in the preliminary article has been studied. In each experiment 3 g. of the sodium anthraquinone sulfonate was used and 1.25 equivalents of butyl mercaptan in boiling solution. The product was filtered on a small Büchner funnel, well washed with hot water, dried and weighed.

Reactions with Benzyl and p-Nitrobenzyl Mercaptans

Preparation of Mercaptans.—Benzyl mercaptan was prepared by a slight modification of the general method given by Märcker. One and a half moles of crystallized sodium sulfide was melted at 90° on a water-bath and was saturated with hydrogen sulfide. To this was added an equal volume of ethyl alcohol, and the mixture was resaturated with hydrogen sulfide; finally a mole of benzyl chloride dissolved in alcohol was added. The mixture was allowed to stand in the cold, with frequent shaking for 4 days, kept cold if necessary with running water to prevent as much as possible the oxidation of the mercaptan to the disulfide and the formation of the monosulfide, both of which reactions take place readily at high temperatures. The mixture was then diluted with water, the mercaptan separated and distilled under reduced pressure.

We were unable to prepare p-nitrobenzyl mercaptan in this way, although Strakosch⁵ maintains that he did. Nor was the method proposed by Price and Twiss⁶ found successful. The method finally employed was that of Waters⁷. p-Nitrobenzyl thiocyanate (made by the action of potassium thiocyanate on an alcohol-water solution of p-nitrobenzyl bromide) was dissolved in cold alcohol and saturated with hydrogen chloride, and allowed to stand cold for 8 days. Upon the addition of water, p-nitrobenzyl thiocarbamine ester (p-NO₂C₆H₄CH₂SCONH₂) separated, and was removed, dissolved in alcohol, and heated with a little more than 1 equivalent of zinc acetate. The cooled mixture was poured into a large quantity of water, precipitating the zinc p-nitrobenzyl mercaptide, which was separated, and decomposed with concd. hydrochloric acid, liberating the free mercaptan that melted when pure at 52°.

Reaction of Mercaptans.—Benzyl mercaptan was caused to react with 1-anthraquinone sodium sulfonate, with 1,5- and 1,8-disodium sulfonates and with the thioether sodium sulfonates prepared by Reid, Mackall and Miller. The reactions were slower than with butyl mercaptan, so the time of heating was lengthened to 8 to 10 hours. The thio-ethers so obtained were converted to sulfones by solution in glacial acetic acid, addition of slight excess of concd. water solution of chromic anhydride and heating for half an hour. As this mixture cooled the sulfones separated as yellowish-white crystals which were quite pure.

Reactions with Iso-Propyl Mercaptan

Preparation of iso-Propyl Mercaptan.—The mercaptan was prepared in the same way as benzyl mercaptan, using iso-propyl bromide as described by Claus. ¹⁰ The reaction mixture, in this case, after 4 days was distilled on the water-bath. The distillate was diluted with water, the mercaptan separated, dried over calcium chloride and redistilled; yield, 60%.

Reactions with Anthraquinone Sodium Sulfonates.—The speed of reaction of this substance with anthraquinone sulfonic acids at 100° was naturally very low on account of the low boiling point, 57° . The mixtures were refluxed for 12 hours and the yields averaged above 40%. The properties of the derivatives formed are given in the tables below.

Oxidation of Iso-propyl-anthraquinone-thio-ether and dithio-ethers

On oxidation of α -iso-propyl-anthraquinone-thio-ether with fuming nitric acid, 81% was converted into α -anthraquinone sulfonic acid which was identified by conversion into butyl-anthraquinone-thio-ether; m. p. 114°. A small amount of the sulfone, (CH₃)₂CHSO₂.C₁₄H₇O₂, was obtained, m. p. 182°

Calc. for C₁₇H₂₁O₄S: S, 10.20. Found: 10.30.

Similarly, the 1,5 mixed dialkyl dithio-ethers containing *iso* propyl gave small yields of the disulfones, 80 to 85% being oxidized to the alkyl sulfone-sulfonic acids. The melting points and analyses of these disulfones are given in Table XII.

¹⁰ Claus, Ber., 5, 656 (1872).

From the corresponding 1,8-dithio-ethers no disulfones could be obtained. The 1,8-anthraquinone disulfonic acid resulting from the oxidation of the di-isopropyl-dithio-ether was titrated and required over 96% of the calculated amount of alkali.

The 1,5- and 1,8-alkyl sulfone-sulfonic acids obtained above were boiled with butyl mercaptan under the usual conditions and converted into the corresponding alkyl sulfone-butyl-thio-ethers, the melting points of which are given in Table XIII. All are yellow solids very slightly soluble in water. For identification they were oxidized to the dialkyl disulfones described in the previous article.

Reactions with Monothio-ethylene Glycol

This mercaptan was prepared according to the methods of Rosen and Reid¹¹ and of Bennett.¹² When freshly prepared it reacted with the anthraquinone sulfonic acids under the same conditions as did butyl mercaptan with about the same yields, but poor results were obtained when the mercaptan was not fresh. The monothio-ether had been previously prepared by Gattermann by another method. He gives the same melting point. Owing to the presence of the hydroxyl group, these thio-ethers show a slight solubility in water. The data for the compounds prepared are found in Table XIV. The acetates were made by treating with acetyl chloride and were recrystallized from acetic acid, the hydroxy compounds from butyl alcohol.

¹² Bennett, J. Chem. Soc., 120, 422 (1921).

Reactions with Ethylene Mercaptan

Preparation of Ethylene Mercaptan.—Ethylene mercaptan was made according to the method of Fasbender¹³ with the following modifications. The mixture of the alcohol-water solution of sodium hydrosulfide and of ethylene bromide was allowed to stand for 4 days in cold water, with frequent shaking. The mixture was diluted with water, the mercaptan layer filtered off, dried with calcium chloride and distilled under reduced pressure; yield, about 30%. The mercaptan is exceedingly unstable and gives on heating a large quantity of a white crystalline compound. It is the formation of this compound, containing a high percentage of sulfur that made a study of the reactions of ethylene mercaptan so difficult.

Reaction of Ethylene Mercaptan with Anthraquinone Sulfonic Acids.—Ethylene mercaptan was found to react quite readily with the mono- and disulfonates, giving yields of about 80% of yellow powders. In every case, however, these powders were impure, giving various analyses for sulfur and no definite melting points. One attempt at purification of the monosulfonate reaction product gave a substance that contained 21.75% of sulfur. It did not melt below 250° , showing the absence of appreciable sulfur-containing impurities which were found in most cases to lower the melting points of the crude products to below 100° . The analysis points to the possible compound, $C_{14}H_7O_2.SCH_2CH_2S.CH_2CH_2S.CH_4H_7O_2$ (sulfur: calc., 21.42%), an oxidation product of the derivative $C_{14}H_7O_2SCH_2CH_2SH$ first formed.

1,5-Butyl-anthraquinone-sulfone Sodium Sulfonate,

C4H9SO2.C14H6O2.SO3Na, and its Reactions

The thio-ether sodium sulfonate, or "gold salt," is dissolved in about 2 parts by weight of fuming nitric acid and the solution evaporated to dryness on the water-bath. The oxidation to the sulfone-sulfonate is practically quantitative. This substance was dissolved in a minimum amount of hot water and the solution evaporated until crystals formed. These were separated and the solution was cooled. Nothing further separated until the temperature was below 30° . The crystals from hot water contained 2.89% of water and those from cold, 3.59%; calc.: 0.5 H₂O, 2.05%; 1 H₂O, 4.02%.

The sulfone sodium sulfonate is far more soluble and reacts with mercaptans far more rapidly than the thio-ether sodium sulfonate.

To a boiling solution of 2 g. of this salt in 50 cc. of water, with 4 equivalents of sodium hydroxide, butyl mercaptan was added in slight excess. The butyl-thio-etheranthraquinone-butyl-sulfone separated immediately. The boiling was continued for a few minutes and the crystals were separated and washed with hot water. The yield was practically quantitative.

Analysis. Calc. for C₄H₉S.C₁₄H₆O₂.SO₂C₄H₉: S, 15.40. Found: 15.37.

Fuming nitric acid oxidized it to 1,5-dibutyl-anthraquinone-disulfone, m. p., 184.5°, as described by Reid, Mackall and Miller. Corresponding products were made from other mercaptans. Because of the volatility of methyl mercaptan the reactants were sealed in a tube which was then suspended in boiling water. The melting points of thioether-sulfones and the disulfones into which they were converted by oxidation are given in Table XV.

¹³ Fasbender, Ber., 20, 460 (1887).

TABLE XV

ALKYL THIO-ETHER-ANTHE	RAQUINON	ie-butyi	L-SULFON	es and	DISULFONES
Alkyl, R	Methyl	Ethyl	Propyl	Butyl	isoAmyl
RS.C14H6O2.SO2C4Hg, m. p., ° C.	228	214	201	162	152
SO CUHO SOCH m n ° C	264	104	220	184 3	5 203.5

This reaction, which takes place so quickly and with such high yields, offers an excellent means of identifying mercaptans. For some unknown reason, the melting points of the alkyl thio-ether-butyl-sulfones are not as sharp as is desirable but the disulfones into which they are readily oxidized are excellent derivatives for identification as they are readily purified and melt sharply.

Thiophenol reacts with the butyl-sulfone sodium sulfonate under the same conditions as the mercaptans, though the reaction is slower; yield, 80%. The compound was recrystallized from acetic acid and did not melt even at 350°.

Analysis. Calc. for C6H5S.C14H6O2.SO2C4Hg: S, 14.69. Found: 15.11.

The same reaction takes place with p-nitro-thiophenol though the product remains in solution in the excess of alkali from which it was precipitated by acidifying. The product was extremely insoluble and difficult to purify. It melted above 300° and contained 14.03% of sulfur; calc., 13.32%.

Several attempts were made to prepare the oxygen ether, $C_4H_9O.C_1_4H_9O.2.SO_2C_4H_9$, by using butyl alcohol instead of the mercaptan but no such compound could be obtained. Long boiling in alkaline solution does not give any appreciable amount of the hydroxy derivative.

Summary

The replacement of sulfonic acid groups in the anthraquinone-sulfonic acids has been further studied using benzyl, p-nitrobenzyl, and isopropyl mercaptans and mono- and dithio-ethylene glycols. All of these react, but the second and last do not give products that can be purified.

The *iso*propyl-thio-ethers can sometimes be oxidized to sulfones but usually go to the sulfonic acids.

When 1,5- butyl-thio-ethers-anthraquinone sodium sulfonate is oxidized, the corresponding butyl-sulfone sulfonate is obtained in quantitative yield. This reacts extremely rapidly with mercaptans to form 1,5-butyl-sulfone-anthraquinone alkyl thio-ethers. This reaction offers a ready method for the identification of mercaptans.

THE CONSTITUTION OF THE DICHLOROHYDROXY-ETHYLIDENE-BIS-NITRO-ANILINES

By Alvin S. Wheeler and Samuel C. Smith¹ Received May 23, 1923

In an attempt to reduce the 3 isomeric Schiff's bases obtained by the condensation of chloral and the nitro-anilines Wheeler and Glenn² noted that treatment of these bases with alcoholic potash produced a brilliant red compound. The red compound, however, on purification became yellow and analysis showed that 1 chlorine atom had been replaced by an hydroxyl group, according to the equation: $CCl_3CH(NHC_6H_4NO_2)_2$ + $KOH = CCl_2OHCH(NHC_6H_4NO_2)_2$ + KCl. Sodium methylate gave a product containing the methoxy group in place of a chlorine atom and more recently Wheeler and Smith³ prepared the ethoxy derivative, improved the general method of preparation by using acetone as the solvent for the reaction mixture and extended the reaction to o-nitro-aniline. The group now included the hydroxy, methoxy and ethoxy derivatives of the o- and p-nitro-anilines. No derivatives were obtainable from the Schiff base obtained from m-nitro-aniline.

Having lately some doubt as to the correctness of our idea in attaching the hydroxyl group to the carbon atom to which 2 chlorine atoms are already joined, we undertook a special study to determine the location of the hydroxyl group as well as the methoxy and ethoxy groups. No compounds are known that contain the hydroxyl group and chlorine attached to the same carbon atom. Such compounds, if formed, usually break up with the elimination of hydrogen chloride. In the compounds under review it seemed likely that the hydroxyl group had wandered to the α -carbon atom, producing a tertiary alcoholic group, thus,

$$\begin{array}{c|c} & & & & & & & & & \\ CCl_2OH & & & & & & \\ O_2N & & & NH-CH-NH & & NO_2 & & & NHC(OH)NH & & NO_2. \end{array}$$

We can readily imagine that the hydroxyl group momentarily takes the place of 1 of the 3 chlorine atoms attached to the β -carbon atom and then wanders to the α -carbon atom in order to form the more stable compound. In order to determine the position of the hydroxyl group the compound was decomposed with alkali. p-Nitro-aniline was readily identified among the decomposition products but no other compound of significance could

¹ This paper constitutes Part I of a thesis submitted in June, 1923, to the Faculty of the University of North Carolina by Samuel C. Smith in candidacy for the degree of Doctor of Philosophy.

² Wheeler and Glenn, J. Elisha Mitchell Sci. Soc., 19, 63 (1903).

² Wheeler and Smith, This Journal, 41, 1862 (1919).

be isolated. Concd. sulfuric acid gave a very small quantity of a liquid of strange odor. This liquid was not investigated. Fruitful results however were obtained when the substance was treated with hot 30% sulfuric acid. The compound dissolved and when the solution cooled crystals were deposited which after purification melted at 127°. Neutralization of the mother liquor with sodium hydroxide caused the precipitation of p-nitro-aniline, melting at 147°. The course of the reaction appeared to be: $O_2NC_6H_4NHC(OH)(CCl_2H)NHC_6H_4NO_2 \longrightarrow H_2SO_4$ \longrightarrow O₂NC₆H₄NHCOCCl₂H(p) + O₂NC₆H₄NH₂(p). The first product should be p-nitrodichloro-acetanilide. We could find no such anilide described in the literature, dichloro-acetanilide being the nearest to it. The preparation of the latter compound from dichloro-acetic acid and aniline requires the presence of phosphorus pentoxide.4 Using this method with dichloro-acetic acid and p-nitro-aniline we obtained p-nitrodichloroacetanilide which proved to be identical in physical and chemical properties with the decomposition product described above.

In view of the fact that this bis-nitro-aniline, as well as all of the others, splits easily, cleanly and quickly with dil. acid, giving in every case a product containing oxygen attached to the α -carbon atom, it seems clear that in these derivatives of Schiff's bases the hydroxyl and alkoxy groups are attached to the carbon atom which is joined to the nitrogen atoms. Since the acid decomposition of the alkoxy derivatives yields p-nitro-aniline (or ortho) and not the alkylated nitro-anilines, the reaction must be written: 5 CCl₂HCOCH₃(NHC₆H₄NO₂)₂ + H₂SO₄ = CCl₂HCONH-C₆H₄NO₂ + NH₂C₆H₄NO₂ + CH₃HSO₄.

Experimental Part

p-Nitrodichloro-acetanilide, CCl2HCONHC6H4NO2

(a) By Acid Decomposition of Dichlorohydroxy-ethylidene-bis-p-nitro-aniline.—Ten g. of the hydroxyethylidene compound (m. p., 178°) was dissolved in 40 cc. of the 30% sulfuric acid and then heated for 2 minutes with a direct flame. The solution was then diluted with an equal volume of water and allowed to cool thoroughly. A heavy deposition of crystals of the anilide occurred. These melted at 124° and weighed 80% of the calculated amount. Recrystallization was best effected with 50% alcohol, 80% of the crude product being recovered in a pure condition. This new acetanilide forms pale yellow needles; m. p., 127°; CCl₂HCOH(NHC₆H₄NO₂)₂ + H₂SO₄ = CCl₂HCONHC₆H₄NO₂ + NO₂C₆H₄NH₂.H₂SO₄. p-Nitrodichloro-acetanilide is unstable toward alkalies but very stable in the presence of acids. It may be dissolved in acids, including nitric, and is unchanged on reprecipitation. It is insoluble in water and soluble in acetone, alcohol, benzene and chloroform.

⁴ Cech, Ber., 10, 1265 (1877).

⁵ If phosphorous pentoxide is omitted in the reaction between dichloro-acetic acid and o-toluidine, the product contains 3 chlorine atoms and, therefore, is not dichloro-o-toluidide. This surprising result led to a study of the reaction between dichloro-acetic acid and a number of aromatic amines. Part II of Mr. Smith's thesis will deal with this unusual reaction. It will be published shortly. A. S. W.

Analysis. Subs., 0.3167: AgCl, 0.3694. Calc. for $C_8H_5O_3N_2Cl_2$ (mol. wt., 249) Cl, 28.51. Found: 28.85.

p-Nitro-aniline, the second product of the reaction, was readily isolated from the mother liquor by the addition of an excess of alkali, as yellow needles; m. p., 147°.

(b) By Acid Decomposition of Dichloromethoxy-ethylidene-bis-p-nitro-aniline.— The methoxy derivative (m. p., 177°) was treated in the same manner with hot 30% sulfuric acid. The insoluble product, after recrystallization from 50% alcohol, melted at 127° and consisted of yellow needles.

Analysis. Subs., 0.2556: AgCl, 0.2941. Calc. for $\dot{C}_8H_6O_5N_2Cl_2$ (mol. wt., 249): C1, 28.51. Found: 28.46.

 $CCl_2HCOCH_3(NHC_6H_4NO_2)_2 + H_2SO_4 = CCl_2HCONHC_6H_4NO_2 + NO_2C_6H_4NH_2 + C-H_3HSO_4$,

(c) By Acid Decomposition of Dichloro-ethoxy-ethylidene-bis-p-nitro-aniline.— The ethoxy derivative (m. p., 147°) was treated with sulfuric acid in the same manner and the same product, melting at 127°, was obtained.

Analysis. Subs., 0.2542: AgCI, 0.2919. Calc. for $C_8H_6O_3N_2Cl_2$ (mol. wt., 249): Cl, 28.51. Found: 28.41.

(d) By the Action of Dichloro-acetic Acid on p-Nitro-aniline.—To 5.0 g. of p-nitro-aniline was added 5.0 g. of phosphorus pentoxide and 5.0 g. of dichloro-acetic acid. The mixture was heated under a reflux condenser for 10 minutes. Cold water was added and the whole was well shaken. The crystalline product was separated and recrystallized from 50% alcohol as light yellow needles; m. p., 127°.

Analysis. Subs., 0.1422: AgCl, 0.1632. Calc. for $C_8H_6O_3N_2Cl_2$ (mol. wt., 249): Cl, 28.51. Found: 28.34.

o-Nitrodichloro-acetanilide, CCl2HCONHC6H4NO2

(a) By Acid Decomposition of Dichlorohydroxy-ethylidene-bis-o-nitro-aniline.—Five g. of the hydroxy derivative (m. p., 143°) was dissolved in 20 cc. of hot 30% sulfuric acid and heated for 2 minutes. An equal volume of water was added; as the solution cooled a liquid separated. When this was removed from the acid solution and washed well, it solidified. When an attempt was made to recrystallize it from alcohol, it separated again as an oil. However, it was obtained in crystallized condition by solution in alcohol, 70% strength, at 70° and cooling, as bright yellow plates; m. p., 70–72°.

Analysis. Subs., 0.0748: AgCl, 0.0866. Calc. for $C_8H_6O_3N_2Cl_2$ (mol. wt., 249): Cl. 28.51. Found: 28.64.

The compound is insoluble in water but soluble in acetone, alcohol, ether, benzene and chloroform. The yield was 70%. The ortho compound was also obtained by the action of hot sulfuric acid on the methoxy and ethoxy derivatives of o-nitro-aniline. In each case the product melted at $70-72^{\circ}$ and crystallized in bright yellow plates.

(b) By the Action of Dichloro-acetic Acid on σ-Nitro-aniline.—Five g. of σ-nitro-aniline was mixed with 5.0 g. of phosphorus pentoxide and 5.0 g. of dichloro-acetic acid. Much heat was generated. The mixture was heated for a few minutes longer, and then poured into 200 cc. of cold water, whereupon a heavy oil separated, which, after it had stood overnight, solidified; yield, 6 g. It forms yellow plates; m. p., 70–72°.

m-Nitrodichloro-acetanilide, CCl2HCONHC6H4NO2

Since trichloro-ethylidene-bis-m-nitro-aniline gives no hydroxy or alkoxy derivatives with basic reagents we could only use the direct method for preparing the meta compound. Equal amounts of m-nitro-aniline, phosphorus pentoxide and dichloro-acetic

⁶ Ref. 3, p. 1864.

acid were heated together. The product separated as an oil when the mixture was poured into water, but it solidified after standing a day. The crude product was light brown and melted at 65°. Purification by alcohol raised the melting point to 103°. It crystallizes in almost colorless needles, that are soluble in acetone, alcohol, ether, benzene or chloroform.

Analysis. Subs., 0.1591: AgCl, 0.1849. Calc. for $C_8H_6O_3N_2Cl_2$ (mol. wt., 249): Cl, 28.51. Found: 28.75.

Summary

- 1. The three new nitrodichloro-acetanilides were prepared.
- 2. The p-compound appeared as a decomposition product when dichlorohydroxy-ethylidene-bis-p-nitro-aniline was treated with hot dil. sulfuric acid. Its production established the location of the hydroxyl group on the α -carbon. The methoxy and ethoxy derivatives gave the same anilide.
 - 3. The o-nitrodichloro-acetanilide was similarly obtained.
- 4. The *ortho* and *para* compounds were also obtained by the action of dichloro-acetic acid on the nitro-anilines in the presence of phosphorus pentoxide.
- 5. The *meta* isomer could be obtained only by the direct method since the hydroxy and alkoxy derivatives of trichloro-ethylidene-bis-*m*-nitro-aniline cannot be prepared

MERCURATED 1-METHYL-1,2-DIHYDRO-BENZOFURANS

By Lindley E. Mills with Roger Adams¹ Received May 24, 1923

In a recent paper by Roger Adams, F. L. Roman and W. N. Sperry,² involving a discussion of the structure of compounds produced from olefins and mercury salts, it was shown that mercury salts and *o*-allylphenol reacted readily to give mercurated 1-methyl-1,2-dihydro-benzofurans according to the following equation.

$$\begin{array}{c}
\text{OH} \\
\text{CH}_2\text{CH} = \text{CH}_2
\end{array}
\rightarrow
\begin{array}{c}
\text{OH} \\
\text{CH}_2\text{CH} \times \text{CH}_2\text{HgX}
\end{array}
\rightarrow
\begin{array}{c}
\text{CHCH}_2\text{HgX} + \text{HX}
\end{array}$$

A study of the preparation of the corresponding compounds from mercury salts and substituted o-allylphenols, and a study of their chemical reactions had been made. In view of the fact that the mercurated 1-methyl-1,2-dihydro-benzofurans, in contrast to the compounds from mercuric salts

¹ This communication is an abstract of a thesis submitted by L. E. Mills in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry at the University of Illinois.

² Adams, Roman and Sperry, This Journal, 44, 1781 (1922).

and other olefins, are unusually stable toward hydrochloric acid, a comparison of the chemical reactions of these compounds with the chemical reactions of the alkyl mercuric halides and with the chemical reactions of the compounds from simple olefins and mercuric salts was of especial interest.

It has been shown that the addition of mercuric salts to *o*-allylphenols is a general one. Mercuric acetate and mercuric chloride react readily with the following compounds: 2-allyl-4-methylphenol, 2-allyl-5-methylphenol, 2-allyl-6-methylphenol, 2-allyl-4-bromophenol, 2-allyl-4-carboxyphenol, 2-allyl-6-carboxyphenol, 2-allyl-6-carboxyphenol and 2-allyl-4-carboxyvinylene-phenol. The only difference noticed among any of the reactions is the speed with which they take place. The yields are almost quantitative in every reaction.

The acetoxy or chloromercurimethyl-1,2-dihydro-benzofurans show the usual reactions of various types of acetoxy and chloromercuri compounds with solutions of bromides or iodides, giving the corresponding bromoor iodomercuri compounds. No mercuri-bis compounds or compounds free from mercury are formed by the action of iodides.³

The 1-halogen-mercurimethyl-1,2-dihydro-benzofurans react with the greatest ease with both alcoholic potassium cyanide and alcoholic potassium thiocyanate to yield the corresponding cyanomercuri or thiocyanatemercuri compounds. It is impossible by longer refluxing with excess of reagent to convert these into the corresponding mercury-bis compounds.

$$\begin{array}{c} O \\ CHCH_2HgCl + MX \longrightarrow \begin{array}{c} O \\ CHCH_2HgX + MCl \\ CH_2 \end{array} \\ \text{where X = Br, I, SCN, CN.} \end{array}$$

This behavior of the 1,2-dihydro-benzofurans is in contrast to that of alkyl mercuric halides which generally give mercury-bis compounds, and to that of the compounds obtained from mercuric salts and olefins which lose their mercury entirely under such treatment, giving the original unsaturated compound.⁴ It is interesting to note that 2,5-dinitratemercurimethyl-dioxane

with the mercurated dihydro-benzofurans under consideration not only is stable to acid but also yields a dicyanomercuri compound by the action of aqueous potassium cyanide.⁵

The 1-hydroxymethyl-1,2-dihydro-benzofurans are readily obtainable from the corresponding chlorides by the action of absolute alcoholic sodium hydroxide. The sodium chloride is filtered and the alcoholic filtrate is concentrated to obtain the hydroxymercuri compounds. These substances are crystalline solids and have the expected property of being readily neutralized by all types of organic or inorganic acids such as hydrochloric, sulfuric, tartaric, oxalic, p-nitrobenzoic acids, etc. The hydroxymercuri compounds precipitate insoluble metallic hydroxides such as cupric hydroxide from neutral solutions of their salts.

Most aliphatic hydroxymercuri compounds recorded in the literature have been obtained from the corresponding bromides or iodides by the action of moist silver oxide. The present experiments suggest a better method for making these compounds. The mercury dialkyls made by the method of Marvel⁶ and others, when treated with mercuric chloride in alcohol, give quantitative yields of alkyl mercuric chlorides. When these are treated with sodium hydroxide in absolute alcohol, the corresponding hydroxides should be formed. This method has been tested in the case of methyl mercuric chloride with perfect success. Presumably, any of the series could be formed similarly.

The 1-halogen-mercurimethyl-1,2-dihydro-benzofurans react with an alkaline solution of sodium stannite to give an immediate precipitate of metallic mercury and a quantitative yield of the corresponding allylphenol. No indication of an intermediate mercury compound was noted. The reaction of alkaline sodium stannite with both alkyl mercury salts and compounds of mercuric salts and olefines is usually to give compounds of the mercuri-bis type and metallic mercury. No previous example could be found in the literature in which mercury is completely removed from an organic mercury compound by means of sodium stannite.

The 1-halogen-mercurimethyl-1,2-dihydro-benzofurans react instantaneously with ammonium sulfide, potassium hydrosulfide or hydrogen sulfide in dil. acid solution to give quantitative yields of the corresponding allylphenol and mercuric sulfide. No intermediate organic mercuri sulfides were isolated. This reaction is in contrast to the action of sulfides upon alkyl mercuric salts which almost invariably form organic mercuri sulfides of varying stability; these decompose to mercury-bis compounds and mercuric sulfide. The su fide reagents react in different ways with compounds from olefins and mercuric salts; a complex organic mercuri sulfide may be formed, the mercuri grouping may be replaced by hydrogen, or the original unsaturated compound may be regenerated, this latter

⁶ Marvel and Gould, This Journal, 44, 153 (1922). Marvel and Calvery, ibid., 45, 820 (1923).

⁷ Dimroth, Chem. Zentr., 1901, I, 451. Ref. 5c.

reaction being analogous to that observed with the 1-halogen-mercuri-methyl-1,2-dihydro-benzofurans.8

Sodium thiosulfate is a reagent that has been used frequently for converting aromatic organic mercuric salts to the corresponding mercury-bis compounds. Very frequently an intermediate sodium thiosulfate-mercuri compound of the general formula RHgSSO₂Na has been isolated. Nothing could be found in the literature, however, on the action of sodium thiosulfate upon alkyl mercuric halides or upon compounds from olefins and mercuric salts. By treating 1-chloromercurimethyl-1,2-dihydro-benzofurans with a cold saturated solution of sodium thiosulfate, a 1-sodium thiosulfate-mercurimethyl-1,2-dihydro-benzofuran is obtained. The product darkens in the air in a few minutes and decomposition is complete within a few hours; when the substance is heated the decomposition is made much more rapid. Red mercuric sulfide and the corresponding allylphenol are formed. The compounds in general are so unstable that even recrystallization from water is impossible without decomposition.

The only reagent tested which converts the 1-halogen-mercurimethyl-1,2-dihydro-benzofurans into the corresponding mercury-bis compounds is sodium amalgam and alcohol. In the preliminary paper it was mentioned that 1-chloromercurimethyl-1,2-dihydro-benzofuran was converted readily to the corresponding mercury-bis compound in this way. It has now been found that other derivatives, such as the 1-chloromercurimethyl-4-methyl-1,2-dihydro-benzofuran, react in a similar manner under the same conditions. Sodium amalgam-alcohol also converts alkyl mercuric halides into mercury-bis compounds.

The mercurated 1-methyl-1,2-dihydro-benzofurans are unaffected by boiling with methyl iodide or acetyl chloride. Alkyl halides do not react with these reagents, but compounds from olefins and mercuric salts react with alkyl halides to regenerate the original olefin and with acetyl chloride to yield the acetyl derivative of the hydroxyl group without affecting the substituted mercury radical.⁹

The 1-halogen-mercurimethyl-1,2-dihydro-benzofurans react with 2 atoms of bromine in cold chloroform suspension to yield a precipitate of mercuric salts and a solution containing 1-bromomethyl-1,2-dihydro-benzofuran. Under these conditions no hydrogen bromide is evolved, although when the proper precautions as regards temperature are not followed, hydrogen bromide is evolved and probably bromination in the benzene ring takes place.

It is obvious from the comparative reactions that have been made that

⁸ Whitmore, "Organic Compounds of Mercury," Chemical Catalog Co., 1921, pp. 50-53.

⁹ Ref. 4, p. 1349. Ref. 5b, p. 1393. Kutscheroff, Ber., 17, 21 (1884).

the mercurated-methyl-1,2-dihydro-benzofurans resemble in many of their reactions the alkyl mercuric halides, and in many others the compounds from olefins and mercuric salts. In some of the reactions such as those with potassium thiocyanate, potassium cyanide, sodium thiosulfate and sodium stannite, they may be said to stand midway between the two classes.

The reactions of these mercurated-1-methyl-1,2-dihydro-benzofurans, as described above, certainly offer still further convincing evidence that the compounds are not "molecular" substances but actually true addition compounds as suggested and discussed in the preliminary paper.

Experimental Part

The o-allylphenols used in this investigation were prepared according to the directions of Claisen.¹⁰ The 2-allyl-4-carboxyvinylene-phenol was prepared according to the same general procedure, and the details are given in the latter part of the experimental section.

The method of analysis for mercury in the various compounds was similar to that described in the preliminary article. A few minor details were changed; silver nitrate was standardized against very pure mercuric chloride in the same way as it was titrated in the analyses for mercury in the organic compounds. The mercuric chloride had been resublimed several times and was analyzed gravimetrically. Another slight change was that the solution containing the precipitate of mercuric sulfide was heated almost to boiling and hydrogen sulfide passed in again for a few minutes just before filtration.

General Method for the Preparation of Substituted 1-Mercurimethyl-1,2-dihydro-benzofurans.—To a solution of 1 molecular equivalent of mercuric acetate or mercuric chloride in water, 10 g. of a substituted oallylphenol was added slowly while the mixture was vigorously stirred. With the mercuric chloride a saturated solution was used, with the acetate about 10 g. of salt in each 100 cc. of water. When mercuric acetate was used, the time of addition was from 1/2 to 1 hour and stirring was continued for several hours longer to insure completion of the reaction. When mercuric chloride was used the substituted o-allylphenol was added slowly and a flocculent precipitate of product was formed. In the case of oallylphenol itself a rate of 4 to 5 drops per minute was found to give the best results. In the case of the substituted o-allylphenols it was found more convenient to add the phenol during a period of 1 hour and then to continue the stirring until the heavy oil solidified. Stirring was then discontinued and the solid material pulverized with a stirring rod and the mixture stirred again. Six to 8 hours was usually required for the complete procedure when 2-allyl-4-methylphenol, 2-allyl-5-methylphenol or

¹⁰ Claisen and Eisleb, Ann., 401, 21 (1913).

2-allyl-6-methylphenol was used, as compared to 3 hours for 2-allylphenol itself. The 2-allyl-4-bromophenol required 10 hours. The 2-allyl-6-carbomethoxyphenol required 15 hours' stirring and 2 days' standing. In the case of 2-allyl-4-carboxyphenol, 2-allyl-6-carboxyphenol and 2-allyl-6-carboxyvinylene-phenol the best results were obtained by adding just enough sodium hydroxide to a suspension of the carboxyphenol in water to dissolve it and then adding an aqueous solution to the theoretical amount of mercuric chloride. In each case a precipitate of the desired product began to form immediately and was complete in a few minutes.

With the exception of mercuric acetate with 2-allyl-5-methylphenol, 2-allyl-4-methylphenol and with 2-allyl-4-bromophenol, all of the compounds obtained were solids. The three just mentioned were obtained as oils and did not solidify under the conditions used. Their conversion, however, by treatment with sodium halide into the corresponding halogen mercury compounds, indicated without question that an addition had taken place.

The solid compounds were white and well crystallized. They were purified from alcohol, except 1-chloromercurimethyl-6-carbomethoxy-1,2-dihydro-benzofuran, for which methyl alcohol was used.

The 1-chloromercurimethyl-6-methyl-, 1-chloromercurimethyl-5-methyl-, 1-chloromercurimethyl-4-methyl-, and the 1-chloromercurimethyl-4-bromo-

1,2-dihydro-benzofurans described in the following table were made not only by addition of mercuric chloride to the proper o-allylphenol, but also by the treatment of the corresponding acetate with sodium chloride solution according to the general method described immediately after Table I.

General Method for the Conversion of 1-Chloromercuri- or 1-Acetoxy-mercuri-methyl-1,2-dihydro-benzofurans into the Corresponding Bromides and Iodides.—A solution of 5 g. of the chloromercuri- or acetoxy-mercurimethyl-1,2-dihydro-benzofuran in absolute alcohol was mixed with a boiling, absolute alcohol solution of 1 molecular equivalent of potassium halide. As the mixture cooled the halogen mercury compound separated. After this was washed with water to remove the potassium salts, it was necessary to make one recrystallization from alcohol in order to obtain a pure product.

The conversion of the acetoxymercuri compounds to the corresponding chlorides, bromides or iodides, took place more readily than the conversion of the chloromercuri compounds to bromides or iodides. It was often unnecessary to heat the reaction mixture in order to effect the former conversions.

The same reaction could be carried out by dissolving or suspending 5 g. of the acetoxy or chloromercuri compounds in 200 cc. of water and then heating the mixture for about an hour on a water-bath with an aqueous solution of 1 molecular equivalent of potassium halide. As the reaction mixture cooled the precipitate solidified; it was separated, washed and recrystallized from alcohol.

1-Hydroxymercurimethyl-1,2-dihydro-benzofurans.—From a solution of 10 g. of the substituted 1-chloromercurimethyl-1,2-dihydro-benzofuran in 1 molecular equivalent of sodium hydroxide in 50 cc. of warm absolute

ethyl alcohol, sodium chloride immediately precipitated. The solution was filtered and evaporated to half its volume and then cooled slowly. It was finally allowed to remain in an ice-salt mixture for several hours, and the sides of the beaker were rubbed vigorously from time to time with a glass rod. Crystallization gradually took place and the crystals were separated, washed with a small amount of cold alcohol and dried. They were then recrystallized in the same manner from 95% alcohol.

The hydroxymercuri compounds were readily soluble in most organic solvents but only slightly soluble in water, giving solutions which were slightly alkaline to litmus.

All the hydroxymercuri compounds studied were very readily soluble in alcohol, tended to form supersaturated solutions and then to precipitate as oils. By following the procedure indicated above, white crystalline solids were obtained except in the case of 1-hydroxymercurimethyl-6-methyl-1,2-dihydro-benzofuran, which was obtained only as an oil. The yields of the hydroxymercuri compounds were quantitative.

1-Hydroxymercurimethyl-1,2-dihydro-benzofuran was also obtained in 80% yield by refluxing 5 g. of 1-chloromercurimethyl-1,2-dihydro-benzofuran with the calculated amount of moist, freshly precipitated silver oxide in 75 cc. of ethyl alcohol.

Mercurated 1,2-Dihydro-benzofurans by Neutralization of the Hydroxymercuri Derivatives with Acids.—When alcoholic or aqueous solutions of 1-hydroxymercurimethyl-1,2-dihydro-benzofurans were neutralized with dil. hydrochloric acid, the corresponding chloromercuri compounds were precipitated. For the preparation of the organic acid salts the hydroxymercuri compounds were dissolved in hot alcohol and the solution was then diluted with hot water, the amount added being insufficient to cause the precipitation of any of the mercury compound. A hot alcoholic or aqueous alcoholic solution of the proper acid was then added until a faint acid reaction to litmus was obtained. The solution was allowed to cool and was filtered. The precipitated products were recrystallized from alcohol in which they were somewhat soluble when hot and practically insoluble when cold. All of the salts were well-crystallized solids.

The p-nitrobenzoates of the mercury compounds were yellow but all the others were white.

1-Cyanomercurimethyl and 1-Thiocyanate-mercurimethyl Derivatives of Substituted 1,2-Dihydro-benzofurans.—Into a hot saturated solution of 1 molecular equivalent of potassium cyanide or potassium thiocyanate in absolute alcohol, was stirred 10 g. of powdered 1-chloromercurimethyl-1,2-dihydro-benzofuran. An immediate precipitation of potassium chloride occurred. After a few minutes the mixture was filtered and the filtrate allowed to cool. The cyanomercuri or thiocyanatemercuri compound crystallized. Upon filtering and concentrating the filtrate, or upon pouring it into water a further quantity of the material was obtained. These substances are readily purified from alcohol, forming white crystals. The yield in every case was almost quantitative.

1-Sodiumthiosulfate-mercurimethyl-1,2-dihydro-benzofuran.—Just enough water was added to 10 g. of finely ground 1-chloromercurimethyl-1,2-dihydro-benzofuran to moisten it, and the latter was then quickly and thoroughly stirred into a hot saturated solution of 3.4 g. of sodium thiosulfate in water. A large amount of the material turned black because of the formation of mercuric sulfide. The mixture was immediately filtered hot by gentle suction and the filtrate cooled. Glistening white scales of the sodium salt separated. These were separated and dried on a porous plate.

Analysis. Subs., 0.2184: 18.61 cc. of 0.02608 N AgNO₃. Calc. for C₃H₉HgO₄S₂-Na: Hg, 44.90. Found: 44.75.

This compound was also prepared by triturating together the same quantities of materials in the cold for a few minutes and then filtering and washing with a very small amount of cold water. The product weighed 11 g., which is about a 92% yield. No method for recrystallization was found.

It is very soluble in hot water, decomposing into mercuric sulfide and o-allylphenol. After the original reaction mixture had been warmed on the steam-bath for 2 hours the decomposition of the intermediate sodium salt was complete. The sulfide was filtered and washed well with acetone. The mixture of the washings and the filtrate was extracted with ether and dried with calcium chloride. A yield of 2.9 g. of o-allylphenol, or 87%, was obtained from 10 g. of 1-chloromercurimethyl-1,2-dihydro-benzofuran.

When heated, the salt turned dark at about 120°. At ordinary temperatures the decomposition proceeded more slowly. The crystals began to darken after a few minutes and were completely decomposed after about 12 hours. All the experiments in which the decomposition took place at room temperature gave rise to the red modification of mercuric sulfide.

1-Sodiumthiosulfate-mercurimethyl-4-methyl-1,2-dihydro-benzofuran.—This substance was prepared in the same way as was the preceding compound which it resembled closely in properties. The yield by the hot method was low, by the cold method almost quantitative. The properties of the product were identical with those of the previous compound.

Analysis. Subs., 0.2491: 20.52 cc. of 0.02618 N AgNO₃. Calc. for $C_{10}H_{11}HgO_4$ -S₂Na: Hg, 43.53. Found: 43.25.

When the reaction mixture was warmed for 2 hours and the 2-allyl-4-methylphenol recovered as in the previous case of o-allylphenol, an 85% yield was obtained.

Reaction of 1-Chloromercurimethyl-1,2-dihydro-benzofurans with Alkaline Sodium Stannite Solution.—An alkaline solution of sodium stannite was prepared by dissolving 3 g. of stannous chloride crystals in 50 cc. of water and then adding 50% more of 10% sodium hydroxide solution than was sufficient just to dissolve the precipitate. A thin paste of 5 g. of 1-chloromercurimethyl-1,2-dihydro-benzofuran and water was then slowly stirred in. A gray precipitate of mercury was formed immediately. After the liquid had been warmed on the steam-bath for a few minutes it was decanted, made acid with dil. hydrochloric acid and extracted with ether. The ether solution was dried over calcium chloride and the ether distilled. There was obtained 1.4 g. or an 83% yield of o-allylphenol.

A yield of 85% of 2-allyl-4-methylphenol was obtained from 5 g. of 1-chloromercurimethyl-4-methyl-1,2-dihydro-benzofuran by the same procedure.

Reaction of 1-Chloromercurimethyl-1,2-dihydro-benzofurans with Sulfides. WITH HYDROGEN SULFIDE.—A suspension of 5 g. of finely ground 1-chloromercurimethyl-1,2-dihydro-benzofuran was made in 100 cc. of water containing 2 cc. of coned. hydrochloric acid and the solution shaken frequently while being saturated with hydrogen sulfide. The precipitate of mercuric sulfide was allowed to settle and the liquid decanted. The mercuric sulfide was washed thrice with acetone by decantation and the washings were added to the liquid first decanted. After extraction with ether there was obtained 1.3 g. or a 77% yield of o-allylphenol. Similar treatment of 1-chloromercurimethyl-4-methyl-1,2-dihydro-benzofuran gave an 85% yield of 2-allyl-4-methylphenol.

With Ammonium Sulfide.—Ten g. of 1-chloromercurimethyl-1,2-dihydro-benzofuran was suspended in 100 cc. of water containing 5 cc. of concd. ammonium hydroxide (d., 0.90) and saturated for 1 hour with hydrogen sulfide while it was shaken frequently. The mercuric sulfide was separated and the o-allylphenol recovered as in the preceding case; yield, 3.2 g., or 90%. A similar result was obtained with the 4-methyl derivative.

WITH POTASSIUM HYDROSULFIDE.—To 5 g. of 1-chloromercurimethyl-1,2-dihydro-

benzofuran suspended in 100 cc. of water was added slowly with stirring a solution containing 2 g. of potassium hydrosulfide in 50 cc. of water. The precipitated mercuric sulfide was filtered and the o-allylphenol recovered as in the preceding case. The yield was 1.5 g., or 89%. This reaction was also carried out in absolute alcohol with similar results.

In no case was any intermediate organic mercuric sulfide isolated. The initial precipitate in each instance was black. It was noted that upon first forming, the precipitate was somewhat bulky and flocculent, indicating the possible formation of a very unstable organic mercuri sulfide. This precipitate became granular after it had stood for a few minutes.

1,1-Mercuridimethylenebis-(4-methyl-1,2-dihydro-benzofuran).—A mixture of 15 g. of 1-chloromercurimethyl-4-methyl-1,2-dihydro-benzofuran and 100 cc. of absolute alcohol was placed in a 200 cc. round-bottom flask and refluxed with 1.5 g. of sodium in the form of a 3% amalgam in exactly the same manner as directed for 1-chloromercurimethyl-1,2-dihydro-benzofuran in the preceding paper.² The product was purified by crystallization from ether. The yield was 5.5 g. of pure white crystals, or 35%; m. p., 89.5° .

Analysis. Subs., 0.2174: 15.07 cc. of 0.02618 N AgNO₅. Calc. for $C_{20}H_{22}O_2Hg$: Hg, 40.53. Found: 40.37.

Reaction of 1-Chloromercurimethyl-1,2-dihydro-benzofuran with Methyl Iodide and Acetyl Chloride.—A mixture of 10 g. of 1-chloromercurimethyl-1,2-dihydro-benzofuran and 10 g. of methyl iodide in 75 cc. of absolute alcohol was refluxed for 4 hours. As the mixture cooled, 93% of the unchanged chloromercurimethyl compound crystallized.

A mixture of 10 g. of 1-chloromercurimethyl-1,2-dihydro-benzofuran and 2.2 g. of redistilled acetyl chloride in chloroform was refluxed. After the solution had cooled, the precipitate that formed was found to consist of 9.6 g. of the unchanged chloromercurimethyl compound.

Reaction of 1-Chloromercurimethyl-1,2-dihydro-benzofuran with Bromine.—A suspension of 10 g. of 1-chloromercurimethyl-1,2-dihydro-benzofuran in 50 cc. of carbon tetrachloride was made, and 4.5 g. of bromine in carbon tetrachloride solution was added slowly at 0° to 5°. The bromine was decolorized immediately, and no evolution of hydro-bromic acid was noted. The mixture was filtered and the precipitate washed with a little carbon tetrachloride and dried. The weight of the precipitate was 7.8 g. corresponding to a 91% yield based on the amount of mixed chloride and bromide of mercury. The carbon tetrachloride solution was evaporated on the water-bath, when there was obtained 5.7 g. or 96% of the calculated amount of light brown, viscous oil, which boiled at 140–143° (20 mm.), showing it to be 1-bromomethyl-1,2-dihydro-benzo uran. 11

When more than 4.5 g. of bromine was added, hydrogen bromide was evolved, and a total of 4 atoms of bromine was absorbed before immediate decolorization ceased, indicating bromination in one position in the ring. No attempt was made to identify the bromination product.

Solution of 1-Chloromercurimethyl-6-carboxy-1,2-dihydro-benzofuran in Sodium Hydroxide.—A suspension of $0.3185\,\mathrm{g}$. of the 6-carboxy compound in 50 cc. of water was titrated with $0.103\,N$ sodium hydroxide solution. For complete solution $15.2\,\mathrm{cc}$. was required. A faint alkaline reaction to litmus resulted. This is almost exactly 2 molecular equivalents of sodium hydroxide. Upon titration of the solution with $0.0952\,N$ hydrochloric acid, no permanent precipitate was observed until $8.2\,\mathrm{cc}$. (8.1 cc. = 1 molecular equivalent) had been added. After a total of $16.5\,\mathrm{cc}$. had been added, precipitation was complete and the solution was filtered. The filtrate contained no mercuric ions.

Methyl Mercuric Hydroxide from Methyl Mercuric Chloride and Sodium Hydroxide.—A solution of 10 g. of methyl mercuric chloride in 75 cc. of warm absolute

¹¹ Adams and Rindfusz, This Journal, 41, 655 (1919).

methyl alcohol was treated with 1.6 g. of sodium hydroxide in 16 cc. of absolute methyl alcohol. An immediate precipitate of sodium chloride was formed. An equal volume of dry ether was added to complete the precipitation of the sodium chloride and the mixture filtered. The precipitate weighed 2.4 g. which is 100% of the calculated amount of sodium chloride. Upon evaporation of the ether and alcohol from the filtrate at room temperature in a vacuum there remained 8.3 g. of grayish-white crystals which melted at 95° after one precipitation from methyl alcohol by means of ether, proving the product obtained to be methylmercuric hydroxide. Dil. hydrochloric acid converted the hydroxide instantaneously into methylmercuric chloride.

4-Allyloxy Methyl Cinnamate: (p)CH₂—CH—CH₂OC₆H₄CH—CHCO₂CH₃.—A mixture of 25.3 g. of the methyl ester of p-cumaric acid, ¹³ 18 g. of allyl bromide, 21 g. of anhydrous potassium carbonate and 30 g. of acetone was refluxed on the steam cone. The completion of the reaction was determined by withdrawing a sample, diluting it with ether, extracting this with dil. sodium hydroxide solution and neutralizing the sodium hydroxide layer with dil. hydrochloric acid. A precipitate indicated the presence of unchanged p-cumaric acid. When the mixture was poured into 400 cc. of cold water the 4-allyloxymethyl cinnamate separated and was recrystallized from 80% alcohol. The yield was 22.5 g. or 73%. The material formed white, glistening plates melting at 65.5°.

Analysis. Subs., 0.3231: 495.8 cc. of CO_2 (25.5°, 725.9 mm.). Calc. for $C_{13}H_{14}O_3$: C, 71.52. Found: 71.83.

3-Allyl-4-hydroxy Methyl Cinnamate: $3-(CH_2-CHCH_2)4-(HO)C_0H_3CH-CHCO_2-CH_3$.—When 8.5 g. of the allyl ether of methyl p-coumarate was heated under a reflux condenser in an oil-bath for 2 hours at 230–245°, rearrangement took place. The ambercolored residue was dissolved in ether, extracted with 10% sodium hydroxide solution and the alkaline solution run into dil. hydrochloric acid at 0° . 3-Allyl-4-hydroxy methyl cinnamate separated as a brown, soft mass which gradually hardened after a few hours' exposure to the air. This substance was not purified further but was used directly in the preparation of the free acid. The yield was 7 g. of crude material.

3-Allyl-4-hydroxycinnamic Acid, 3-(CH₂=CHCH₂)4-(HO)C₆H₃CH=CHCO₂H.—A solution of 4 g. of the crude 3-allyl-4-hydroxy methyl cinnamate in 25 cc. of 10% sodium hydroxide solution was refluxed gently for 4 hours. The mixture was then poured slowly into dil. hydrochloric acid at 0°. The precipitate was filtered, washed with water, dried, dissolved in ether and extracted with 10% sodium bicarbonate solution. The aqueous solution was poured into cold dil. hydrochloric acid solution and the precipitate recrystallized from 80% alcohol. The yield was 2.1 g. of pure white crystals, m. p. 169°, and 0.5 g. of impure crystals, or a total of 63%.

Analysis. Subs., 0.2409: 361.2 cc. of CO_2 (25.5°, 725.9 mm.). Calc. for $C_{12}H_{12}$ - O_3 : C, 70.57. Found: 70.22.

Summary

- 1. The addition of mercuric salts to o-allylphenols has been shown to be a general one. Several substituted o-allylphenols have been treated with mercuric salts with the formation of mercurated-methyl-1,2-dihydro-benzofurans.
- 2. The reactions of these compounds have been extensively studied and compared with the reactions of alkyl mercuric halides and compounds from mercuric salts and olefins.
 - 3. The 1-acetoxy- or 1-halogen-mercurimethyl-1,2-dihydro-benzofurans
 - 12 Sneed and Maynard, This Journal, 44, 2946 (1922).
 - 13 Fischer and Nouri, Ber., 50, 619 (1917).

react with alcoholic or aqueous sodium or potassium bromide or iodide to give the corresponding bromo- or iodomercuri compounds; with alcoholic potassium cyanide and alcoholic potassium thiocyanate, to give the corresponding cyanomercuri or thiocyanatemercuri compounds. In none of these reactions was it possible with excess of reagent to convert the compounds into mercury-bis derivatives.

- 4. The 1-chloromercurimethyl-1,2-dihydro-benzofurans react readily with potassium or sodium hydroxide in alcohol to give the corresponding hydroxymercuri compounds and sodium or potassium chloride. The method is apparently general for alkyl mercuric chlorides since methyl mercuric chloride was converted to methylmercuric hydroxide by a similar procedure. The 1-hydroxymercurimethyl-1,2-dihydro-benzofurans react with acids to form the corresponding salts and, in general, show the typical reactions of any of the known hydroxymercuri compounds.
- 5. The 1-halogen-mercurimethyl-1,2-dihydro-benzofurans react with sodium stannite to give a quantitative yield of the corresponding allylphenol and metallic mercury.
- 6. The 1-halogen-mercurimethyl-1,2-dihydro-benzofurans react with ammonium sulfide, potassium hydrosulfide or hydrogen sulfide in dil. acid solution to give quantitative yields of the corresponding allylphenols and mercuric sulfide.
- 7. The 1-halogen-mercurimethyl-1,2-dihydro-benzofurans react with sodium thiosulfate to give 1-sodiumthiosulfate-mercurimethyl-1,2-dihydro-benzofurans which are unstable compounds decomposing readily into mercuric sulfide and the corresponding allylphenol.
- 8. The 1-halogen-mercurimethyl-1,2-dihydro-benzofurans react with sodium amalgam and alcohol to give the corresponding mercuri-bis compounds.
- 9. The 1-halogen-mercurimethyl-1,2-dihydro-benzofurans do not react with methyl iodide or acetyl chloride.

URBANA, ILLINOIS

NEW BOOKS

History of Chemistry. By Francis Venable, LL.D. D. C. Heath and Company, Boston, New York, Chicago, 1922. vii + 168 pp. 19 × 13 cm. Price, \$1.60.

The perusal of this little volume has brought genuine pleasure to the reviewer. The author's profound knowledge of his subject and his long experience as a teacher have enabled him to present the essentials to the earnest student in such a simple and attractive fashion that these essentials will be readily grasped and easily understood.

To teachers, in the exposition of the history of chemistry, this little book will serve as a nucleus about which to develop a more comprehensive course. It is, indeed, a book full of texts, upon any one of which splendid elaborations are readily possible.

The layman also will find in it things he will wish to know regarding the gradual development of the science which, in the process of its upbuilding, has touched him on so many sides.

The first edition of the book appeared in 1894, followed by many more until the present one, which has been entirely re-written and now appears in a new dress, covering the great advances made in the science in the years which have elapsed since it first ventured forth as an American contribution in this interesting field.

EDGAR F. SMITH

Thermodynamics and the Free Energy of Chemical Substances. By Gilbert Newton Lewis, Professor of Chemistry in the University of California, and Merle Randall, Associate Professor of Chemistry in the University of California. McGraw-Hill Book Company, Inc., 370 Seventh Avenue, New York City; 6 and 8 Bouverie Street, E. C. 4, London; 1923. xxiii + 653 pp. Illustrated. 23.5 × 15 cm. Price \$5.00.

Thermodynamics, as sciences go, is venerable. The patient labor of a multitude of students and the genius of many great minds have given to it a generality, a simplicity, and a refinement of form which constitute beauty. Although austere in aspect by reason of this very perfection, thermodynamics is none the less a handy tool for daily use, a succinct language and an illuminating philosophy of natural science. As the authors of this book say in their dedication, "The fascination of a growing science lies in the work of the pioneers at the very borderland of the unknown, but to reach this frontier one must pass over well travelled roads; of these one of the safest and surest is the broad highway of thermodynamics." Finally, thermodynamics though venerable is still rapidly growing, and its new advances promise an even wider outlook and greater usefulness.

This treatise by Lewis and Randall succeeds to a remarkable degree in presenting, with elegance and yet with freshness, all these aspects of thermodynamics. It is not a textbook in the ordinary sense of the term. As the authors say, "Our book is designed rather as an introduction to research, and as a guide to anyone who wishes to use thermodynamics in productive work." It is divided into three parts, "of which the first treats of the foundations of thermodynamics, the second deals with the special methods of applying the fundamental principles to chemical problems, and the third is devoted to a systematic consideration of the data of thermodynamic chemistry."

The authors use very little mathematics and, besides, give a clear preliminary exposition of this, so that the non-mathematical reader need have no fears. The authors have made such a sane and illuminating statement on this subject that it is worth quoting in full,

This book is the fruition, or culmination of a long series of brilliant researches which Lewis and his students or collaborators have carried out, and which already have been, for the most part, published in This Journal. Naturally, therefore, the authors have drawn largely upon these researches for the illustration and elucidation of their theories. Indeed, we can imagine that Europeans, not appreciating this, may feel that their own achievements have been given too scanty recognition; but this should serve as a useful corrective to many French and German treatises which leave the reader with the impression that the science under discussion is an exclusively Gallic or Teutonic one!

To facilitate mastery of the subject by the isolated and independent student, numerous problems, many of a numerical nature, have been introduced. This is excellent pedagogy. I regret that the authors have not given answers to the numerical problems, for it is my experience that the confidence which a student gains from knowing that he has achieved the correct solution of a problem is of very great value.

"Thermodynamics" is a capital book; clear, vigorous, convincing, and interesting. It is alive throughout with scientific curiosity and enthusiasm. It will broaden the insight and heighten the ardor of its readers. It will be a guide and an inspiration.

ARTHUR B. LAMB

Chemistry. The Science of Matter and its Changes. By HIPPOLYTE GRUENER, Professor of Chemistry, Western Reserve University. Harper and Brothers, New York and London, 1922. 384 pages. Illustrated. 20 × 13 cms. Price \$3.00.

The publishers' notice says that "this volume is one of a new series which will be devoted to scientific subjects of interest to everyone, treated in a clear and readable manner." The author has succeeded in giving a clear and readable general view of the whole scope of chemistry. The last nine chapters in particular, which deal with such subjects as Geo-Chemistry, the Organic Chemical Industries, Sanitary and Agricultural Chemistry, etc., could be read with profit and would be read with interest by any intelligent non-chemist.

It is a tour de force to cover the entire subject of chemistry in a book of this size, and the book suffers, as might be expected, from the omission of important facts and from over-simplification of statement. The discussion of nitrogen fixation is inadequate, the Bucher process is not mentioned, and the diagram which illustrates the Nitrogen Cycle in Nature is not as clear or as complete as others which we have seen. Confronted with the statement (p. 111) that "matter is indestructible, for the atom never changes," one understands the for to mean because and is tempted to object "Nay, that follows not." Moreover, we question the truth of the premise. The statement (p. 309) that the polariscope "is a physical instrument which gives us a glimpse of the internal structure of the molecule" gives an entirely false notion of the uses of the instrument.

The information in the book has not been assembled in a manner to take best advantage of the psychology of the reader. While the first few chapters deal clearly and in a simple and readable fashion with the nature of chemical changes, with the conduct and structure of matter, with oxygen, hydrogen, and water, they deal with them ex cathedra and the reviewer found himself constantly pausing to ask "How do we know this?" "What is the evidence?" And it may fairly be expected that the uninstructed but ready-to-be-interested reader will fail to react cordially to cold information in the absence of the intriguing thinking by which it is deduced. The statement (p. 169) that "antimony is used in alloys to give hardness" and that "its compounds are used to some extent in the match industry and for giving certain qualities to rubber" would be much more interesting, and no more difficult to understand, if the particular alloy were specified and the particular compound for the special purposes. In speaking of platinum, the observation (p. 173) that "many a crucible has been ruined because the operator assumed that platinum was inactive to everything" would have some value if the substances which attack platinum had only been named. One other instance (p. 223): the author speaks of the meaning of the term carbohydrate, carbon and water, and adds that "this composition, however, is only apparent." His failure to mention the sirup and sulfuric acid experiment is another lost opportunity to increase the interest of his account.

The author's effort to treat chemistry in a simple fashion has had the fortunate consequence that the book contains many valuable suggestions for the teacher. His treatment of normal solutions and of the periodic law is excellent. His distinction between aliphatic and aromatic compounds (p. 234) would be of use in the class room—"Paraffin hydrocarbons are little reactive, but the carbon nucleus is rather easily disintegrated. Benzenes are reactive in that they readily form derivatives, but the carbon nucleus is a very stable one, persisting through a great variety of reactions." An ideal is set up by his statement (p. 297) that "it is the work

of physical chemistry to acquire the necessary data by careful measurement, and from them to derive the laws and theories by which we weave the whole together."

The book is well printed. We have found no typographical errors. The full page pictures are well done and generally represent some technical application of the science. The lack of an index will probably be felt by the reader who is not a chemist. The glossary at the end of the volume contains some excellent definitions, all of them in simple language, and could be studied with advantage by teachers of chemistry. The book will be of interest to educated people who are not chemists, and ought to fill a real want with high school students who wish for something to read beyond their textbook.

TENNEY L. DAVIS

Atomic Form with Special Reference to the Configuration of the Carbon Atom. By EDWARD E. PRICE. Longmans, Green and Company, 39 Paternoster Row, London, E. C. 4; 55 Fifth Avenue, New York; Toronto; Bombay, Calcutta and Madras, 1922. xi + 140 pp. 64 figs. 19 × 12 cm. Price \$1.75 net.

This book is a presentation of what the author calls "The Theory of Atomic Form." The assumptions are made at the start (1) that every carbon atom has the shape of a tetrahedron, each face of which is an isosceles triangle whose altitude equals its base, and (2) that two atoms (of carbon or other elements) may be bonded to one another by having a face in common.

A few of the startling conclusions reached by the author, in attempting to make the facts accord with these hypotheses, are the following: that double and triple bonds do not exist; that mellitic acid has the structural formula,

that the "methane carbon" in triphenylmethane is attached to but one of the three phenyl groups; that the accepted explanations of the stereoisomerism of such compounds as the malic and tartaric acids are all wrong; and that cyclohexane is a cyclic compound, but cyclopropane, cyclobutane, cyclopentane, cycloheptane, and cyclo-octane are not. Mention is not made of the fact that the theory would necessitate large numbers of isomers which have not been found (such as two isomers of any compound of the general formula H₂CA₂, and three of H₂CAB), nor of the fact that the structures he assumes for the diamond and for graphite are not in agreement with the results of X-ray analysis. Of the facts "explained" by this theory, the reviewer has been able to find none which are not better and more simply accounted for on the basis of the ordinarily accepted ideas.

A model of the benzene nucleus is proposed in which there are 12 exposed faces, 6 above and 6 below the plane of the "Benzenoid." To account for the fact that hydrogens are attached to only 6 of these faces, the author writes:

"It is assumed that the figures of Carbon and its compounds when in the gaseous state are floating in a medium which supports them in much the same way as water supports any objects floating in it, and that the molecules are subject to the same laws of gravity and mutual attractions as are observable in other and larger objects. If it be allowed that the Hydrogen Atom has the form of a very oblate pyramid, it will follow that nascent Hydrogen will adopt a position in which the base of the pyramid will be above and the apex will occupy the lower position.

"In this position the Hydrogen Atoms will readily combine with the lower surface of the Benzenoid, but it will be practically impossible for them to make stable attachments to the upper surface; to do so it would be necessary for the Hydrogen to make a complete inversion of its position so that the base may be below and the apex above, such a change of position would be unlikely. In this view, it would be the *upper* surface of the Benzenoid which would be free from Hydrogen."

The author makes absolutely no use of any of the developments of the past 25 years in the field of atomic and molecular structures.

The book is written in a clear, readable style, and is well illustrated with many diagrams and photographs.

MAURICE L. HUGGINS

Catalysis in Organic Chemistry. By Paul Sabatier, Dean of the Faculty of Sciences of Toulouse. Translated by E. Emmet Reid, Professor of Organic Chemistry, Johns Hopkins University. D. Van Nostrand Company, 8 Warren Street, New York, 1922. xxiv + 406 pp. 23.5 × 15.5 cm. Price \$5.00 net.

Dr. Reid purported to translate the 1920 edition of Professor Sabatier's book but gave us a volume that has all of the many good points of the original with several invaluable ones added. The chief worth of the second French edition, which is approximately a half larger than the 1913 edition, lies neither in the theoretical treatment nor in the critical judgment of experimental results, but in the assembling of a great many scattered references and observations on the subject of catalysis in organic chemistry by the man who is preëminent in this field. To list the subjects treated in the book would be but to itemize the fundamental reactions of organic chemistry, since almost all are subject to the influence of catalysts. It was to be expected that more space would be devoted to heterogeneous

catalysis and specifically to hydrogenation than to other phases of the subject. One may pick out topics such as the use of copper in the Ullmann reaction which are inadequately treated, but in general the book is well balanced and is a veritable storehouse of facts comparable to Dr. Bancroft's book on Colloids. Dr. Reid has given an excellent translation and has added references to the literature of 1920–22 and many pages of footnotes by himself and others which contain important, interesting, and otherwise unpublished information. These footnotes give a little of that critical examination of the literature which is so greatly needed in the field covered by this book.

The usefulness of the French edition is restricted because it lacks an author or subject index. Dr. Reid at the expense of a great deal of labor has devoted 56 pages to a subject index having some 7000 entries and an author index of 1100 names.

A 2-page sketch of Professor Sabatier's life by the translator and a 12-page article by Dr. Wilder D. Bancroft on "Theories of Contact Catalysis" have been added.

A rapidly widening circle of chemists will find that they owe a great debt of gratitude to Professors Sabatier and Reid for having brought together in a well indexed, convenient, and suggestive form the material contained in this book.

HOMER ADKINS

Organic Chemistry or Chemistry of the Carbon Compounds. By Victor von Richter. Edited by Professor R. Anschütz and Dr. H. Meerwein. Vol. III. Heterocyclic Compounds. Translated from the eleventh German edition, by E. E. Fournier D'Albe, D.Sc. P. Blakiston's Son and Company, 1012 Walnut Street, Philadelphia, 1923. xviii + 326 pp. 22.5 × 15 cm. Price \$6.00 net.

With the publication of Volume III (Heterocyclic Compounds) of Victor von Richter's "Organic Chemistry" the complete translation of the eleventh German edition (published in 1913) of this well-known text and reference book is now available. The English translation has appeared in three volumes whereas the German edition appeared in two volumes, the second covering both carbocyclic and heterocyclic compounds. This book is so well known and has been so useful to organic chemists for general reference that it is hardly necessary to mention that Volume III describes the chief compounds and reactions of all except the rarest classes of heterocyclic compounds.

As mentioned in the review of Volume II of the English translation [This Journal, 44, 2067 (1922)], it is regretable that a book which has required so much time and expense in preparation should be 10 years old in subject matter, at its date of appearance. In spite of this fact, all organic chemists will welcome the completed English edition.

Hexosamines, Their Derivatives, and Mucins and Mucoids. By P. A. Levene, M.D. Monograph No. 18. The Rockefeller Institute for Medical Research, New York, 1922. 104 pp. 25 × 17.5 cm.

The monograph is a review of a narrow field of organo-biological chemistry by one of the world's foremost organic chemists who has devoted his time to the organic chemistry of biological products. The purpose of the author as stated in the preface is not to offer a complete review of all the literature on the subject but to bring together that part of it which has appeared from his laboratory in the course of many years.

Of the two sections of his work, the first is devoted to the 2-amino-hexoses and their derivatives and was undertaken with the object of procuring data for the purpose of identification of these compounds. The question as to the configuration of carbon atom 2 cannot as yet be answered by direct chemical evidence and, therefore, the use of indirect evidence is justified. The indirect evidence from his own and the work of others is presented. The experimental part consists of experiments on the (1) conversion of hexosaminic acids into their epimers, (2) preparation of hexosaminic acid from 1-aminopentosides, (3) synthesis of hexosamines, (4) 2-5-anhydro-pentoxycaproic acids, (5) 2-5-anhydro-tetroxyadipic acids, (6) chitose and epichitose, and (7) 3-aminoheptonic acids.

Part 2 deals with the mucins and mucoids and in particular with available data and experimental work on chondroitin-sulfuric acid and mucoitin-sulfuric acid, together with a discussion of the distribution of acids of various types in organs and tissues.

W. R. BLOOR

Injury, Recovery and Death, in Relation to Conductivity and Permeability. By W. J. V. OSTERHOUT, Professor of Botany at Harvard University. Monographs on Experimental Biology. J. B. Lippincott Company, Philadelphia and London, 1922. 259 pp. 96 fig. 21 × 14 cm. Price \$2.50.

The volume is noteworthy for two things: (a) The quantitative study of rates in the processes occurring in living matter; (b) the development of precision in the definition of such concepts as life, vitality, injury, recovery and death. Due in part to a fortunate choice of experimental material the author has succeeded in studying processes in vita which had formerly been known chiefly in vitro. The discussion of the problems rests on the assumption that the processes which occur in the organism may be represented by a simple catenary system which obeys the laws of chemical dynamics. The data justify the assumption that life processes consist largely of a series of consecutive unimolecular reactions.

Much of the discussion is based upon changes in permeability of the protoplasm to ions. The permeability is computed from the electrical resistance of the tissues, although other means of determining permeability are also used. Permeability is assumed to be dependent upon the amount

of some substance, M, which is formed by the breaking down of a substance, A, and in turn breaks down continually into another substance, B, according to the scheme, $A \longrightarrow M \longrightarrow B$.

The system for marine plants is in equilibrium in sea water; M is renewed as fast as it breaks down. If the velocity of the first reaction be increased, the amount of M will be increased; if the velocity of the second reaction be increased, the amount of M will diminish. When the resistance of the tissue falls to 10% of its original value, death ensues. If tissue be transferred from a toxic solution to sea water before the resistance has fallen too low, recovery occurs, but recovery is incomplete unless the fall of resistance was very slight. The author advances the view that the death process is always occurring, even in an actively growing cell, and produces no untoward effects unless unduly accelerated by an agent which upsets the normal balance and produces such injury that the life process is terminated.

The concepts of all other workers on the nature of cell permeability are regarded as faulty and are discarded. The author assumes that permeability is governed by the amount of a hypothetical combination between various ions and some constituent of the protoplasm. In the case of cells bathed by a solution containing sodium chloride and calcium chloride, the compound is supposed to have the formula, Na₄XCa, in which X represents some constituent of the protoplasm. Further assumptions are made concerning the amounts of Na₄XCa which will be found when cells are immersed in varying proportions of salt and calcium chloride.

Contemporary students of the physico-chemical problems of living matter find no little difficulty in relating Osterhout's assumptions to the principles of physical chemistry on one side, or to biological principles on the other. The discussion is devoted mainly to injury, death and recovery, but is not correlated with the processes upon which the continuance of life depends such as the absorption of water and of solutes from solutions having concentrations comparable to those from which terrestial plants obtain their nutrients. We cannot lightly assume that there is any sharp boundary between these phases of biological dynamics. In view of the relation between the colloidal state and the absorption of water, it would have been advantageous to have had a discussion of their role in determining permeability.

The work constitutes an advance in the analysis of an important problem in biology which workers in that field cannot afford to overlook.

ABSORPTION SPECTRA OF NITROSYLSULFURIC ACID AND OF THE COMPLEX COMPOUNDS OF COPPER SULFATE AND OF FERROUS SULFATE WITH NITRIC OXIDE^{2,3}

By H. I. Schlesinger and Albert Salathe Received September 1, 1922

In the argument with which Raschig supports his theory⁴ of the chamber process for the manufacture of sulfuric acid, his view that nitrosylsulfuric acid is stable only in solutions containing more than 80% of sulfuric acid plays an important role. The evidence for this view lies in the production of the blue substance, considered by him to be nitrosisulfonic acid (H₂S-NO₅), by reduction of nitrosylsulfuric acid with mercury (a reaction that takes place only in solutions containing more than 80% of sulfuric acid) and in the failure to obtain this blue substance by action of sulfur dioxide on nitrosylsulfuric acid in such solutions. The fact that mercury does not produce the blue color in the more dilute solutions is taken as evidence that these solutions contain no nitrosylsulfuric acid; the fact that sulfur dioxide gives rise to the blue color only in the more dilute solutions is believed to demonstrate that sulfur dioxide reacts only with nitrous acid and not with nitrosylsulfuric acid to yield nitrosisulfonic acid, and that in the more dilute solutions all of the nitrosylsulfuric acid has been hydrolyzed to ni-

trous acid. Generally, however, the formation of the blue substance itself is not relied upon because it is too unstable. Addition of copper sulfate (or ferrous sulfate) which intensifies the color reaction is made use of on the assumption that the intense coloration produced under these conditions is due to the formation of a copper (or ferrous) salt of nitrosisulfonic acid. Upon the basis of this evidence Raschig concludes that nitrosylsulfuric acid cannot exist in the presence of sulfuric acid of concentrations such as are found in the lead chambers and that therefore it cannot be an intermediate in the chamber process. After thus ruling out nitrosylsulfuric acid, he develops from other experimental evidence his theory that the formation of the blue "nitrosisulfonic acid" is the important step in the reactions which finally result in the formation of sulfuric acid.

Raschig's views concerning the stability of nitrosylsulfuric acid have already received rather cogent criticism from two sources. Reynolds and Taylor⁵ have shown that by evaporation of solutions of 60-80% sulfuric acid containing nitrites, crystals of nitrosylsulfuric acid can be obtained. They therefore conclude that the latter must be stable in these solutions. While our work has confirmed their conclusions fully, we were of the opinion that their results might have been open to another interpretation and that further confirmation was desirable. In the second place, Manchot⁶ has called attention to the fact that the blue coloration produced when copper sulfate is used in the reactions described above and used by Raschig as a test for the presence of nitrosylsulfuric acid, might readily be due to the formation of the deep violet complex salt of copper sulfate and nitric oxide, a salt analogous to the similar well-known complex salt of ferrous sulfate and nitric oxide. If Manchot's contention is correct, Raschig's color reaction has no necessary bearing on the question of the presence or formation of nitrosylsulfuric acid. This phase of the problem will receive further consideration later.

In the first part of this paper we are reporting the results of an investigation of the absorption spectra of nitrosylsulfuric acid dissolved in sulfuric acid of various concentrations. From the data obtained it is possible to conclude definitely that the nitrosylsulfuric acid is not completely hydrolyzed until the concentration of the sulfuric acid, used as solvent, has been lowered to 40% by addition of water. It therefore follows that Raschig's criticism of the older theory of the chamber process on the ground of instability of nitrosylsulfuric acid is unjustified. With his other arguments this paper does not deal, except that in the second part some preliminary data bearing on the nature of "nitrosisulfonic acid" are presented.

The absorption spectra of the solutions were examined with a quartz spectrograph of high accuracy. A spark discharge between carbon electrodes impregnated with oxides

Reynolds and Taylor, J. Soc. Chem. Ind., 31, 367 (1912).

⁸ Manchot, Z. angew. Chem., 24, 13 (1911).

of molybdenum and uranium served as the source of light. Time of exposure varied for different types of solution from 30 to 45 seconds except for some of the most opaque solutions for which 90 seconds or more were required.

The solutions were contained in cells such as described by Baly. The windows were of quartz. The bulb was placed as near the end of the outer tube as possible to allow entrance of an inlet tube carrying nitric oxide for the experiments to be described in Part II. In the experiments with nitric oxide, the neck of the bulb was fitted with a 2-holed stopper in order to make it possible to keep the solution continuously saturated with the gas. Rubber tubing, 37 mm. in diameter, such as is used with Gooch crucibles, was employed to join the inner and outer tubes in the usual way. This tubing was found to lose its elasticity on subjection to the action of acid mixtures containing 75% of sulfuric acid and upwards, but to be singularly live after having been subjected to the action of weaker acids for considerable periods of time. The quartz windows were joined to the glass by means of water glass. This, if properly applied, will hold against concd. and dil. sulfuric and nitric acids for hours. After each experiment, the cells were immersed in lukewarm water, and in about half an hour the cement had dissolved and both quartz and glass were then thoroughly cleaned and made transparent by immersion in very dilute hydrofluoric acid.

The curves for the spectra are plotted in the usual way, with oscillation frequencies⁸ as abscissas and logarithms of thickness in millimeters as ordinates. In many cases, however, no reference concentration is given because the concentration of the absorbing substance is not known. The usual method of procedure was followed in making the photographs: first a photograph of the scale was taken, then a photograph of the whole spectrum through the empty Baly tube, then photographs of the absorption spectra of the solution and, finally, another photograph of the thinner layers of the solution. In this way the possibility of contamination of the solutions by the cement or the rubber was tested and excluded. Blank tests with sulfuric acid alone confirmed this observation.

I. Absorption Spectra of Solutions of Nitrosylsulfuric Acid in Sulfuric Acid of Various Strengths

The nitrosylsulfuric acid was prepared by the method of Weber.⁹ Further details of the method of preparation will be found below in connection with a discussion of the effect of impurities on the spectra. A series of $0.1\,N$ solutions was prepared by dissolving the solid nitrosylsulfuric acid in 95.6%, 88.1%, 80%, 70%, 60%, 50% and 39.6% sulfuric acid. Two solutions, one in 93.1% and the other in 74.3% sulfuric acid, which were $0.025\,N$ with respect to nitrosylsulfuric acid were examined and are included in the figure with the $0.1\,N$ solutions. Fig. 1 represents the spectra of all of these solutions, plotted in the usual way and referred to $0.1\,N$ solutions as standard.

There are two striking phenomena exhibited in Fig. 1. In the first place there is the increased ultraviolet absorption, or shift of end absorption toward the visible, with decrease in concentration of sulfuric acid used as solvent. In the second place there is the appearance of an absorption band in the ultraviolet as the concentration of the sulfuric acid approaches

⁷ Uhler and Wood, Carnegie Inst. Pub., 1907, 69.

⁸ Wave number per mm.

⁹ Weber, J. prakt. Chem., [1] 97, 489 (1866).

40%. The incipiency of the band is noticeable at 50%, while at 39.6% acid the band is well defined. The interpretation of these phenomena is that the end absorption is due to nitrosylsulfuric acid and that the spectrum with the absorption band is due to nitrous acid.

This interpretation is based on the following evidence. The spectrum of nitrites is known. 10 Spectra of potassium nitrite in 39.6% sulfuric acid,

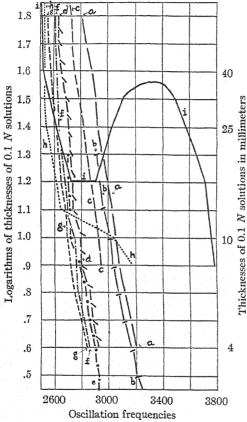

Fig. 1,—Absorption spectra of nitrosylsulfuric acid in sulfuric acid of various concentrations

c = 88.1% f = 70.0% i = 39.6%

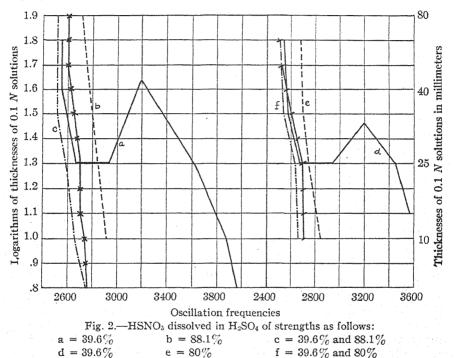

photographed by us, checked with those of aqueous solutions of alkali metal nitrites within the limits of experimental error and are identical with the spectrum of nitrosylsulfuric acid in 39.6% sulfuric acid. It follows, therefore, that in sulfuric acid of this concentration, nitrosylsulfuric acid is completely hydrolyzed to nitrous acid.

Inasmuch as the chemical evidence (slight bubbling and momentary appearance of blue color) showed that this hydrolysis occurs when the sulfuric acid is diluted to 60% while the spectra gave no evidence of nitrous acid at this concentration, it seems probable that the nitrosylsulfuric acid, still undecomposed, blots out the spectrum of the nitrous acid. greater opacity of the former makes this suggestion a very reasonable one, but it was thought best, nevertheless, to prove its correctness experimentally. For this pur-

pose one Baly tube was filled with a solution of 0.1~N nitrosylsulfuric acid in 39.6% sulfuric acid. This solution gives the spectrum of nitrous

¹⁰ Baly and Desch, *J. Chem. Soc.*, **93**, 1755 (1908). In this article the absorption spectrum of nitrosylsulfuric acid will also be found but for only one concentration of sulfuric acid. Our data on nitrites are not reproduced in order to save space.

acid as was made clear above. This tube was preceded by another which contained, in one experiment, $0.1\ N$ nitrosylsulfuric acid in 88.1% sulfuric acid and, in the second experiment, the same concentration of the solute in 80% sulfuric acid. Both of the solutions in the more concentrated acids exhibit the spectrum of the nitrosylsulfuric acid. In order to accommodate the two Baly tubes the source of light was placed $89\ cm$. from the slit and, to allow for the longer distances through which the light had to traverse the solutions, longer exposures were employed. In making the photographs, the length of the column of the solutions in the concentrated acids

was kept constant and the length of the solutions in the dilute acid was varied. If the assumption that the spectrum of the nitrosylsulfuric acid "blots" out that of the nitrous acid is correct, the resulting curves should be like those for a solution of nitrosylsulfuric acid in a concentration of sulfuric acid between 39.6% and that of the stronger acid used. If the decomposition of the nitrosylsulfuric acid is proportional to the decrease in concentration of the sulfuric acid this intermediate concentration of the latter should be the average of the strengths of the weaker and the stronger acids used in the experiment. While there is no reason to believe that this is necessarily the case, the curve for this average concentration is given in crossed lines with the curves for each of the solutions used and with

the curve of the superimposed spectra in Fig. 2. It is seen that while the spectrum of the acid of the average concentration is slightly different from that of the superimposed solutions, the similarity of the two is so great that there can be no doubt of the correctness of the assumption that the spectrum of nitrosylsulfuric acid masks that of nitrous acid. It follows from this that in solutions of sulfuric acid as dilute as 50% there is left undecomposed an appreciable quantity of nitrosylsulfuric acid. In so far as Raschig's criticism of the older theory of the chamber process is based upon his statement that nitrosylsulfuric acid cannot exist in the lead chambers, that criticism is unjustified.¹¹

The data presented in Fig. 2 also aid in interpreting the shifting end absorption observed as the sulfuric acid is diluted from 96 to 60%. The most concentrated solution undoubtedly represents one in which little, if any, of the solute, nitrosylsulfuric acid, is decomposed. But, as the solution becomes more dilute (with respect to the concentration of the sulfuric acid used as solvent), more and more nitrous acid is formed and the absorption due to this substance is added to that due to the nitrosylsulfuric acid left in solution.¹² Since the extent of the decomposition is not known, the curves for the spectra of solutions in sulfuric acid lying between 96 and 39.6% cannot be calculated. It is not likely, however, that the explanation given for the shift in the end absorption can completely account for the phenomenon, because the concentration of the nitrosylsulfuric acid decreases as that of the nitrous acid increases. The phenomenon may in part also be due to the influence exerted by the change in the character of the solvent. Similar shifts have been observed in other solutions, notably by Schaefer in the case of nitric acid dissolved in sulfuric acid. 13 The similarity in the absorption spectra of nitrosylsulfuric acid, just described, and those of nitric acid in varying concentrations of sulfuric acid, described by Schaefer, is too striking to be passed by without comment. In both cases dilution of the sulfuric acid with water causes first a shift in the end absorption toward the visible, and then the gradual appearance of an absorption band. In both cases the band appears at approximately the same concentration.

It was at first thought that this striking similarity might be due to the presence of nitric acid in our nitrosylsulfuric acid. This was suspected al-

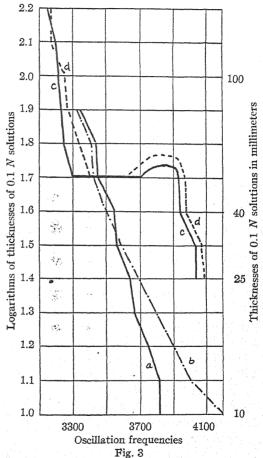

¹¹ While qualitative spectroscopic evidence cannot lead to definite conclusions concerning the relative amounts of nitrosylsulfuric acid and of nitrous acid in these solutions, the fact that the shift in the end absorption is greater when the concentration of sulfuric acid is varied from 100 to 80% than when varied from 80 to 60% suggests that much of the decomposition of the nitrosylsulfuric acid occurs before the concentration of sulfuric acid has been lowered to 80%.

¹² For the theory concerning the effect of two substances on the absorption spectrum of the resulting solution see, for example, Kayser, "Handbuch der Spektroskopie," S. Hirzel, Leipzig, 1905, vol. 3, p. 92.

¹³ Schaefer, Z. anorg. Chem., 97, 285; 98, 77 (1916).

though the end absorption in the nitric acid and the band which develops as the water is added are both found much farther in the ultraviolet region than is the case with nitrosylsulfuric acid. To make sure that this difference in the region of absorption was not due to an error in the scale of wave lengths, either in Schaefer's work or in ours, we made a plate of nitric acid in 39.6% sulfuric acid. Our curve and Schaefer's agree well (See Fig. 3).

Error in scale is, therefore, excluded. In order to make sure that impurities played no role in our spectra of nitrosylsulfuric acid the following solutions were examined. In preparing the substance, the crystals were washed with glacial acetic acid and with carbon tetrachloride in order to dry them rapidly and free them from nitric acid. Examination of solutions of sulfuric acid to which a little carbon tetrachloride and glacial acetic acid had been added, showed that these impurities left the sulfuric acid transparent and that they could not have been responsible for the spectra. The fact that nitric acid is far more transparent than our solutions excludes it as the absorber. Finally, the fact that only nitrosylsulfuric acid could have been responsible for the absorption was demonstrated by photographing spectra of solutions prepared by (a) using the crystals purified

a and b = HNO₃ in 88.1% H₅SO₄; a before, b after gently boiling for $^{1}/_{2}$ hour. c = KNO₃ in 39.6% H₂SO₄, d = KNO₃ in 40% H₂SO₄, after Schaefer

as described above, (b) dissolving pure sodium nitrite in concd. sulfuric acid, (c) dissolving, in sulfuric acid, nitrogen tetroxide prepared in one case by heating lead nitrate and in another by heating copper nitrate. All of these solutions gave absorption spectra which, except for unavoidable

differences in concentration, were identical. The curves are not reproduced in order to save space.

It has thus been shown that the great similarity between the absorption spectra of nitric and of nitrosylsulfuric acids in sulfuric acid of various strengths is not due to any common impurity. It is, therefore, probably due to a common cause, most probably the dehydrating action of sulfuric acid. In the case of the nitrous acid this action results in the formation of the mixed anhydride, nitrosylsulfuric acid. It is possible that with nitric acid a similar anhydride may be obtained or dehydration may proceed as far as nitrogen pentoxide. 14 The latter possibility suggests that a solution of nitric acid in concd. sulfuric acid might readily lose oxygen on account of the great instability of nitrogen pentoxide. If this occurs, nitrosylsulfuric acid must result. Lunge15 states that this is the case and says further "this transformation takes place almost completely after brief boiling" for concentrations of acid of d. 1.71 (78.04%) and upwards. In the spectroscopic method we have a much more accurate means of testing the correctness of Lunge's statement than any means he used. A 0.1 N solution of nitric acid in 88.1% sulfuric acid was prepared and photographed. was then gently boiled during half an hour open to the air and again photographed. Reference to Fig. 3 shows that very little if any nitrosylsulfuric acid was formed, for if it had been formed in even small amount absorption should have been greatly increased; as a matter of fact, the curves show slightly less absorption after boiling the acid, due, no doubt, to a small loss of nitric acid by evaporation. These findings were confirmed by chemical tests which, however, are not as sensitive as the spectra. While this result thus differs from the findings of Lunge, it is possible that the difference may be due to difference in concentration of the nitric acid.

One further suggestion in connection with our curves for nitrosylsulfuric acid is of interest. Since sulfuric acid is transparent in the range of frequencies examined, one might expect its mixed anhydride with nitrous acid to exhibit a spectrum similar to that of the latter. This is not the case; nitrous acid has an absorption band, nitrosylsulfuric acid only end absorption. This may indicate that in the latter there is an NO₂ group, since the evidence is fairly good that in nitrous acid the absorption spectrum is due to the ONO group. This point is not considered definitely proved; too little work on that type of isomerism in inorganic compounds, particularly with reference to absorption spectra, has as yet been done to warrant drawing definite conclusions. Further work along these lines is in progress.

¹⁴ It is also possible that in the solutions in concd. acid a nitrate of sulfuric acid may exist. See Stieglitz, This Journal, 44, 1293 (1922).

¹⁵ Lunge, "Sulfuric Acid and Alkali," D. Van Nostrand Co., 1913, vol. I, part I, p. 343.

¹⁶ Simple anhydride formation usually does not greatly modify the absorption spectrum. See Hantzsch and Scharf, *Ber.*, **46**, 3570 (1913).

It may be added that the nitrosulfonic acid structure for nitrosylsulfuric acid has already received considerable attention.¹⁷

II. Absorption Spectra of the Complex Compounds of Ferrous and of Cupric Sulfate with Nitric Oxide. Comparison of these Spectra with that of Nitrosisulfonic Acid

As has already been mentioned, Manchot⁶ has pointed out that the intensely colored compounds produced by reduction of nitrosylsulfuric acid by mercury in the presence of ferrous or cupric sulfate might be complex salts of the type FeSO₄.NO instead of being nitrosisulfonates as supposed by Raschig. A comparison of the spectra of solutions of the colored compounds prepared by reduction of nitrosylsulfuric acid with those of solutions prepared by passing nitric oxide into the sulfate solutions should afford a means of deciding this question and the necessary observations have. therefore, been made by us. The complex salts of nitric oxide have been studied in detail by Kohlschütter¹⁸ and by Manchot¹⁹ and their work, has shown that there are two classes of compounds of the same composition. In the case of ferrous sulfate, for example, a brown compound is formed when nitric oxide is passed into an aqueous solution of the salt while a deep red compound results from the action of nitric oxide on ferrous sulfate dissolved in concentrated solutions of sulfuric acid. For this reason it seemed necessary to study the absorption spectra of the ferrous sulfate-nitric oxide complexes in sulfuric acid of various strengths. It should be mentioned that Kohlschütter has already reported visual observations of these spectra, but these observations are not sufficiently precise to serve our purpose.20

The apparatus used in this part of our work was the same as that described in the first part of the paper. The nitric oxide was generated from copper pellets and nitric acid, diluted 1:1 with water. The gas was purified by passing it over soda lime, through concd. sodium hydroxide solution and then through concd. sulfuric acid. It is essential that the solutions in which the nitric oxide is absorbed be thoroughly freed from traces of oxygen, since the presence of the latter would give rise to the formation of either nitrosylsulfuric acid or of nitrous acid in the solutions. Each of these

In the last named article a complete list of references to Manchot's work is given.

²⁰ Before publication of this paper, we communicated with Professor Kohlschütter in order to make certain that he would not consider our work an infringement of his field. He not only assured us that this would not be the case but also most courteously put at our disposal some unpublished notes. We take great pleasure in acknowledging his kindness in this matter.

e = 59.4%

substances has an absorption spectrum that would interfere with the absorption spectra to be studied. To exclude oxygen, oxygen-free hydrogen was passed through the solutions until air had been completely removed and the solutions thereafter were not allowed to come into contact with any gas except hydrogen or nitric oxide.

Fig. 4 contains the curves for the compounds of ferrous sulfate and nitric oxide. The solutions were prepared by dissolving the salt in a little water and then adding enough diluted sulfuric acid to the mixture to produce the desired concentration of salt and of acid. After the air had been displaced

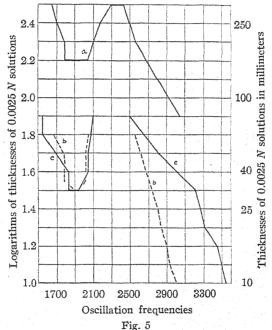

from the solution by hydrogen, the solution was saturated with nitric oxide. The solutions represented by the curves of Fig. 4 were $0.025\,N$ with respect to the iron salt; the strength of the acid was varied from 93.1% to 0%. The absorption spectra of the compound of nitric oxide with ferrous sulfate in 93.1, 82.3 and 71.5% sulfuric acid, respectively, all show an absorption band with head in the frequency interval from about 1750 to 2100; maximum transmission is approximately at 2300. These three curves, in other words, are very similar indicating that in this range of concentration of the sulfuric acid no change has occurred in the nature of the complex salt.

g = 15%

h = 0%

f = 45.0%

The curves for 65.0% and for 59.4% acid are quite different in character. The absorption band is no longer well defined and the region of absorption is much shallower. Further dilution produces still further change. With 45.0% acid there is again an absorption band, similar to the one just described, but its head is now in the frequency interval 2000 to 2400 and maximum transmission has been displaced to 2500. From this concentration of acid to solutions in water, the new absorption band remains unchanged except that it becomes deeper, that is, the solution becomes more opaque in the region of absorption. While the difference exhibited by these various curves is not very great, it is sufficiently definite and occurs at so definite a range of concentrations that it fully warrants the conclusion that there are two compounds, one existing in concd. sulfuric acid and the

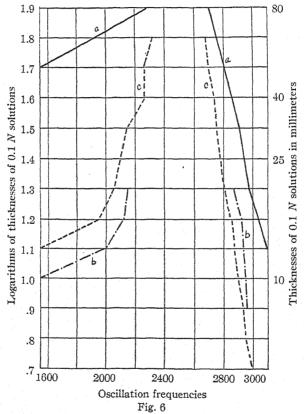

a=0.025~N FeSO4 with NO in 93.1% H_2SO_4 . b= ferrous nitrosisulfonate in 93.1% H_2SO_4 ; Fe = 0.0025 N. c=0.0025~N FeSO4 with NO in 93.1% H_2SO_4

other in dilute acid or in water. As the concentration of the acid is changed from about 65% to about 50%, the one compound is transformed into the other. In the interval between these extremes, both compounds are apparently present and this fact causes the indefiniteness of the character of the curves for 65% and for 59.4% acid. These results corroborate the visual observations of Kohlschütter¹⁸ and the conclusions of Manchot¹⁹ based on chemical evidence but make much more precise the location of the

two bands and show, for the first time, the existence of the definite range of transition.²¹

Fig. 5 was made in order to show the identity of the compound of ferrous sulfate with nitric oxide, formed in concd. sulfuric acid, with Raschig's ferrous nitrosisulfonate. The latter was prepared as follows. Ferrous sulfate was dissolved in water, sulfuric acid was added in sufficient amount to give a strength of 93.1%, and the mixture cooled. Sodium nitrite, finely

a = 0.1 N CuSO₄ with NO in 82.3% H₂SO₄. b = 0.1 N CuSO₄ with NO in 93.1% H₂SO₄. c = Cu nitrosisulfonate in 93.1% H₂SO₄; Cu = 0.1 N

ground and carefully dried, was then added slowly. The mixture was rotated until all of the particles of sodium nitrite had passed into solution. A few drops of mercury were added to this solution and the mixture was violently shaken for about 15 minutes. The characteristic red color developed and deepened during this interval. The concentration of the iron salt in this experiment was $0.0025\ N$ and to make the comparison satisfac-

²¹ Kohlschütter (see Ref. 18 particularly 18c), gives a very well founded theory to account for the existence of these isomers. See also Manchot, Ref. 19c.

tory we prepared the iron compound, described in the preceding paragraph of this concentration also and photographed its spectrum. Curves b and c of Fig. 6 reproduce the experimental results. It is quite clear that Raschig's nitrosisulfonate of ferrous iron and the complex compound of ferrous sulfate and nitric oxide formed in concd. sulfuric acid are identical.²²

Fig. 6 shows that the compound obtained when nitric oxide is passed into copper sulfate dissolved in concd. sulfuric acid is identical with Raschig's nitrosisulfonate of copper. The two compounds were prepared in quite analogous fashion as described for the respective iron salts. Both in the photographs of iron and of copper "nitrosisulfonates," ultraviolet end absorption is superimposed on the spectra of the salts themselves. This is due to the fact that the method of preparation makes the exclusion of nitrogen tetroxide impossible. Furthermore, probably not all of the nitrosylsulfuric acid is reduced. This last fact also makes somewhat uncertain the concentration of the compound; all that can be given with accuracy is the concentration of the original metal salt.

The identity of the nitric oxide complexes with the supposed nitrosisulfonates makes a study of the absorption spectrum of the latter of great interest. Balv and Desch¹⁰ report an observation on copper nitrosisulfonate which agrees well with our data. Kohlschütter and Sazanoff²³ report a visual observation of the free acid which they find to have a spectrum quite different from that of the complex salts. Our investigation by the more exact photographic procedure led to the opposite result as is shown in Fig. 7. Curve a, represents the spectrum of nitrosisulfonic acid prepared as described for its ferrous salt, except that no ferrous sulfate was added. The solution is very unstable and photography difficult.²⁴ Owing to the impossibility of determining whether the reaction of the nitrite with mercury is complete or how much nitrosisulfonic acid has decomposed, it is impossible to say what the concentration of the solution is. The nitrite was used in such concentration as to give a $0.5\ N$ solution. Curve b represents another photograph of the spectrum of the copper salt. The concentration of the reagents here was only 0.1 N because of the greater opacity of the solution. Nevertheless, the actual data are recorded for both curves, since any attempt to recalculate them to a common basis of reference would have been quite arbitrary in view of the uncertainty concerning the concentrations.²⁵ The two curves are seen to be closely similar.

 $^{^{22}}$ Fig. 5 contains also the curve for FeSO₄NO in concd. sulfuric acid, but with an iron concentration 0.025 N. Both curves are referred to the concentration 0.0025 N. It is seen that Beer's law does not hold. This phenomenon will be further investigated.

²³ Ref. 18c. More details are given in the dissertation by Sazanoff (Berne).

²⁴ Exposures of 15 seconds were employed.

 $^{^{25}}$ A second curve for "nitrosisulfonic acid" is shown in "c" of Fig. 7. This solution was prepared by action of sodium sulfite on $0.5\ N$ sodium nitrite dissolved in sulfuric acid in order to avoid the presence of mercury. Curves a and c agree well except for differences due to unavoidable differences of concentration.

Both show an absorption band with head about at 1900 and additional absorption (possibly a second incipient band) in the far red. Another striking point about these curves is that the absorption band is found in the same range of frequencies as is the absorption band for the compound which

a = nitrosisulfonic acid from 0.5 N NaNO₂, H_2SO_4 and Hg. b = the Cu salt of a. c=nitrosisulfonic acid from 0.5 N NaNO₂, H_2SO_4 and Na_2SO_3

ferrous sulfate and nitric oxide form when mixed in the presence of concd. sulfuric acid.

This striking similarity suggests that "nitrosisulfonic acid" is really a complex compound of sulfuric acid and nitric oxide whose formula might be written H₂SO₄.NO. According to this point of view, the supposed com-

plex has a very high dissociation pressure and can be formed only when nitric oxide is generated in contact with sulfuric acid so that there would be a high degree of supersaturation of the former. While Raschig has brought forward a number of experimental facts that tend to prove the correctness of his formulation for "nitrosisulfonic acid," practically all of them accord as well with the view here presented as with Raschig's. The fact that Manchot 19 has been able to prepare a complex compound 26 of hydrogen chloride and nitric oxide, stable only at very low temperatures, favors the point of view here presented.²⁷ The spectroscopic evidence thus far available is not adequate, however, to decide this question definitely and more detailed discussion is, therefore, out of place. Work has already been begun on the study of non-aqueous solutions of the complex compound of ferrous chloride and nitric oxide, on aqueous solutions of nitroso ferrous phosphate containing varying amounts of phosphoric acid and on other nitroso metallic salts by the spectroscopic method in order to obtain further data bearing on this question.28

In conclusion it gives us great pleasure to acknowledge to the Director of the Research Laboratory of the General Electric Company at Schenectady our sincere appreciation of his courtesy in granting to us the use of a room and of the facilities of the Laboratory for carrying out this research. We wish to include in this expression of appreciation all others of the staff of the Laboratory who most kindly aided us in securing apparatus and materials and in many other ways.

Summary

- 1. The absorption spectra of nitrosylsulfuric acid dissolved in sulfuric acid of various concentrations have been obtained. The spectra show that appreciable quantities of the former remain undecomposed when the sulfuric acid is diluted with water to 50% and that, at higher concentrations of the latter acid, relatively large amounts of nitrosylsulfuric acid are present. This finding disproves one of the fundamental assumptions made by Raschig in developing his theory of the chamber process.
- 2. Absorption spectra of the complexes formed by ferrous sulfate with nitric oxide in solutions of sulfuric acid of various strengths have been photographed. The spectroscopic data confirm the view that there are two such complexes, both of the composition FeSO₄.NO, and show that one of them is stable when the sulfuric acid has a concentration above 65% and
- ²⁶ Further information concerning this compound is found in the paper by Rodebusch and Yntema, This Journal, 45, 332 (1923).
 - ²⁷ For a similar view, see Wentzki, Z. angew. Chem., 24, 392 (1911).
- ²⁸ Since the above was written, preliminary experiments have shown that the compound FePO₄.NO is brown in aqueous solution, and red in the presence of concd. phosphoric acid. This is quite definite evidence that the change in spectrum described above in the case of FeSO₄.NO is not related to any special property of the sulfate ion.

the other when the concentration of the acid is below 50%. Spectra of the complex, CuSO₄.NO, have also been obtained and the spectra of these complex salts have been compared with those of the so-called ferrous and cupric nitrosisulfonates and have been found to be identical.

- 3. A preliminary study of the absorption spectrum of "nitrosisulfonic acid" has shown it to be very similar to that of the ferrous sulfate-nitric oxide complex existing in concd. sulfuric acid solution. This finding supports the view that possibly nitrosisulfonic acid should be looked upon as an unstable solution of a complex compound of sulfuric acid and nitric oxide.
- 4. Examination of the spectra of solutions of nitric acid in coned. sulfuric acid, before and after heating the solutions, has shown that nitric acid is not readily decomposed in such solutions into nitrosylsulfuric acid, at least if the solution is not very concentrated with respect to nitric acid.
- 5. The character of the absorption spectrum of nitrosylsulfuric acid favors the view that this substance is present in solution largely as nitrosulfonic acid.

Further work along these lines is in progress. In addition, the investigation is being extended to other acids of sulfur, particularly the polythionates, polysulfides and to acids of sulfur and nitrogen.

THE ESTIMATION OF SIMPLE, SOLUBLE CYANOGEN COMPOUNDS, MAKING USE OF THE PRINCIPLE OF AERATION

By Joseph H. Roe Received March 21, 1923

The older methods for the estimation of cyanides have their limitations in the presence of interfering substances. When impurities are encountered the usual procedure has been to dissolve the sample, acidify with a mineral acid, distil, and determine the hydrogen cyanide in the distillate. Distillation of hydrocyanic acid from an acidified cyanide solution is objectionable as a quantitative procedure because (1) it involves some loss, because of hydrolysis according to the reaction HCN + $2H_2O \longrightarrow HCOONH_4$; (2) great care must be exerted to prevent escape of hydrogen cyanide during the boiling, as this substance is highly toxic, making distillation undesirable from the point of view of safety to the operator; (3) a cyanide cannot be separated from complex cyanogen compounds such as ferrocyanides by distillation since boiling with an acid decomposes the latter, giving a false yield of hydrogen cyanide: $2K_4Fe(CN)_6 + 3H_2SO_4 \longrightarrow 6HCN + 3K_2SO_4 + K_2Fe_2(CN)_6$. Furthermore, distillation methods are not successful if it is desirable to determine slightly.

dissociable mercuric cyanide in the presence of interfering substance. Because of these limitations, a new method, making use of the principle of aeration, was developed.

Principle.—Hydrocyanic acid can be removed quantitatively from a solution at ordinary temperatures by passing a current of air through the solution for an appropriate time. If free hydrogen cyanide is present, it is thus aerated by means of an ordinary suction pump from one flask into another flask containing a solution of sodium or potassium hydroxide of correct concentration. The sodium or potassium cyanide solution thus obtained in the second flask is then titrated with standard silver nitrate solution using potassium iodide as an indicator (the Denigès modification of Liebig's method). When a cyanide is to be determined, it is dissolved in water, the solution is acidified properly and then aeration into a second flask is carried out, and the cyanide solution finally titrated as described above. This procedure overcomes all the objections to separation of a cyanide from impurities by distillation as pointed out above. The method thus possesses the advantages of being an easy procedure, yielding highly accurate results, and affording entire safety to the operator.

The titration is based upon the principle that when silver nitrate is added to an alkaline cyanide solution, a soluble double salt is formed. AgNO₃ + 2KCN \longrightarrow KAg(CN)₂ + KNO₃. After a few drops of a solution of potassium iodide have been added to the mixture, grayish-white insoluble silver iodide separates when all the cyanide has been converted into the double salt of silver. Potassium iodide thus produces a very sensitive end-reaction, since silver iodide is the most insoluble of all the silver salts. In this process, $1 \text{AgNO}_3 = 2 \text{KCN}$, and 1 cc. of a 0.1 N standard solution of silver nitrate would have the following values: $0.005404 \, \text{g}$. of hydrogen cyanide; $0.013022 \, \text{g}$. of potassium cyanide; $0.009822 \, \text{g}$. of sodium cyanide.

Procedure: For simple, soluble, dissociable cyanides, such as potassium cyanide.—Dissolve a convenient sample, such as 0.050 g. of potassium cyanide, in 100 cc. of water. Prepare apparatus suitable for aeration, as shown in Fig. 1. The double bubble breaker apparatus developed by Folin for determinations of ammonia has been found very serviceable for this work. In Cylinder A place the dissolved cyanide solution with a few added drops of amyl or caprylic alcohol to prevent foaming, and in Cylinder B 100-150 cc. of 5% sodium hydroxide solution. Close the apparatus and start the pump to produce a slow bubbling of air through the flasks. By means of a pipet, introduce into the apparatus at opening of tube marked "E" 25 cc. of saturated (1 g. per cc.) solution of tartaric acid. Adjust the pump until about 3 liters of air per minute passes through the apparatus. This speed is approximated when the films produced by the air bubbles leaving the surface of the fluid in the taller cylinder rise

about 25 mm. above the surface of the liquid. Continue the aeration for 2 to 3 hours. Stop the pump, disconnect the flasks, add 10 drops of 10% potassium iodide solution to flask B and titrate with $0.01\,N$ silver nitrate solution until a faint turbidity appears (as viewed against a dark background). As 1 cc. of $0.01\,N$ silver nitrate solution equals 0.0013 g. of potassium cyanide, the reading of the buret is about 38 cc. and the calculation then is 38×0.0013 or 0.0494 g. of potassium cyanide.

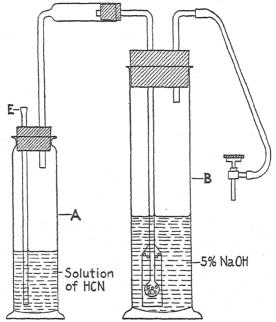

Fig. 1.—Aeration apparatus for determination of hydrogen cyanide

Description and Discussion of the Method

The following factors are of importance.

- 1. Time of Aeration.—Quantitative recoveries were obtained from 2 hours' aeration with a Folin Ammonia Apparatus and a water vacuum pump adjusted to pass about 3 liters of air per minute through the apparatus. It is, therefore, essential to pass 360 to 500 liters of air through the apparatus when analyzing 50mg. samples of cyanide.
- 2. Concentration of the Acid Added.—This must be in excess of the amount necessary to convert all the cyanide present into hydrogen cyanide. Thus in the reaction, $2KCN + H_2SO_4 \longrightarrow 2HCN + K_2SO_4$, it will be seen that very little more than the theoretical amount required for a complete double decomposition is necessary, since hydrogen cyanide is such a weak acid and is constantly being removed from the field, thereby shifting

the equilibrium constant for the reverse reaction towards zero. However, it was found practical to have considerable acid present, since this reduces the time required for aeration; enough acid should be added to make the acid concentration of the solution about 20%; concentrations above this did not interfere with but did not facilitate the process.

- 3. Kind of Acid.—Probably any fairly strong acid could be used. Sulfuric, hydrochloric, and tartaric have been employed interchangeably, and accurate results secured. In practice, tartaric acid was used since it can be added in a highly concentrated form without the production of heat such as occurs when coned. sulfuric or hydrochloric acid is added to the water solution. However, it was found that the heat resulting from the addition of coned. sulfuric acid did not vitiate results, although it caused spattering and vaporization of the liquid not desirable from a mechanical point of view.
- 4. The Concentration of the Alkali.—The concentration of the alkali in the flask into which the hydrogen cyanide is passed is important. If aeration is carried on very slowly but little more than the calculated amount necessary for the neutralization will suffice, but for rapid aeration the solution should contain 100 times the calculated amount. So high a concentration is necessary to prevent the escape of some free hydrogen cyanide through the solution to the pump.
- 5. The Amount of Indicator.—It was found that 1 drop of a 10% solution of potassium iodide per 15 cc. of solution gives accurate results, as checked by other methods.
- 6. The Air Drawn through the Solution.—The atmospheric elements do not interfere with the determination, and the air drawn through the solution, therefore, need not be washed; carbon dioxide serves to facilitate (slightly only) the removal of hydrogen cyanide from the first cylinder. Hydrogen sulfide is the only common impurity of the laboratory that would interfere. When this gas is present in the laboratory, the air should first be passed through a solution of lead nitrate or sodium hydroxide before it is admitted to the cyanide solution.
- 7. Sensitivity of the Method.—It was found very easy to aerate 5 mg. of hydrogen cyanide from 100 cc. of solution and titrate the latter in a 150cc. volume of 5% alkali in the second cylinder. This shows a recovery of 0.00005 g. of hydrogen cyanide per cc. of solution.

This procedure is a highly accurate method for determining simple, soluble cyanides which readily dissociate in solution to produce free hydrogen cyanide when an acid is added. It can be used to determine cyanides in the presence of any impurity, except sulfides, which pass over in the aeration process as hydrogen sulfide and thus interfere with subsequent titration. When sulfides are present, it is necessary to add an excess of lead nitrate to the cyanide solution in Flask A before adding

the acid and aerating. This treatment precipitates the sulfides as lead sulfide and the usual procedure can then be followed.

The Estimation of Mercuric Cyanide

Mercuric cyanide dissociates so little in solution that it does not give a precipitate with silver nitrate. In a pure solution it can be titrated with standard iodine solution (the Fordos and Gelis process). But no method has been developed to determine this substance in the presence of foreign matter, since it defies distillation for quantitative recoveries. A method was, therefore, devised for converting mercuric cyanide into hydrogen cyanide which is then removed by aeration and determined as previously described.

Procedure.—Place 150 cc. of a 5% solution of sodium hydroxide in Cylinder B, and in Cylinder A place a 50mg. sample of mercuric cyanide dissolved in 100 cc. of water and add a few crystals of solid sodium chloride. Close the apparatus tightly and start the pump to aerate slowly. With a pipet introduce into Flask A, through Tube E, 25 cc. of tartaric acid, then 10 cc. of a 5% solution of stannous chloride. A gray to black precipitate of mercurous chloride and metallic mercury appears immediately in the flask, and hydrogen cyanide is evolved and passes over quantitatively into the sodium hydroxide solution in the second flask. Continue aeration at the same speed as described previously for the determination of potassium cyanide for 2 hours, then disconnect and titrate the contents of the second flask with $0.01\ N$ silver nitrate, using $10\ d$ rops of 10% potassium iodide as an indicator. The reading of the buret multiplied by 0.002526 will give the number of g. of mercuric cyanide in the sample.

Description of the Method.—The principle involved here is that mercuric cyanide in solution is reduced to mercurous chloride and metallic mercury in the presence of hydrochloric acid and stannous chloride. The cyanide is liberated as hydrogen cyanide and passes over quantitatively into the second flask when aeration is applied; $2\text{Hg}(\text{CN})_2 + 4\text{HCl} + \text{SnCl}_2 \longrightarrow 4\text{HCN} + 2\text{HgCl} + \text{SnCl}_4$; and $\text{Hg}(\text{CN})_2 + 2\text{HCl} + \text{SnCl}_2 \longrightarrow 2\text{HCN} + \text{Hg} + \text{SnCl}_4$.

A mixture of stannous chloride with hydrochloric acid or with sulfuric acid and sodium chloride, or with tartaric acid and sodium chloride, will give satisfactory results. The author has consistently used tartaric acid as the acidifying agent for reasons previously given. The same principles, as discussed under the potassium cyanide determination, apply to all the other details of procedure for estimating mercuric cyanide.

The methods described above are universal in their application. They can be used to determine simple soluble cyanogen compounds in the presence of practically any other substances. To test their range of application, known amounts of potassium cyanide and of mercuric cyanide

were added to mixtures of blood and organic matter, and quantitative recoveries were obtained by following the procedures as outlined above.

Summary

An aeration procedure for estimating cyanides has been devised in which freed hydrogen cyanide is washed with air into dil. alkali solution, and the mixture then titrated with standard silver nitrate solution, using a little potassium iodide as indicator. The new method has the following marked advantages as compared with the older distillation methods: (1) it avoids loss from hydrolysis of hydrogen cyanide; (2) it can be used to determine cyanides in the presence of ferrocyanides, etc.; (3) it is entirely free from danger to the operator; (4) it offers an excellent method for determining mercuric cyanide provided the latter is previously reduced to mercurous chloride, metallic mercury and hydrogen cyanide with stannous chloride, in the presence of hydrochloric acid; (5) it involves easy technique, gives highly accurate results, and possesses a very wide range of application.

THE REACTION BETWEEN BROMINE AND AMMONIUM SALTS AND ITS EFFECT ON THE PRECIPITATION OF MANGANESE DIOXIDE

By Stephen G. Simpson Received March 26, 1923

One of the standard methods for separating titanium, iron, aluminum and phosphoric acid from bivalent elements such as manganese, magnesium and calcium, is the basic acetate procedure. In the filtrate from this separation, manganese is often precipitated from hot solution by the addition of bromine water: $Mn^{++} + Br_2 + 3H_2O = MnO_2.H_2O + 2Br^- + 4H^{+,1}$ In neutral solution the oxidation and precipitation of the manganese does not take place to an appreciable extent unless the acid formed by the reaction is neutralized, for hot, dil. hydrobromic acid dissolves manganese dioxide. After the basic acetate precipitation, however, the filtrate always contains enough acetate to prevent the formation of an appreciable quantity of free hydrobromic acid, owing to the formation of slightly ionized acetic acid. Sometimes it is the practice to neutralize the solution with dil. ammonia, but owing to the fact that bromine reacts with ammonia $(8NH_4OH + 3Br_2 \longrightarrow 6NH_4^+ + 6Br^- + 8H_2O + N_2)$, a great deal of bromine is used up and it is a rather troublesome operation to precipitate

¹ Compare Wright and Menke, J. Chem. Soc., 37, 22 (1880).

the manganese completely.² When manganese is precipitated from weakly acetic acid solution by bromine, it carries with it elements of the alkali and alkaline-earth group¹ and a single precipitation is not sufficient to effect a complete separation of manganese and these elements, although this method of separation is given in many textbooks. Furthermore, when the solution contains ammonium salts, it is usually difficult in faintly acid solutions to obtain any precipitate of manganese dioxide at all.

The reason why ammonium salts prevent the precipitation of manganese after the basic acetate separation is not generally mentioned in textbooks, and the extent of this interference and the quantitative effects of the several factors involved have been little studied.

Bromine reacts with ammonium salts according to the equation, 2NH₄+ $+3Br_2 \rightarrow 6Br^- + N_2 + 8H^+$, and Ostwald and Raich³ have shown that the velocity of reaction depends upon the strength of the acid forming the negative radical of the ammonium salt. A study of these reactions, moreover, involves a consideration of the reactions between bromine and water. Solutions of bromine contain not only free dissolved bromine, but also hypobromous and hydrobromic acids, Br₂ + H₂O \longrightarrow Br⁻ + HBrO + H⁺, the reaction at 25° using up about 0.8% of the total bromine present.4 Bromine also decomposes water according to the equation $2Br_2 + 2H_2O \rightarrow$ $4Br^{-} + O_{2} + 4H^{+}$, the decomposition increasing rapidly in the sunlight and with increase in temperature.⁵ This latter reaction may be considered simply as a decomposition of the hypobromous acid formed above: 2HBrO \longrightarrow 2H⁺ + 2Br⁻ + O₂. Above 60° bromate is likewise formed:⁶ $3Br_2 + 3H_2O \longrightarrow 5Br^- + BrO_3^- + 6H^+$, or, $3HBrO \longrightarrow BrO_3^- +$ 2Br⁻ + 3H⁺. The various oxidation potentials between these bromine compounds have been determined and the results have been correlated and listed by Abegg.7 The results, however, are found to lie close to one another and likewise close to the oxidation potential between manganous ion and manganese dioxide.8 It is of interest, therefore, to study these reactions experimentally under the conditions where manganese is often precipitated in practice.

Experimental Part

The quantitative effect of the various factors influencing the oxidation of ammonium salts and of manganous salts by bromine was determined experimentally from the amount of bromine used up in each reaction in which

it takes part. Since the precipitation of manganese dioxide by bromine is usually carried out in hot solution, each determination was made in this way. To do this, use was made of a special 500cc. glass-stoppered distilling flask with the side arm forming the inner tube of a Liebig condenser. The total volume of each solution was 100 cc., and in all determinations the conditions were kept as nearly constant as possible. In each case, after the addition of bromine to the solution, the mixture was allowed to remain quiet in the distilling flask for 5 minutes and then heated to boiling for 10 minutes more, all the free bromine being expelled by the end of this time. The bromine evolved was allowed to pass through the condenser and was caught in potassium iodide solution, the liberated iodine being titrated with standard thiosulfate solution. In this way, when the amount of bromine added and the amount recovered were known, the quantity used up in a reaction was found by difference. The solutions of bromine were standardized repeatedly during each series of distillations, and approximately 1.1 milliequivalents of bromine were used in each reaction, that amount being in each case in excess of the amount theoretically required.

The addition of samples of bromine water to potassium iodide solutions was found to liberate iodine from neutral solutions in amounts corresponding to an average of 98.3% of the total bromine present. After acidification of the solution with sulfuric acid, iodine equivalent to the remaining bromine was liberated. This indicates the presence of oxy-acids of bromine in the solutions used in amounts corresponding to 1.7% of the total bromine present. In any oxidation in acid solution by means of bromine water the presence or intermediate formation of hypobromite or bromate has, however, no quantitative effect, since the oxidizing power expressed in equivalents remains the same. A bromine solution in which a part of the bromine reacts with water to form hypobromite or bromate suffers no loss or gain in oxidizing power.

Ten distillations of samples of bromine water in the apparatus and under the conditions mentioned above showed a net loss in oxidizing power between the original solution and the distillate obtained corresponding to an average of 0.032 + 0.006 milliequivalent of bromine. This represents a 3% decomposition into bromide and oxygen. The residual solution did not oxidize iodide in acid solution.

The initial presence of acid in the distillation of bromine water in 10 similar experiments caused a slight decrease in the loss in oxidizing power of the distillate over the original solution taken, the average loss in terms of bromine being reduced to 0.024 + 0.004 milliequivalent. Since the reaction by which hypobromous acid is formed from bromine and water is reversible, the initial presence of acid, by its common ion effect, reverses the reaction and hence retards the loss in oxidizing power caused by decomposition of hypobromite into oxygen and bromide.

In the experimental study of the reaction between bromine and ammonium salt, the sulfate of ammonium was used because of the fact that it reacts with bromine moderately rapidly, being intermediate between the chloride or nitrate and the acetate. The amount of bromine used up in each reaction was determined by means of the apparatus and under the conditions described above. In the absence of sodium acetate and with a large excess of bromine, the reaction between ammonium ion and bromine

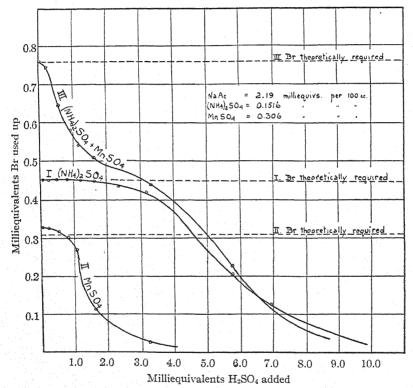

Fig. 1.—Consumption of bromine by boiling for 10 minutes with (I) (NH₄)₂SO₄; (II) MnSO₄; (III) (NH₄)₂SO₄ + MnSO₄ in various concentrations of acid

was found to take place quantitatively according to the reaction, $3Br_2 + 2NH_4^+ \longrightarrow 6Br^- + N_2 + 8H^+$, but the reaction is moderately slow, so that with comparatively great amounts of ammonium sulfate the time of contact with the bromine water was not sufficient to cause the oxidation of all the ammonium salt, for the bromine was expelled before the oxidation was complete. The presence of increasing amounts of acid in the original solutions, on the other hand, caused a corresponding retardation of the reaction and the presence of a moderately high concentration of hydrogen ion was capable of stopping the reaction practically completely.

The extent of the oxidation of ammonium ion by bromine in the presence of sodium acetate under varying concentration of acid and under the experimental conditions is shown in Fig. 1 (I). With a moderate excess of acetate it is seen that the theoretical amount of bromine required for the ammonium salt is consumed. Only when the concentration of acid exceeds that of the acetate is the reaction retarded, and to a degree which increases with the excess of acid present.

The explanation of these phenomena follows from a consideration of the fact that although the reaction $3\mathrm{Br_2} + 2\mathrm{NH_4}^+ \longrightarrow 6\mathrm{Br}^- + \mathrm{N_2} + 8\mathrm{H}^+$ is in itself practically irreversible, the reaction $\mathrm{Br_2} + \mathrm{H_2O} \Longrightarrow \mathrm{Br}^- + \mathrm{HBrO} + \mathrm{H}^+$ is distinctly reversible, and it is the hypobromous acid formed that causes rapid oxidation of ammonium ion: 9 $2\mathrm{NH_4}^+ + 3\mathrm{HBrO} \longrightarrow \mathrm{N_2} + 3\mathrm{Br}^- + 3\mathrm{H_2O} + 5\mathrm{H}^+$. The initial presence of acid, by reversing the equilibrium reaction between bromine and water and hence lowering the concentration of hypobromite, retards the oxidation of ammonium ion. Conversely, the presence of acetate, by removing hydrogen ion in the form of relatively non-ionized acetic acid, causes the equilibrium reaction as written above to proceed to the right and thereby accelerates the oxidation of ammonium ion by the hypobromous acid formed.

Experiments in which a great excess of sodium acetate over the acid initially present was used, showed a consumption of bromine slightly greater than the amount theoretically required for the ammonium alone. The hypobromous acid, in this case being formed in comparatively large amounts, after oxidizing the ammonium ions present, decomposes appreciably into oxygen and hydrobromic acid, and hence causes a corresponding loss in oxidizing power.

In the study of the oxidation of manganese by bromine, the sulfate of manganese was used and the reactions were carried out in the apparatus and under the same conditions as in the oxidation of the ammonium salt. The values obtained are expressed graphically in Fig. 1 (II). Without the presence of alkali acetate, the oxidation of manganese by bromine takes place to a very slight degree; with sodium acetate present in excess, manganous ion is completely oxidized and precipitated by bromine water, provided no acid is originally present in the solution. An increase in the initial concentration of acid causes a marked decrease in the extent of the reaction, and the effect, be it noted, is much greater than in the case of the ammonium salt oxidation.

These reactions can be explained in exactly the same way as was the oxidation of ammonium ion, for although the reaction, $\mathrm{Mn^{++}} + \mathrm{Br_2} + 3\mathrm{H_2O} = \mathrm{MnO_2}, \mathrm{H_2O} + 2\mathrm{Br^-} + 4\mathrm{H^+},$ is in itself reversible, yet the same oxidation may be expressed through the hypobromous acid formed as a product of the equilibrium reaction between bromine and water: $\mathrm{Mn^{++}} +$

Compare Bray and Livingston, This Journal, 45, 1251 (1923).

 ${\rm HBrO} + 2{\rm H}_2{\rm O} = {\rm MnO}_2.{\rm H}_2{\rm O} + {\rm Br}^- + 3{\rm H}^+.$ As with the ammonium-ion oxidation, the initial presence of acid or accetate affects the hypobromite equilibrium sufficiently to retard or accelerate the manganese precipitation. With small amounts of acid, the quantity of bromine used up is seen from the graph to be in excess of the amount theoretically required for the manganese alone, due, as in the case of the ammonium salt reaction, to decomposition of the hypobromous acid into oxygen. Increasing the acetate concentration, even when a moderate concentration of acid had been added, caused increased precipitation of manganese dioxide, but also caused increased loss in oxidizing bromine.

The conditions resulting when bromine reacts with solutions containing both manganous ions and ammonium ions are shown in Fig. 1 (III), where the same experimental conditions were maintained as in the individual reactions. These experiments show that with sodium acetate present, but with little or no acid initially present, the amount of bromine used up is approximately equal to the sum of the theoretical amounts calculated for the manganese salt and for the ammonium salt. Increasing acid concentration, however, rapidly reduces the bromine consumption to a point where both reactions practically cease. Comparison with the individual effects of manganese sulfate and ammonium sulfate shows that under the experimental conditions, when manganous ion and ammonium ion are present together, the addition of bromine causes more rapid oxidation of the ammonium ion than of the manganous ion.

The extent of precipitation of manganese dioxide in the presence of various amounts of ammonium sulfate was next determined using an excess of sodium acetate and a great excess of bromine water. No acid was added, and 0.302 milliequivalent of manganese was employed in each case. After the solution had been boiled, the precipitated manganese dioxide was determined by titration. The results obtained are given below, and from them it is seen that a moderate concentration of ammonium ion inhibits to a marked degree the precipitation of manganese dioxide.

(NH4)2SO4 added Millieq.	Mn pptd. Millieq.	Mn pptd.	(NH ₄) ₂ SO ₄ added Millieq.	Mn pptd. Millieq.	Mn pptd. %
0.000	0.301	100	0.303	0.267	87
.030	.303	100	.394	.170	56
.091	.302	100	.606	.008	1.4
.152	.289	95	.909	.004	0.7
.243	.280	91			

Conclusions

In the precipitation of manganese by oxidation with bromine water to manganese dioxide in hot solution, the presence of ammonium salts has a decidedly inhibiting effect. The extent of the effect depends principally upon three similar reactions, as follows:

```
2Br_2 + 2H_2O = 4Br^- + O_2 + 4H^+

3Br_2 + 2NH_4^+ = 6Br^- + N_2 + 8H^+

Br_2 + Mn^{++} + 3H_2O = 2Br^- + MnO_2H_2O + 4H^+
```

Each of these reactions may be expressed through the intermediate formation of hypobromous acid according to the equilibrium: $Br_2 + H_2O \rightleftharpoons Br^- + HBrO + H^+$, and the subsequent oxidation of the reducing agent in question by the hypobromous acid thus formed, the hypobromous acid reacting more rapidly with the reducing agents than does bromine itself. The initial presence of acid by its common ion effect, and the presence of alkali acetate by its ability to cut down the hydrogen-ion concentration, disturb the above equilibrium reaction, causing marked variation in the hypobromite concentration and hence retard or accelerate the oxidation reactions, as the case may be.

In hot solution and in the presence of alkali acetate, bromine water oxidizes ammonium ion more readily than it does manganous ion. With no acid initially present and with a moderate excess of acetate, ammonium ion is quantitatively oxidized by an excess of bromine. After this oxidation is complete, the presence of large amounts of acetate causes consumption of any excess bromine present, due to the decomposition of hypobromous acid into bromide and oxygen with corresponding loss in oxidizing power. Without the presence of acetate, ammonium salts are likewise oxidized quantitatively by bromine water in neutral solution, but the reaction proceeds much more slowly, and the rate of reaction varies inversely with the ionization of the acid forming the negative radical of the ammonium salt.

The precipitation of manganese by bromine water in hot, neutral solution is almost inappreciable in the absence of acetate. With alkali acetate present, in neutral solution manganese is quantitatively oxidized and precipitated from solution on boiling with excess bromine. The extent of precipitation is greatly influenced by the initial acidity of the solution, more so than in the ammonium salt reaction. A large excess of sodium acetate makes the precipitation of manganese dioxide more complete, but causes excessive consumption of bromine by its decomposition of water which occurs almost simultaneously. Manganese dioxide can be precipitated quantitatively from neutral solution in the presence of a slight amount of ammonium salts when sodium acetate is present in excess, and in such a case both the ammonium salt and the manganese salt are completely oxidized. With an increase in the concentration of the ammonium salt, the precipitation of the dioxide is retarded, and with a moderate excess of ammonium salt can be almost entirely prevented. The ammonium salt, being oxidized more rapidly, forms by its reaction a sufficient concentration of hydrogen ion to prevent the manganese precipitation.

When manganese is to be precipitated as dioxide after a basic acetate separation, it is important, therefore, that no appreciable amounts of ammonium salts are present. If present, they should be removed previous to the precipitation by evaporation with aqua regia. It sometimes happens that in the evaporation of the filtrate from a basic acetate separation, a small precipitate results which may be (1) manganese dioxide due to oxidation of the manganese by the air; or (2) more basic acetate of a tervalent element due to incomplete basic acetate separation; or (3) a mixture of the two. In such a case, the precipitate should either be put through another basic acetate procedure, or it may be dissolved in acid and the tervalent element precipitated by ammonium hydroxide in the presence of ammonium salt10 and removed by filtration. In the latter case, the filtrate containing any possible manganese should not be added to the main filtrate. since it now contains ammonium salts and would prevent the subsequent precipitation of manganese dioxide. This auxiliary filtrate should, therefore, be saved and added to the main solution after the manganese dioxide has been precipitated, redissolved, and is ready for precipitation as manganese ammonium phosphate.

Summary

- (1) The effect of the presence of ammonium salt on the precipitation of manganese dioxide by bromine water following a basic acetate separation was studied by determining the amounts of bromine used up in reactions with solutions of (a) ammonium sulfate, (b) manganous sulfate, (c) mixtures of the two, under varying degrees of initial acidity and in the presence of varying amounts of alkali acetate. The numerical values obtained are graphically tabulated for comparison.
- (2) The tabulated results show that each of the reactions is progressively retarded by an increase in the initial concentration of acid, and progressively accelerated by an increase in the concentration of acetate present, and the effect is greater in the case of the manganese salt than in the corresponding case of the ammonium salt.
- (3) In the absence of acid, ammonium ion and manganous ion are quantitatively oxidized by bromine water, but the amount of free bromine used up is slightly in excess of the amount theoretically required.
- (4) The results obtained can be explained by considering the mass-action effect of hydrogen ion and of acetate ion on the equilibrium reaction between bromine and water, and assuming that the hypobromous acid formed oxidizes ammonium ion and manganous ion more readily than does bromine, and under the existing conditions also decomposes slightly into oxygen and bromide.
- (5) When ammonium salts and manganese salts are present together in neutral solution in the presence of acetate, the ammonium ion is more ¹⁰ See Lundell and Knowles, This Journal, **45**, 676 (1923).

readily oxidized by bromine water, and by its formation of hydrogen ion retards the precipitation of manganese dioxide.

The general photochemical equation of Plotnikow¹ provides for reactions involving more than one photosensitive substance, and also "dark" reactants indispensable but not activated under the given conditions

$$-dM/dt = KA_1A_2...A_n(a-x)^{n_1}(b-x)^{n_2}...(p-x)^{n_n}$$

where A_1 and A_2 are the rates of light absorption by Reactants 1 and 2, to which the concentrations of their activated molecules C_1' and C_2' are approximately proportional, while (a-x), (b-x) are concentrations of "dark" reactants. The reaction between these molecular species, determined by these concentrations, has a velocity constant k_1 .

The photochemical oxidation of quinine by chromic acid in the presence of sulfuric acid was investigated in 1906-7 by Luther and Forbes.²

The first two reactants are known to be photosensitive in various reactions; the third is undoubtedly a dark reactant. The data of this research should, therefore, serve to test Plotnikow's equation. When the test is made, however, it is found that chromic acid seems to behave only as an inert light filter, and that the reaction velocity is independent, within the limit of error, of the light absorbed by it, and not proportional to the latter, as Plotnikow's equation requires. Plotnikow's is of the opinion that some experimental error or inadequate analysis of the data on absorption is responsible for the discrepancy. We desire first to show deductively that in a system containing 2 photosensitive reactants capable of reacting even in the dark, there are doubtless partial reactions not provided for in Plotnikow's equation. The discrepancy may be explained in terms of these. Also, with the help of new experimental data, we shall thereafter demonstrate the limitations inherent in that factor of Plotnikow's equation which deals with the dark reactant.

Let the concentrations of unactivated molecules of 2 photosensitive reactants be C_1 and C_2 . In the dark, $-dM/dt = k_2C_1^{\ p}C_2^{\ q}(a-x)^{n_1}$... and k_2 may be evaluated. During illumination, according to the usual

¹ Plotnikow, "Allgemeine Photochemie," Vereinigung Wissenschaftlicher Verleger, 1920, p. 185.

² Luther and Forbes, This Journal, 31, 770 (1909).

³ Ref. 1, pp. 215, 416, 583.

assumptions, C_1 and C_2 are still large compared with C_1' and C_2' , and k_2 still applies to these unactivated portions. Then the contribution to the total reaction velocity in the illuminated system made by C_1 and C_2 is calculated from k_2 and the *total* concentrations of the reactants. This contribution is usually subtracted from the total reaction velocity in light to find -dM/dt, the photochemical reaction velocity proper, due to C_1' and C_2' . Obviously, the general equation anticipates these two and only these two reaction types.

But two other partial reactions, not provided for by previous investigators, now appear inevitable. For if the unactivated C_2 reacts with unactivated C_1 and (a-x), it can scarcely escape reaction with the activated C_1' and (a-x), introducing the velocity constant k_3 , where $k_1 > k_3 > k_2$. Likewise C_1 will react with C_2' and (a-x), introducing a fourth constant k_4 , where $k_1 > k_4 > k_2$. The greatest divergences from Plotnikow's equation should now occur if C_1' and C_2' are both relatively small, and k_3 , for instance, is almost as great as k_1 while k_4 is but little greater than k_2 . The experimenter would then conclude that -dM/dt was closely proportional to A_1 , and practically independent of A_2 . If now we write quinine as Reactant 1 and chromic acid as Reactant 2 in the above picture, we have at once a rational explanation of the anomaly which led Plotnikow to object to the conclusions of Luther and Forbes.

Such a mechanism virtually assigns to chromic acid the role of a dark reactant, to whose concentration or some power of the same the reaction velocity should perhaps be proportional. But Luther and Forbes found no such relation, except when C_2 was small compared with C_1 , and A_1 was relatively large. They explained this in terms of two consecutive reactions, the first involving activation of quinine, the second actual oxidation by chromic acid. When C_2 fell below 0.0005, C_1 was not, by oxidation, diminished much below the constant stationary value C_1 which it could have attained under conditions the same except for complete absence of chromic acid. Then -dM/dt should be closely proportional to C_2 , as Luther and Forbes observed. But when C_2 was large, and especially when a-x was large also, C_1 was at all times much less than C_1 ". One would now expect that changes in C_2 would be relatively unimportant, but that C_1 and A_1 would practically determine reaction velocity, as was also proved.

But it was the influence of the dark reactant proper (sulfuric acid in this case) that chiefly interested us. According to Plotnikow's equation the reaction velocity should be in all cases proportional to some constant power one, for instance of the concentration of such a dark reactant. The previous data bearing on this problem are scanty. Most workers on photochemistry, Luther and Forbes among them, have evaded it by keep-

⁴ Plotnikow, Z. physik. Chem., 58, 219 (1907).

ing a-x both large and unvaried. Some, like Chapman,⁵ in his work on the chlorine-hydrogen reaction, mentions the minimum concentration which is without influence on reaction velocity. We know of no adequate experimental study of such questions.

Materials.—v. s. p. Quinine sulfate, thrice recrystallized and dried over sulfuric acid, melted at 204.6° . The potassium dichromate was recrystallized and dried at 110° before weighing out. Standard sodium thiosulfate solutions made up from thrice recrystallized salt a month before the work began gave titers of 0.01091 and 0.02285 against dichromate.

The light source was a Cooper-Hewitt quartz mercury lamp, type designed for 110 volts and 4 amperes. Owing to the well-known inconstancy of such lamps, each new reaction mixture was exposed to light side by side with a reference solution in which the initial concentrations were invariably: $C_1 = 3$ g./liter, $C_2 = 0.010$ g. equivalent (0.0033 mole) per liter, a = 0.977 g. equivalent per liter.

The reaction vessel was a 95mm, crystallizing dish divided into semicircular segments by a vertical partition. We proved by special experiments that typical reaction mixtures maintained their titer unchanged for a long time in contact with considerable surfaces of the de Khotinsky cement used. The 95mm. dish was placed inside a 140mm. dish on ledges several millimeters high, and surrounded by water and ice frequently renewed. The temperature variations were unimportant. The combination was mounted on a pivoted wooden disk which, by means of a geared-down electric motor and an eccentric, was made to turn back and forth through an angle of 150° a dozen times per minute. Glass grids dragging through the solutions in the inner dish kept them well stirred. The lamp was fastened in a position always the same with respect to the reaction vessel, about 10 cm. above it. As the segments were not exactly equal in area, or in illumination received, experiments were made at intervals with identical solutions in both segments. The ratio between the quantities of chromic acid reduced was used as a factor to correct the ratios found in the regular experiments. The time of exposure to light was planned, as closely as possible, to reduce about 10% of the reference solution, and it was then assumed that the corrected ratio between the quantities of chromic acid reduced represented nearly enough the ratio between total reaction velocities at the start of the given experiment.

In each experiment a third solution, identical with the new reaction mixture, was made up simultaneously, left in the dark during the run, and then titrated under strictly parallel conditions. Less frequently the dark reaction of the reference solution was checked. Upon subtraction, $-\mathrm{d}M/\mathrm{d}t$ resulted with elimination of systematic titration errors.

Iodimetry was adopted in spite of well recognized uncertainties, some of which have since been cleared up.⁶ The contents of reaction vessels, with rinsings, were transferred to conical flasks. Oxygen was excluded by a stream of carbon dioxide. Equal quantities of water were added, and of acid also, except when the original solutions contained a sufficient excess. The iodine set free when excess of iodide was added was at once discharged by standard thiosulfate solution, adding the starch at the end. The flasks, sealed for half an hour were again titrated, and once more after an additional 2 hours, if necessary. Thus the liberation of iodine, very

⁵ Chapman and Whiston, J. Chem. Soc., 115, 1267 (1919).

⁶ Vosburgh, This Journal, 44, 2120 (1922).

slow in presence of very dilute chromic acid, became complete without error from atmospheric oxygen.

Weigert and Saveanu⁷ have investigated the photochemical oxidation of quinine by atmospheric oxygen. Fearing that this might complicate the oxidation by chromic acid, we repeated typical experiments previously made in air, surrounding the reaction vessel with a tall cylinder kept full of carbon dioxide from a tank. Actual analyses gave 70% to 90% by volume. The results were unchanged, within the limit of error.

With acid concentrations not greater than $0.02\,N$ the quantities of acid consumed during illumination were estimated through preliminary experiments, and enough $0.5\,N$ acid was gradually added to keep its concentration nearly constant.

Data and calculation of a typical experiment follow.

Solution 1: Segment I, 0.15 g. of quinine, 0.0245 g. of potassium dichromate, 0.0239 g. of sulfuric acid, volume, 50 cc. Then $C_1 = 3$ g. per liter, $C_2 = 0.01$ equivalent normal, a = 0.977 equivalent normal. Solution 2: volume 50 cc., Segment II, $C_1 = 3$ g. per liter; $C_2 = 0.01$, a = 0.106. Dark solutions 3 and 4, identical with 1 and 2.

Titers after 2 hours at 0°, nearly: (1) = 42.65 cc. of sodium thiosulfate, (3) = 46.85 cc.; $-\Delta C_2 = 4.20$. (2) = 43.20 cc., (4) = 46.48 cc.; $-\Delta C_2 = 3.28$.

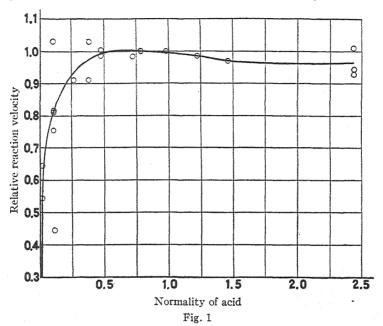

Ratio corrected for inequality of segments = $3.28/4.20 \times 0.971 = 0.78$.

Let us first predict the effect of changing chromic acid concentration, C_1 and a being constant. In the present research A_1 was much greater than in the work of Luther and Forbes through substitution of a quartz lamp for one of uviol glass, and by eliminating 2 layers of common glass between lamp and solution. This fact, and our lower acid concentrations, should make the order of reaction with respect to chromic acid increase beyond zero before its concentration fell below $0.0005\ N$. This point is reserved for later investigation.

As the experimental conditions were not reproducible, complete data are not given. The results, where C_2 was constant, are presented simply by plotting against acid concentrations the ratios of reaction velocities in various solutions to that in $0.977\ N$ acid under conditions otherwise the same. Above $0.5\ N$, velocity is nearly independent of acid concentration. No explanation for the slight but unmistakable maximum could be found. Perhaps there is an increased absorption in this region. Below $0.5\ N$ the order of reaction with respect to acid rapidly increases. Between $0.02\ N$ and $0.01\ N$ it is 1, and at lower concentrations it presumably tends toward 2, the order in the dark which we established by special experiments over long periods. Insoluble precipitates, forming when a < 0.01, discouraged investigations in such solutions. It is clear, however, that photochemical reaction velocity could be proportional to the expected power of this dark reactant only at very low concentrations of the latter. Here the actual rate of oxidation of the quinine is slow in comparison with

Weigert and Saveanu, Nernst-Festschrift, 1912, 464.

its speed of activation, and determines the total reaction speed. In this region, and in this region only, Plotnikow's generalization as to the dark reactant is applicable. On the other hand, it would apply over the widest ranges of concentration, in reactions where the velocity of the reaction

stage involving the dark reactant was always small in comparison with the speed of activation.

We gratefully acknowledge a grant from the Cyrus M. Warren Fund for the purchase of a quartz lamp, and a grant from the Du Pont Fund.

Summary

With 2 photochemically activated reactants the total reaction velocity should be the sum of 4 partial reactions with 4 different velocity constants. One involves 2 activated molecular species, another only unactivated species, and 2 others involve 1 activated and 1 unactivated species. It is shown how species known to be activated in some reactions may give no evidence of activation in others.

The concentration of a photochemically unactivated reactant is shown to be without effect upon the velocity of a photochemical reaction provided that its concentration is not so small that its reaction with activated reactants does not become the slow stage of the total process.

THE INFLUENCE OF NEUTRAL SALTS ON THE TEMPERATURE COEFFICIENT OF REACTION VELOCITY

By F. O. RICE AND WILLIAM LEMKIN¹
Received May 9, 1923

The reaction we studied is that between acetone and iodine in dilute aqueous solution, and our technique and methods are described in a previous paper. The velocity constant used throughout this paper is the (calculated) number of moles of iodine disappearing per minute from 1 liter of a solution containing 1 mole of acetone, 1 gram equivalent of acid, about $0.01\ N$ iodine, and a stated amount of neutral salt. The solution also contained $0.025\ M$ potassium iodide to keep the iodine in solution. When this constant was determined at two temperatures for a solution of the same composition, the ratio is referred to as the temperature coefficient of the reaction. We are thus comparing the velocities at two temperatures for solutions containing the same concentration of total acid.

Lamble and Lewis³ have attempted to calculate the temperature coefficient for solutions of equal hydrogen-ion concentration. Since, in the case of our solutions, there are no reliable data for making the necessary calculations, and there is not even agreement as to the nature of the catalyst,⁴ we have not attempted to calculate the temperature coefficient for equal concentrations of catalyst.

The abnormal action of neutral salts is commonly ascribed to hydration effects and therefore, we made a preliminary study of the effect of lithium nitrate on the velocity and temperature coefficient of the reaction. We selected this salt because it shows very abnormal changes in solubility over the temperature range 20–30°. The solubility of lithium nitrate is almost doubled between 23° and 30°, and the salt also possesses a congruent melting point and a transition point, $3\rm{H}_2\rm{O}-1/2\rm{H}_2\rm{O}$, between these two temperatures. In previous investigations the salts used showed normal changes in solubility over the region investigated and we hoped, therefore, to find the velocity measurement affected by the abnormal hydration effects.

We crystallized the lithium nitrate twice from distilled water, and by a blank test showed that a 2N solution of the salt absorbed no appreciable amount of iodine over a period of 4 hours. We also tested to see whether

¹ The work included in this paper is summarized from the thesis presented by William Lemkin, submitted as part of the requirement for the degree of Doctor of Philosophy in New York University.

⁴ Kendall, Proc. Nat. Acad. Sci., 7, 56 (1921).

lithium nitrate alone had any catalytic activity. The results in Table I show that the neutral salt alone has no measurable catalytic action.

Table I

Effect of Lithium Nitrate on the Reaction, CH₃COCH₃ + I₂

Concentration of acetone, 0.071 (M)

Concentration of acceptate, 0.071 (m)							
Salt present	None	None	$2.2~M~{ m LiNO_3}$	2.2 M LiNO3

With no salt present. $k_{30}/k_{23} = 2.2393$, precision measure = 0.20%.

With 2.10 M LiNO₃ present $k_{20}/k_{23} = 2.2401$, precision measure = 0.20%.

The precision measure of a single experiment was taken to be 0.20%.

These solutions all contained about 0.1 $\it M$ acetone, 0.1 $\it N$ HNOs, 0.01 $\it N$ iodine and 0.025 $\it M$ KI.

The result shown in Table II was entirely unexpected because, on the basis of the radiation theory, the great increase in the velocity should be accompanied by a smaller temperature coefficient. Our next step was to investigate whether this behavior was shown by other salts.

Effect of the Neutral Salts of Strong Acids on the Temperature Coefficient

We selected 23° and 25° as the two temperature limits, and measured the temperature coefficient by the method already described which did not involve the measurement of the two velocity constants separately. However, in several cases we measured the velocity constants at the two

temperatures and showed that the temperature coefficients, obtained in this manner, checked with those obtained by the shorter method. The neutral salts used were the highest grades that could be purchased, and in all cases were tested for absorption of iodine. Only those specimens that gave a negligible absorption over the period of an experiment were used. Table III contains the ratios obtained for 6 strong acids alone and in presence of various neutral salts.

 $\label{thm:complex} Table~III \\ Temperature~Coefficients~of~the~Reaction,~CH_3COCH_3~+~I_2,~when~Catalyzed~\\ \text{by Various~Strong~Acids~Alone~and~in~the~Presence~of~Neutral~Salts}$

Acid used	k_{25}/k_{23}	Acid used	Neutral salt M	k_{25}/k_{23}
HNO_3	$\begin{cases} 1.2650 \\ 1.2623 \end{cases}$	HNO3 HCl	2.0 NaCl 1.0 NaCl	1.2625 1.2624
HC1	1.2623	HNO_3	2.0 KNO ₃	1.2634

Benzenesulfonic	1.2613	HNO_3	2.1 LiNO ₃	1.2670
Trichloro-acetic	1.2581	HNO_3	1.81 KNO ₃	1.2642
β -Naphthalenesulfonic	1.2594		Mean	1 = 1.2632
Mean	n = 1.2617			

The acids were present at a concentration about 0.1 N. 0.025 M KI was present to keep the iodine in solution. The precision measure of each experiment is 0.20%.

From Table III we see that the reaction has the same temperature coefficient when catalyzed by strong monobasic acids, and the temperature coefficient is unaffected by the presence of the salts of these acids. In one of our experiments with nitric acid as catalyst we had the solution saturated with sodium chloride and also some of the solid salt present. The temperature coefficient was the same as when no salt was present.

Effect of Moderately Strong Acids and Weak Acids on the Temperature Coefficient, in both the Presence and the Absence of Their Salts

We investigated first the temperature coefficient of the reaction using sulfuric acid alone and in the presence of various concentrations of sodium sulfate. In these cases we measured the velocities of the reactions. The results are given in Table IV.

It will be readily seen from Table IV that the presence of $0.434\ M$ sodium sulfate hardly affects the velocity, yet the temperature coefficient is greatly diminished. In another experiment using less sodium sulfate we found that both the velocity and the temperature coefficient were lowered, which is the opposite of the effect predicted by the radiation theory.

In Table V we give the results for the other acids that we investigated. In the cases of the very weak acids the results are probably slightly higher

TABLE IV

VELOCITY CONSTANTS OF THE REACTION, CH₃COCH₃ + I₂, WHEN CATALYZED BY SULFURIC ACID ALONE AND IN THE PRESENCE OF SODIUM SULFATE

Salt present	None	None 0	434 M NacS	O ₄ 0.434 M	0.87 M	$0.87\ M$	
Temp., ° C		25	23	25	23	25	
Av	12.52	15.56	12.98	15.87	15.56	18.93	
For H ₂ SO ₄ , no sait	present.	k_2	$k_{23} = 1.3$	2430; henc	e Q = 19,	070.	
0.434 M Na ₂ SO ₄ p:	resent.	k_2	$_{5}/k_{20} = 1.3$	2225; henc	eQ = 17	610.	
0.87 M Na ₂ SO ₄ pre	esent.	k _o	$s/k_{00} = 1$	2169: henc	$e \hat{O} = 17$	010	

The precision measure of each experiment is 0.20%, so that the precision measure of k_{25}/k_{23} is 0.28% and the precision measure of Q is 1.2%. For strong monobasic acids Q = 20.540.

Q was calculated from the Arrhenius formula as in the previous paper.2

than the true values, because the hydriodic acid liberated in the reaction probably took part in the catalytic action, and this would tend to raise the temperature coefficient slightly.

Effect of Small Quantities of Neutral Salts on the Velocity of Reaction

We investigated the effect of adding small quantities of neutral salts, especially those salts of the higher alkali metals which are not so extensively hydrated as lithium and sodium salts. We first tried the effect of rubidium nitrate on the reaction catalyzed by nitric acid. There was a distinct increase in the velocity. We then determined to try the effect of still smaller concentrations of salt. It must be remembered however, that in all our experiments it was necessary to have present $0.025\ N$ potassium iodide in order to keep the iodine in solution. By using hydriodic acid as the catalyst we avoided the necessity of having potassium iodide present since iodine is soluble in aqueous hydriodic acid.

We therefore measured the velocity, with hydriodic acid as catalyst and with no neutral salt whatsoever present, and then measured the velocity again after the addition of small quantities of various neutral salts. We did these experiments in pairs, each pair being performed simultaneously in the same thermostat under similar conditions. The absolute velocities were not measured but the conditions were such that we obtained the relative velocities with a high degree of precision. In no case did we detect any fall in velocity due to the addition of neutral salt. If hydriodic acid was 95% dissociated, the addition of $0.01\ N$ neutral salt should diminish the hydrogen-ion concentration about 0.5%, assuming

that the simple mass-action law holds. These results, therefore, in conjunction with the temperature-coefficient measurements give some support to the complete dissociation theory for strong acids.

A theoretical discussion of the results obtained in the paper will be given in a succeeding communication.

TABLE VI

Effect of Very Small Concentrations of Neutral Salt on Velocity of Reaction

Conen. M	0.079	0.053	0.01	0.01	0.01	0.01	0.1
Salt	$RbNO_3$	RbNO ₃	KNO_3	KI	KI	CsNO ₃	$CsNO_3$

% incr. in V	1.9	9.1	2.7	0.16	0.10	0.32	3.0

In the two experiments with RbNO3, 0.025 M KI was present to keep the iodine in solution. This was omitted in all the other experiments.

^a In 30% C₂H₅OH.

Summary

- 1. We have measured the temperature coefficient of the reaction, $CH_3COCH_3 + I_2 = CH_3COCH_2I + HI$, when catalyzed by various acids alone and in presence of their salts.
- 2. The temperature coefficient of all strong acids is the same, and is unaffected by the presence of their salts.
- 3. The reaction has a lower temperature coefficient when catalyzed by weak acids. If the acids are arranged in descending order of their strengths this is also the order of diminishing temperature coefficients.
- 4. When the reaction is catalyzed by sulfuric acid the presence of one of its salts diminishes the temperature coefficient considerably. This is probably true for all weak acids.
- 5. Small quantities (about 0.01 M) of salts of the alkali metals increase the velocity slightly. There is no indication of any diminution such as we might expect on the basis of the mass-action law.

A CORRECTION TO THE FREEZING-POINT DIAGRAM OF LEAD-SODIUM ALLOYS

By G. Calingaert and W. J. Boesch Received June 16, 1923

The compounds capable of existing in lead-sodium alloys, as found in the literature¹ are: Na₄Pb, Na₂Pb, NaPb and Na₂Pb₅, and were identified by Mathewson as corresponding to the maxima of the freezing-point diagram of these alloys.

The thermal data obtained by one of the authors of this paper for lead-sodium alloys of approximately the composition, Na₂Pb (66.6 atomic per cent. of sodium), differed appreciably from the results reported by Mathewson. The freezing-point data were therefore determined for alloys between 50 and 75 atomic per cent. of sodium.

Experimental Procedure

The cooling curves were determined on about 100g. samples of each alloy, using a nickel crucible, an iron agitator and a well-lagged electric furnace. In order to prevent oxidation, a slow current of hydrogen was passed through the furnace during all the experiments. The temperature was read at 30- or 60-second intervals by means of a calibrated chromelalumel thermocouple, using a Leeds and Northrup potentiometer. The thermocouple was protected from the corrosive action of the alloys by a Pyrex glass tube, which was but slightly attacked by the sodium.

The lead used was pure, as indicated both by analysis and melting-point determination. The sodium was melted and cut under paraffin oil to free it from hydroxide, and to prevent oxidation. The composition of the alloys was determined by analysis. It was found that the analytical method used by previous experimenters, namely decomposition of the alloy by water, and titration of the sodium hydroxide formed, invariably gave low results, due to incomplete decomposition of the alloy. Accurate analyses were obtained by decomposing the alloy with water, dissolving the residue in nitric acid and then converting both metals into sulfates. After separation from the lead, the sodium was determined gravimetrically as sulfate.

Results

The results are summarized in Table I and plotted in Fig. 1. Fig. 2 is a complete phase diagram of lead-sodium alloys, as given by Mathewson, but corrected according to the work of the authors for the alloys of com-

Discussion

These results indicate that the following corrections should be made to the diagram as reported by Mathewson.

- 1. The pure compound separating from alloys of composition between 58.8 and 76.6 atomic per cent. of sodium is Na₅Pb₂ and not Na₂Pb.
- 2. This compound forms solid solutions with both NaPb and Na₄Pb and not only with the latter.
- 3. Alloys of composition between 58.8 and 71.4 atomic per cent. of sodium rearrange at 182° on cooling; the compound Na₅Pb₂ disappears, and a new compound, Na₂Pb, is formed.

It is concluded therefrom that the freezing-point diagram of lead-sodium alloys, as given in the literature should be replaced by the Fig. 2 given above.

The failure of earlier work to show the exact reaction taking place in alloys can be attributed to two reasons: (1) the insufficient number of points investigated; (2) the too rapid rate of cooling which does not enable the slight changes such as that corresponding to the formation of Na₂Pb to be detected.

Summary

It is shown that the pure compound separating from alloys of lead and sodium, whose composition is between 58.8 and 76.6 atomic per cent. of sodium, is Na₅Pb₂, this compound forming solid solutions with both NaPb and Na₄Pb.

Alloys containing 58.8 to 71.4 atomic per cent. sodium rearrange at 182° on cooling, the compound Na₅Pb₂ disappears and a new compound Na₂Pb is formed.

The complete diagram of lead sodium alloys is given corrected for the above results.

CAMBRIDGE 39. MASSACHUSETTS

NOTE

A Source of Trouble in Electrometric Measurements of Hydrogen-Ion Concentration.—If a mercury-calomel-saturated potassium chloride half cell is used for electrometric measurements of hydrogen-ion concentration, it is advisable to introduce an intermediate vessel of potassium chloride solution, which may be renewed from time to time, between the end of the tube leading from the calomel electrode and the "salt bridge" or connecting tube leading to the measuring vessel.

A reason commonly given in the literature for this precaution is that it avoids danger of the potassium chloride in the mercury electrode chamber becoming contaminated by substances that might diffuse back from the measuring vessel.

In the opinion of the authors, the real danger is this: mercuric chloride is formed in the mercury calomel cell according to the well-known reaction, $Hg_2Cl_2 \longrightarrow HgCl_2 + Hg$. The gray color of calomel which has been in

contact with potassium chloride solutions is due to the metallic mercury which is liberated in small quantities by this reaction. Equilibrium is reached when the concentration of mercuric chloride attains a certain value; this equilibrium concentration depends partly on the concentration of potassium chloride in the electrode. The stronger the potassium chloride, the more mercuric chloride will be formed. This mercuric chloride diffuses out of the electrode through the connecting tubes and, unless an intermediate vessel is used, eventually finds its way into the hydrogen electrode chamber. Here it "poisons" the hydrogen electrode, slightly at first but more as time goes on, until no reliable measurements can be made even with freshly platinized electrodes.

A convenient test for mercuric chloride is to add a drop or two of sodium sulfide solution to the potassium chloride solution to be tested. Mercury

in sufficient concentration to poison a hydrogen electrode will give a brown coloration.

A calomel half cell has been devised for use with potentiometers having a quadrant electrometer for a null instrument, which obviates the necessity of changing the intermediate solution. In this cell the potassium chloride solution is separated from the intermediate chamber by a thin (0.05 mm.) glass bulb which conducts electricity sufficiently to charge a quadrant electrometer. See Fig. 1. This half cell cannot be

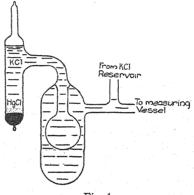

Fig. 1

used with a galvanometer as the resistance of the bulb is too high, but in case an electrometer must be used for other determinations the above electrode might be convenient for work involving measurement of hydrogen-ion concentration.

It takes several days for the glass surface potentials of the bulb to become constant after the electrode is filled and, as the potential finally reached may be slightly different from that of an ordinary calomel electrode, a correction must be made for the discrepancy. This discrepancy can easily be measured by determining the potential of the mercury electrode against the hydrogen electrode in a solution of known hydrogenion concentration.

An electrode of this type has been used in this Laboratory for several months and has given satisfactory results.

BIOPHYSICS LABORATORY HARVARD UNIVERSITY BOSTON 17, MASSACHUSETTS Received May 24, 1923 W. T. Bovie Walter S. Hughes

SYNTHESIS OF PHENYLANTHRANILIC ACIDS

By NEAL TUTTLE Received May 23, 1921

The discovery was made by Ullmann, that the mobility of halogens in the benzene ring was greatly increased by the addition of copper as catalyst. The first reaction studied in detail was the formation of phenylanthranilic acid by the action of aniline on o-chlorobenzoic acid, as represented by the following equation: C_6H_5 . $NH_2 + Cl. C_6H_4$. $COOH = C_6H_5$. $NH. C_6H_4$. COOH + HCl. Besides the copper, Ullmann added 2 equivalents of potassium carbonate, one to form the potassium salt of o-chlorobenzoic acid and the other to neutralize the hydrochloric acid resulting from the reaction. In this manner he obtained crude phenylanthranilic acid of exceptionally good quality in a yield of 97%.

In the years immediately following the discovery, this method was employed by Ullmann and his pupils in the synthesis of many substituted anthranilic acids, salicylic acids and naphthalene derivatives;² but since it attained commercial importance almost at once, it was soon buried in patents and has not often been applied in pure synthetic organic chemistry.

The present investigation deals with the action of the dialkyl-p- and m-phenylenediamines and piperidine on o-chlorobenzoic acid and its monoand dinitro derivatives which are accessible by direct nitration. The ultimate object is the conversion of these substituted phenylanthranilic acids into unsymmetrical acridones and acridines, and the following is a brief summary of the results which have been obtained.

Action of Dialkylphenylene-Diamines

On o-Chlorobenzoic Acid.—Dimethyl-p-phenylenediamine reacts with o-chlorobenzoic acid in the presence of copper to give 4'-dimethylamino-diphenylamine-2-carboxylic acid (I).

$$\begin{array}{c|c} COOH \\ \hline \\ NH \\ \hline \\ II \\ \hline \\ N(CH_3)_2 \\ \hline \\ NH \\ \hline \\ N(CH_3)_2 \\ \hline \\ NH \\ \hline \\ NH \\ \hline \\ NIII \\ \hline \end{array}$$

By heating this acid a few degrees above its melting point, it is converted almost quantitatively into 4-dimethylamino-diphenylamine (II). The properties of this compound were found to agree with those previously reported.³

When treated with coned. sulfuric acid, 4'-dimethylamino-diphenyl-

- 1 Ullmann, Ber., 38, 2211 (1905).
- ² Ullmann, Ann., (a) 355, 312 (1907); (b) 366, 79 (1909); etc.
- ² Fischer, Ber., 21, 2612 (1888).

amine-2-carboxylic acid is converted completely into 2-dimethylamino-acridone (III).

Similar results were obtained by the reaction of o-chlorobenzoic acid with diethyl-p-phenylenediamine as well as with both dimethyl- and diethyl-m-phenylenediamine.

On 5-Nitro-2-chlorobenzoic Acid.—Dimethyl-p-phenylenediamine reacts smoothly with 5-nitro-2-chlorobenzoic acid in the presence of copper to give 4-nitro-4'-dimethylamino-diphenylamine-2-carboxylic acid (IV).

It was expected that this reaction would be complete in a shorter time than the reaction between the same base and o-chlorobenzoic acid, since it is a well-established fact that a negative substituent in the ortho position with respect to the halogen in the benzene ring greatly increases its mobility, and that a negative group in para position to the halogen has a similar, though considerably smaller, labilizing effect.⁴

However, on investigating the action of dimethyl-p-phenylenediamine on 5-nitro-2-chlorobenzoic acid, the author found that the reaction required $2^1/2$ hours for completion, or approximately the same time as was required by o-chlorobenzoic acid. In the action of dimethyl-m-phenylenediamine on these two acids, as will be shown later, 5-nitro-2-chlorobenzoic acid had to be digested more than twice as long as o-chlorobenzoic acid to complete the reaction. On account of these unexpected results, the relative reactivities of the chlorine in the two cases was tested by the digestion of the acids with sodium hydroxide solution, precipitation with nitric acid and testing the filtrates with silver nitrate. o-Chlorobenzoic acid was recovered unchanged, the filtrate giving only the slightest cloudiness with silver nitrate. The filtrate obtained by the same procedure with 5-nitro-2-chlorobenzoic acid gave, however, a voluminous precipitate with silver nitrate, and the recovered acid was identified as a mixture of 5-nitro-2-chlorobenzoic acid and 5-nitrosalicylic acid.

These results prove that the nitro group in the para position does make the chlorine more labile, and the discrepancies with the dimethyl-phenyl-enediamines are probably more apparent than real. The condensation products of o-chlorobenzoic acid with the dialkyl phenylenediamines decompose to some extent during the reaction, while those of 5-nitro-2-chlorobenzoic acid appear to be more stable at the temperature of the reaction, possibly because they melt at a higher temperature.

An unexpected result was obtained when diethyl-m-phenylenediamine

4 Schöpff, Ber., 22, 3281 (1889).

acted on 5-nitro-2-chlorobenzoic acid in the presence of copper. The crude product was contaminated with a large amount of tar, as if the diamine had not entered into the reaction. After the tar had been removed by prolonged boiling of the sodium carbonate solution with animal charcoal, acidification yielded a white substance that melted sharply at 257°, without decomposition. On investigation it was found that this product had resulted from the elimination of 2 chlorine atoms from 2 molecules of 5-nitro-2-chlorobenzoic acid and was, in fact, 4,4'-dinitro-diphenyl-2,2'-dicarboxylic acid (V).

On 3,5-Dinitro-2-chlorobenzoic Acid.—As was to be expected, this acid acts so readily that the addition of copper is unnecessary.

Action of Piperidine

On o-Chlorobenzoic Acid.—When an amyl alcohol solution of piperidine and o-chlorobenzoic acid was digested in the presence of copper, a curious reaction occurred. The product was a white acid that crystallized from dil. alcohol in fine needles, melted at 155–156°, was free from chlorine and nitrogen, and proved to be salicylic acid.

Since the question immediately arose as to whether the salicylic acid owed its formation to the basic properties only of the piperidine, the process was repeated under the same conditions except that potassium hydroxide was substituted for the piperidine. In this case, however, most of the o-chlorobenzoic acid was returned unchanged, there being only qualitative indications that salicylic acid had been formed.

On 5-Nitro-2-chlorobenzoic Acid.—In amyl alcohol in the presence of copper, piperidine reacts with 5-nitro-2-chlorobenzoic acid, yielding 2-piperidino-5-nitrobenzoic acid (VI).

On 3,5-Dinitro-2-chlorobenzoic Acid.—Before either of the two reactions just described had been studied, an aqueous solution of piperidine, 3,5-dinitro-2-chlorobenzoic acid and sodium acetate was digested in the presence of copper, in the expectation that the piperidine nucleus would not enter in place of the chlorine between the nitro and carboxyl groups. The mixture became orange-colored as soon as warmed, and after the liquid had digested for 2 hours it was filled with fine green needles. These were collected and it was then observed that all the copper had disappeared. Renewed digestion of the mother liquor in the presence of fresh copper yielded more of the same needles. At the end a small amount of the copper remained undissolved. An attempted determination of the melt-

ing point of the green needles resulted in disaster, for at 320° the substance exploded violently, shattering the melting-point tube to dust. The analysis, which was made with great difficulty on account of the explosive nature of the compound, ultimately proved that the substance was the copper salt of 3,5-dinitrosalicylic acid (VII).

Labilizing Influence of the Nitro Group on Chlorine in the Benzene Ring

During the course of the syntheses already described, the author has investigated the mobility of the chlorine in o-chlorobenzoic acid and the influence of a nitro group in each of the four possible positions, 3, 4, 5 and 6. Of these 4 acids, the chlorine of 3-nitro-2-chlorobenzoic acid is the most labile, as would be expected, since the nitro and carboxyl groups occupy the two most influential positions. In the presence of copper, aniline reacts with 3-nitro-2-chlorobenzoic acid in alcoholic solution, yielding 2-nitrodiphenylamine-6-carboxylic acid (VIII).

The second acid, in order of the lability of the chlorine, should be 5-nitro-2-chlorobenzoic acid, containing 1 negative group in the *ortho* position with respect to the chlorine and the other in the *para* position. This actually seems to be the case, for the chlorine, as previously described, is removed from 5-nitro-2-chlorobenzoic acid by bases at the temperature of boiling water.

In 4-nitro- and 6-nitro-2-chlorobenzoic acid the nitro group in meta position with respect to the chlorine would be expected to exert no influence on its mobility. Since Ullmann condensed 4-nitro-2-chlorobenzoic acid with a large number of bases without commenting on the mobility of the chlorine it would appear that the nitro group of this acid is without influence on the chlorine. On the other hand, when the author digested 6-nitro-2-chlorobenzoic acid with excess of aniline in the presence of copper, it was wholly charred, and under other conditions was either charred or returned unchanged. These results seem to indicate that the nitro group in the 6 position makes the chlorine less labile than in o-chlorobenzoic acid. The difficulty of obtaining this 6-nitro acid, however, has prevented the author from completing the investigation.

The experimental part falls under the following headings: (I) dimethyl-p-phenylenediamine; (II) dimethyl-m-phenylenediamine; (III) diethyl-p-phenylenediamine; (IV) diethyl-m-phenylenediamine; (V) piperidine; (VI) investigation of the mobility of the chlorine in o-chlorobenzoic acid and its nitro derivatives.

Experimental Part

The o-chlorobenzoic acid was prepared at first by diazotization of o-toluidine and oxidation of the resulting o-chlorotoluene with potassium permanganate; but since the oxidation of o-chlorotoluene can be conveniently performed only with small quantities, this method was soon discarded in favor of the well-known process for the preparation of anthranilic acid from phthalimide.⁵ The anthranilic acid was always diazotized without being isolated.

The 5-nitro- and 3,5-dinitro-2-chloro-benzoic acids were prepared by direct nitration of o-chloro-benzoic acid.⁶

The dimethyl- and diethyl-phenylenediamines were prepared from the dialkyl anilines and were purified by distillation in a current of hydrogen. They were preserved in sealed tubes from the oxidizing action of the air.

Dimethyl-p-phenylenediamine

4'-Dimethylamino-diphenylamine-2-carboxylic Acid (I).—Three g. of o-chlorobenzoic acid, 2 g. of dimethyl-p-phenylenediamine, 3 g. of potassium carbonate, 35 cc. of amyl alcohol and about 0.2 g. of copper powder were digested over a free flame for $2^1/4$ hours. After distillation of the amyl alcohol in a current of steam, the dark green solution was boiled for about an hour with animal charcoal. It was then filtered free from charcoal and copper powder and neutralized while still hot, whereupon all the product separated at once as an amorphous, green solid, that was dried (3.1 g.) and crystallized twice from alcohol, from which it separated in pale green prisms or needles.

In the first attempts to prepare this acid, copper was employed which had been made by the addition of zinc to a solution of copper sulfate, and no pure product could be isolated. Substitution of the so-called "molecular copper," which can be bought in the market, yielded a good product at once.

Since dimethyl-p-phenylenediamine becomes impure so rapidly in contact with the air, a steady stream of dry hydrogen was passed through the apparatus during the digestion.

Analyses. Subs., 0.1350: 12.5 cc. of N_2 (14°, 753 mm.). Subs., 0.1208: CO_2 , 0.3109; H_2O , 0.0688. Calc. for $C_{15}H_{16}O_2N_2$: C, 70.5; H, 6.3, N, 10.9. Found: C, 70.2; H, 6.3; N, 10.8.

The substance melts at 216° with decomposition. It is practically insoluble in water and only slightly soluble in xylene and alcohol. It dissolves more readily in acetic acid but does not separate on cooling.

4-Dimethylamino-diphenylamine (II).—One g. of 4'-dimethylamino-diphenylamine-2-carboxylic acid was heated in an oil-bath at about 220° until the evolution of carbon dioxide ceased. When cold the dark residue was extracted with hot alcohol, and the purple solution decolorized by boiling with animal charcoal. Concentration and cooling yielded fine, white needles, and two more crystallizations raised the melting point to 130°, that found by O. Fischer.³

2-Dimethylamino-acridone (III).—Two g. of 4'-dimethylamino-diphenylamine-2-carboxylic acid was dissolved in 20 g. of concd. sulfuric acid and the solution heated to 100°. It became fluorescent at once, and after 10 minutes was poured into 500 cc. of

⁵ Compt. rend., 10, 6 (1901); etc.

⁶ Graebe, Ann., 276, 40 (1893). Holleman and de Bruyn, Compt. rend., 20, 209 (1911). Ref. 2b.

water. Neutralization with ammonia yielded the acridone as a yellow, amorphous precipitate; yield, about 95%. It crystallized from alcohol in small, bright yellow clusters; m. p., $289-290^{\circ}$.

Analyses. Subs., 0.1024: CO₂, 0.2842; H₂O, 0.0550. Subs., 0.1054: 10.6 cc. of N₂ (16°, 760 mm.). Calc. for $C_{15}H_{14}ON_2$: C, 75.63; H, 5.88; N, 11.76. Found: C, 75.68; H, 5.96; N, 11.72.

This acridone is only slightly soluble in all organic solvents. In alcohol and concd. sulfuric acid the fluorescence is blue; in acetic acid, green.

4-Nitro-4'-dimethylamino-diphenylamine-2-carboxylic Acid (IV).—Three g. of 5-nitro-2-chlorobenzoic acid, 2 g. of dimethyl-p-phenylenediamine, 2 g. of potassium carbonate, 35 cc. of amyl alcohol and about 0.2 g. of copper were digested for $2^1/_2$ hours. The amyl alcohol was then distilled with steam, and the red solution, after purification with charcoal, was neutralized with hydrochloric acid. The brown amorphous product was crystallized twice from alcohol, forming small, coppery needles; m. p., 234–235°.

Analyses. Subs., 0.1058: CO₂, 0.2330; H₂O, 0.0486. Subs., 0.1000: 11.8 ec. of N₂ (15°, 758 mm.). Calc. for $C_{16}H_{15}O_4N_3$: C, 59.8; H, 4.98; N, 13.95 Found: C, 60.05; H, 5.10; N, 13.8.

When the process just described was carried out in an atmosphere of hydrogen, the yield of crude product amounted to only 50%. Without the hydrogen, however, the yield was 75%.

This synthesis was also accomplished by digesting for 6 hours a solution of 2 g. of 5-nitro-2-chlorobenzoic acid, 1.35 g. of dimethyl-p-phenylenediamine and 2.7 g. crystallized sodium acetate in 20 cc. of water, with about 0.2 g. of copper. The product, however, was much more tarry and difficult to purify.

2,4-Dinitro-4'-dimethylamino-diphenylamine-6-carboxylic Acid.—One and sixtenths g. of dimethyl-p-phenylenediamine was added, drop by drop, to a solution of 3 g. of 3,5-dinitro-2-chlorobenzoic acid and 3.3 g. of crystallized sodium acetate in 20 cc. of water. A vigorous reaction took place, the mixture became brown, and a yellow precipitate separated; yield, 100%. The product was collected and purified by crystallization of the hydrochloride from dil. hydrochloric acid. The hydrochloride forms reddish-brown plates, is sparingly soluble in water and dil. hydrochloric acid, and melts gradually at 240–260°.

Analysis. Subs., 0.0806: 10.1 cc. of N_2 (13°, 754 mm.). Calc. for $C_{15}H_{15}O_6N_4C1$: N, 14.64. Found: 14.81.

A part of the pure hydrochloride was dissolved in water and the free 2,4-dinitro-4'-dimethylamino-diphenylamine-6-carboxylic acid precipitated with sodium acetate. Obtained in this manner, the acid was a bright yellow, amorphous powder, melting at 253° with decomposition.

Analysis. Subs., 0.1132: 15.5 cc. of N_2 (16°, 760 mm.). Calc. for $C_{15}H_{14}O_5N_4$: N, 16.18. Found: 15.96.

Dimethyl-meta-phenylenediamine

3'-Dimethylamino-diphenylamine-2-carboxylic Acid.—Three g. of o-chlorobenzoic acid, 2 g. of dimethyl-m-phenylenediamine, 3 g. of sodium carbonate, 35 cc. of amyl alcohol and 0.2 g. of copper were digested in an atmosphere of hydrogen for 2:05 hours. After removal of the amyl alcohol with steam and treatment of the solution with animal charcoal, the clear brown solution was cooled in ice and neutralized. The pale brown precipitate was collected rapidly and dissolved in hot 50% alcohol. As this cooled, pale brown needles separated, which after two more crystallizations were colorless and melted at 155°, without decomposition.

Analyses. Subs., 0.1120: CO₂, 0.2880; H_2O , 0.0644. Subs., 0.1096: 10.5 ec. of N_2 (18°, and 755 mm.). Calc. for $C_{15}H_{16}O_2N_2$: C, 70.31; H, 6.25; N, 10.93. Found: C, 70.12; H, 6.38; N, 10.99.

4-Nitro-3'-dimethylamino-diphenylamine-2-carboxylic Acid.—This acid was obtained by digestion for 5 hours of a mixture of 3 g. of 5-nitro-2-chlorobenzoic acid, 2 g. of dimethyl-m-phenylenediamine, 2 g. of sodium carbonate, 35 cc. of amyl alcohol and about 0.2 g. of copper. After recovery of the amyl alcohol by distillation with steam and purification of the solution by boiling with animal charcoal, the product was precipitated by neutralizing the solution with hydrochloric acid. It was crystallized thrice from alcohol, forming small, greenish-brown needles without definite melting point. Heated gradually to 300°, it sintered and became black without actually melting, but when dipped into a bath at 247° it melted sharply, with decomposition.

Analyses. Subs., 0.1062: CO₂, 0.2336; H₂O, 0.0485. Subs., 0.1248: 15.3 ec. of N₂ (21°, 756 mm.). Calc. for $C_{15}H_{15}O_4N_3$: C, 59.80; H, 4.98; N, 13.95. Found: C, 59.98; H, 5.07; N, 13.88.

2,4-Dinitro-3'-dimethylamino-diphenylamine-6-carboxylic Acid.—This acid was prepared in two different ways. (1) A solution of 3.7 g. of 3,5-dinitro-2-chlorobenzoic acid and 2 g. of dimethyl-m-phenylenediamine in 80 cc. of absolute alcohol, was digested under a reflux condenser for 35 minutes. As the mixture cooled, fine green needles separated (3.5 g.), and cautious addition of water to the mother liquor yielded more needles (0.4 g.). Obtained thus, the acid is quite pure, as shown by analysis.

Analysis. Subs., 0.1445: 20.1 cc. of N_2 (19°, 766 mm.). Calc. for $C_{15}H_{14}O_6N_4$: N, 16.18. Found: 16.12.

The substance turned dark when heated above 300° but did not melt. It is very sparingly soluble in all organic solvents except alcohol. (2) A solution of 3 g. of 3,5-dinitro-2-chlorobenzoic acid, 1.6 g. of dimethyl-m-phenylenediamine, and 3.3 g. of crystallized sodium acetate in 20 cc. of water was digested under a reflux condenser for 1 hour. The product began to separate very soon and at the end entirely filled the volume of the liquid; yield, 100%. Made in this way, the acid is amorphous. In the present case it was dissolved in hot, dil. hydrochloric acid and as this solution cooled the hydrochloride separated in green needles.

Analysis. Subs., 0.1518: 19.2 cc. of N $_2$ (22°, 753 mm.). Calc. for $C_{15}H_{18}O_6N_4C1$: N, 14.64. Found: 14.18.

When heated to 320° the hydrochloride sintered but did not melt.

Diethyl-para-phenylenediamine

4'-Diethylamino-diphenylamine-2-carboxylic Acid.—Two g. of o-chlorobenzoic acid, 2 g. of diethyl-p-phenylenediamine, 2 g. of sodium carbonate, 35 cc. of amyl alcohol and about 0.2 g. of copper were digested for 90 minutes. After distillation with steam and treatment with animal charcoal the clear brown solution was cooled to 0° and neutralized slowly. A light blue substance separated which did not become tarry on standing for 2 hours in the solution at 0°. As soon as it was collected, however, it became gummy and black. All attempts to crystallize the free acid, its sodium salt and its acid salts were unsuccessful.

4'-Diethylamino-4-nitro-diphenylamine-2-carboxylic Acid.—A mixture of 2.5 g. of 5-nitro-2-chlorobenzoic acid, 2 g. of diethyl-p-phenylenediamine, 2.5 g. of sodium carbonate, 35 cc. of amyl alcohol and about 0.2 g. of copper was digested for $2^1/2$ hours. The amyl alcohol was recovered by distillation with steam and the solution of the sodium salt freed from a small amount of tar by boiling it with animal charcoal. Neutralization then yielded an olive-green precipitate that weighed 3.1 g.; yield, 78%. This

was crystallized twice from alcohol, separating the second time in fine brown needles; m. p., $239-240^{\circ}$.

Analyses. Subs., 0.1112: CO₂, 0.2518; H_2O , 0.0601. Subs., 0.1125: 12.3 cc. of N_2 (17°, 750 mm.). Calc. for $C_{17}H_{19}O_4N_3$: C, 62.00; H, 5.77; N, 12.76. Found: C, 61.59; H, 5.98; N, 12.51.

4'-Diethylamino-2,4-dinitrodiphenylamine-6-carboxylic Acid.—A solution of 3 g. of 3,5-dinitro-2-chlorobenzoic acid, 2 g. of diethyl-p-phenylenediamine and 3.5 g. of crystallized sodium acetate in 20 cc. of water was warmed, whereupon a precipitate appeared, and after the liquid had been boiled for 5 minutes it was entirely filled with a brown amorphous solid. When this was cold, 4 g. of product was collected and dissolved in hot, dil. hydrochloric acid; the solution as it cooled deposited the hydrochloride in orange-colored flakes; m. p., 252–253°.

Analysis. Subs., 0.0950: 10.9 cc. of N_2 (13°, 754 mm.). Calc. for $C_{17}H_{19}O_6N_4Cl$: N, 13.64. Found: 13.44.

A portion of the pure hydrochloride was dissolved in hot water and the free acid precipitated with sodium acetate.

Analysis. Subs., 0.1135: 14.7 cc. of N_2 (16°, 760 mm.). Calc. for $C_{17}H_{18}O_6N_4$: N, 14.97. Found: 15.10.

The substance was a bright yellow powder; m. p., 259°. It is either insoluble or very sparingly soluble in ethyl alcohol, methyl alcohol, benzene, acetone, acetic acid, chloroform, xylene, toluene, ether, carbon tetrachloride or water. It dissolved in boiling pyridine but did not separate when the solution was cooled.

Diethyl-meta-phenylenediamine

 $3^\prime\text{-Diethylamino-diphenylamine-2-carboxylic}$ Acid.—A mixture of 5 g. of o-chlorobenzoic acid, 5 g. of diethyl-m-phenylenediamine, 5 g. of sodium carbonate, 60 cc. of amyl alcohol and about 0.2 g. copper was digested for 1 hour. The amyl alcohol was recovered by distillation with steam and the solution was boiled with animal charcoal. After this had cooled to 0° , neutralization yielded a dark blue precipitate, which did not collect into a tar as long as it remained in suspension. When collected on the filter, however, it became black and gummy at once. As in the case of its isomer previously described, neither the acid nor any of its salts could be obtained in a pure state.

Action of Diethyl-m-phenylenediamine on 5-Nitro-2-chlorobenzoic Acid. 4,4'-Dinitrodiphenyl-2,2'-dicarboxylic Acid (V).—A mixture of 4 g. of diethyl-m-phenylenediamine, 5 g. of 5-nitro-2-chlorobenzoic acid, 5 g. of sodium carbonate, 60 cc. of amyl alcohol and about 0.2 g. of copper was digested for 31/2 hours. After removal of the amyl alcohol with steam, the liquid contained a large amount of tarry matter which was completely removed by long boiling with animal charcoal. Acidification of the pale yellow solution thus obtained yielded an almost pure product. This was collected and crystallized twice from alcohol, from which it separated in thick, white needles. Dried at 100° the glossy needles lost water of crystallization and then melted at 257°.

Analyses. Subs., 0.1062: CO₂, 0.1961; H₂O, 0.0249. Calc. for $C_{14}H_8O_8N_2$: C, 50.6; H, 2.4. Found: C, 50.4; H, 2.6.

The substance is fairly soluble in hot water and crystallizes with 1 molecule of water of crystallization, which it loses completely only at 150-160°, as stated by Schultz,

Analyses. Subs., 0.3457, 0.6397: loss at 160°, 0.0195, 0.0355. Calc. for $C_{14}H_8O_8-N_2.H_2O$: H_2O , 5.14. Found: 5.64, 5.55.

As final confirmation of the identity of this acid, the dimethyl ester was prepared by the addition of 5 cc. of dimethyl sulfate to a solution of 1 g. of anhydrous 4,4'-dinitro-

⁷ Schultz, Ann., 196, 26 (1879).

diphenyl-2,2'-dicarboxylic acid in 30 cc. of 2 N sodium hydroxide solution, vigorous agitation of the mixture for 4 hours and after 1 hour collection of the white solid which had separated; m. p., 166–172°. After two crystallizations of the substance from methyl alcohol the melting point was 177–178°, which is that reported by Schultz.

3'-Diethylamino-2,4-dinitro-diphenylamine-6-carboxylic Acid.—A solution of 3 g. of 3,5-dinitro-2-chlorobenzoic acid and 2 g. of diethyl-m-phenylenediamine in 90 cc. of 99% alcohol, colorless at first, became red as soon as it was warmed, and after 2 minutes' boiling yellow needles separated. After 5 minutes the solution was cooled and 2 g. of bright yellow needles was collected, washed with alcohol and dried; m. p., 220° (decomp.).

Analysis. Subs., 0.1372: 17.5 cc. of N_2 (14°, 758 mm.). Calc. for $C_{17}H_{18}O_6N_4$: N, 14.97. Found: 14.96.

Piperidine

Action of Piperidine on o-Chlorobenzoic Acid in the Presence of Copper. Formation of Salicylic Acid.—A mixture of 5.6 g. of o-chlorobenzoic acid, 3 g. of piperidine, 6 g. of sodium carbonate, 35 cc. of amyl alcohol and about 0.2 g. of copper was digested with vigorous stirring for 6 hours. After recovery of the amyl alcohol by distillation with steam, the bright green solution, containing only the copper powder undissolved, was treated with animal charcoal, filtered and the filtrate evaporated to about 50 cc. When this concentrated solution was acidified with hydrochloric acid, a slightly yellow precipitate separated. To remove the color the product was dissolved in dil. sodium carbonate solution and again treated with animal charcoal. Acidification then yielded a pure white acid, which crystallized from 25% alcohol in fine, white needles; m. p., 155–156°.

Analyses. Subs., 0.1131: CO_2 , 0.2566; H_2O , 0.0462. Calc. for $C_7H_6O_3$: C, 60.86; H, 4.34. Found: C, 61.87; H, 4.55.

A mixed melting point with pure, known salicylic acid of melting point 156.5° gave 156.5° unchanged.

2-Piperidino-5-nitrobenzoic Acid (VI).—A mixture of 2.4 g. of 5-nitro-2-chlorobenzoic acid, 1 g. of piperidine, 2 g. of sodium carbonate, 20 cc. of amyl alcohol and about 0.2 g. of copper was digested and vigorously stirred for half an hour. After the first 15 minutes the solution was orange-colored and filled with a white solid, and digestion for an additional 15 minutes made no apparent change. The amyl alcohol was then recovered by distillation with steam and the filtered solution acidified. The yellow precipitate thus formed was collected and crystallized thrice from alcohol, the hot solution being treated each time with animal charcoal. The 2-piperidino-5-nitrobenzoic acid was thus obtained as very pale yellow, well-formed rhombic crystals; m. p., 200–202°.

Analyses. Subs., 0.0908: CO_2 , 0.1929; H_2O , 0.0467. Subs., 0.1221: 12 cc. of N_2 (15°, 758 mm.). Calc. for $C_{12}H_{14}O_4N_2$: C, 57.6; H, 5.6; N, 11.2. Found: C, 57.93; H, 5.71; N, 11.47.

Action of Piperidine on 3,5-Dinitro-2-chlorobenzoic Acid. Formation of 3,5-Dinitrosalicylic Acid.—A mixture of 3 g. of 3,5-dinitro-2-chlorobenzoic acid, 1 g. of piperidine, 3.3 g. of crystallized sodium acetate, 50 cc. of water and about 0.2 g. of copper was digested for 3 hours. The solution became orange colored at once, but gradually turned pale yellow, and green needles soon began to separate. After 2 hours, the process was interrupted to collect these needles (2 g.). Since the copper had entirely disappeared, more was added and the digestion continued for another hour. The total yield was 3 g. of the copper salt of 3,5-dinitrosalicylic acid.

The product was crystallized from very dilute alcohol and dried at 100°. As described in the introduction, this copper salt explodes violently at about 320°.

Analysis. Subs., 0.1309: 11 cc. of N_2 (17°, 747 mm.). Calc. for $C_{14}H_6O_{14}N_4Cu$: N, 10.8. Found: 9.6.

Since the analysis for nitrogen was of questionable accuracy on account of the explosive nature of the compound, an analysis for copper was undertaken. Difficulties arose at once, however. After a solution of the copper salt in coned. mineral acids had been boiled for some time, qualitative tests of the solution did not indicate the presence of copper. Furthermore, boiling with dil. sodium hydroxide deposited no copper oxide, and dry ignition was obviously out of the question. The procedure finally adopted was as follows.

In a porcelain crucible 0.4466 g. of substance was moistened with a few drops of coned. sulfuric acid and very cautiously ignited until all the organic matter had been decomposed. The black residue was then readily dissolved in about 5 cc. of coned. nitric acid and the solution transferred to a beaker. The nitric acid was expelled by several evaporations with excess of hydrochloric acid, the solution diluted with water and the copper precipitated with sodium hydroxide.

Analysis. Subs., 0.5001: CuO, 0.0682. Cale. for $C_{14}H_6O_{14}Cu$: Cu, 12.3. Found: 10.9.

Thus the percentages found for both nitrogen and copper were considerably lower than the calculated percentages for the copper salt of 3,5-dinitrosalicylic acid. In explanation of this discrepancy, it was found that the specimen employed in both analyses still contained 10.7% of water of crystallization, which it lost completely only at 180° . When allowance is made for this 10.7% in the calculations, the analyses may be restated as follows.

Analyses. Subs., 0.1169: 11 cc. of N_2 (17°, 747 mm.). Subs., 0.4466: CuO, 0.0682. Calc. for $C_{14}H_6O_{14}N_4Cu$: N, 10.8; Cu, 12.3. Found: N, 10.68; Cu, 12.19.

A later determination of the water of crystallization gave the following result.

Analysis. Subs., 0.8482: loss at 180°, 0.0870. Calc. for $C_{14}H_6O_{14}Cu.3H_2O$: H_2O , 10.1. Found: 10.2

In order to confirm the identity of this compound as the copper salt of 3,5-dinitro-salicylic acid, 1.9890 g., dried at 200°, was boiled with 50 cc. of 20% potassium hydroxide solution for 2 hours. The solution became a deep red almost at once and copper oxide soon began to separate. While the mixture was still hot, the copper oxide was removed (0.2760 g.; Cu, 11.1%). The filtrate and first wash waters were evaporated to a small volume and cooled, whereupon red needles separated. These were twice recrystallized from a small volume of water containing about 10% of alcohol, and dried at room temperature.

Analysis. Subs., 0.3999: loss at 170°, 0.0212. Calc. for $C_7H_2O_7N_2K_2.H_2O$: H_2O , 5.6. Found: 5.3.

This is in agreement with the statement of Hübner.8

When the mother liquors of the dipotassium salt were poured into an excess of dil. hydrochloric acid, the monopotassium salt separated as a yellow powder. After the solution of the monopotassium salt had been boiled for an hour with the excess of hydrochloric acid and concentrated to a small volume, cooling the mixture in ice deposited 3,5-dinitrosalicylic acid. Repeated crystallizations from very dilute hydrochloric acid raised the melting point only to 170°, in comparison with 173° found by previous investigators.

The pure acid was dissolved in 25 cc. of absolute alcohol, the solution saturated with dry hydrogen chloride and allowed to stand overnight. When the mixture was poured into water, a brown oil separated which soon solidified. This ethyl ester crystallized from alcohol in small coppery needles and melted at 99°, as stated by Hübner.8

⁸ Hübner, Ann., 195, 47 (1879).

Finally, the solutions of the copper salt, the free acid and the ethyl ester gave a red color with ferric chloride.

Investigation of the Mobility of the Chlorine in ortho-Chlorobenzoic Acid and its Nitro Derivatives

o-Chlorobenzoic Acid.—A mixture of 2 g. of o-chlorobenzoic acid (m. p., 141°), 2 g. of potassium hydroxide and 20 cc. of water was digested for 4 hours. The solution was acidified with nitric acid, yielding then o-chlorobenzoic acid which melted at 140°. The filtrate gave no precipitate with silver nitrate. When this experiment was carried out in the presence of copper the result was the same.

In this connection may be stated the results of an attempt to convert o-chlorobenzoic acid into salicylic acid by means of potassium hydroxide instead of piperidine.

One g. of potassium hydroxide, 2 g. of o-chlorobenzoic acid, 2 g. of sodium carbonate, 20 cc. of amyl alcohol and about 0.2 g. of copper were digested together for 6 hours. After the amyl alcohol had been removed by distillation with steam and the solution filtered to free it from undissolved copper, acidification with nitric acid yielded 1.9 g. of o-chlorobenzoic acid; m. p., 137–138°. Since the filtrate gave a slight precipitate with silver nitrate it was extracted with ether. Evaporation of the ether left about 0.1 g. of white acid, which after crystallization from water melted at 131–132°. Its solution gave a red coloration with ferric chloride; it was therefore probably a mixture of o-chlorobenzoic acid and salicylic acid. The amount was considered too small to permit a separation of the 2 acids.

5-Nitro-2-chlorobenzoic Acid.—Two g. of 5-nitro-2-chlorobenzoic acid, 2 g. of potassium hydroxide and 20 cc. of water were digested together for 4 hours. Acidification with nitric acid then yielded an acid which melted over a wide range, from 155° to 210°. By several crystallizations from a rather large amount of water, 5-nitrosalicylic acid was obtained in fine, pale yellow needles; m. p., 227°.

3-Nitro-2-chlorobenzoic Acid. Formation of 2-Nitrodiphenylamine-6-carboxylic Acid.—One g. of 3-nitro-2-chlorobenzoic acid, 5 g. of aniline, 0.7 g. of potassium carbonate, 10 cc. of ethyl alcohol and about 0.2 g. of copper were digested for 1 hour. After the excess of aniline had been removed by distillation with steam the solution was filtered and acidified with hydrochloric acid. The bright red alkaline solution hereupon became yellow, and the product separated in yellow clusters. After several crystallizations from dil. alcohol the substance melted at 194°.

Analysis. Subs., 0.0735: 6.7 cc. of N_2 (11°, 758 mm.). Calc. for $C_{13}H_{10}O_4N_2$: N, 10.85. Found: 10.89.

Summary

- 1. In most instances o-chlorobenzoic acid and its nitro derivatives reacted with the dimethyl- and diethyl-p- and m-phenylenediamines to yield the expected products. The only exception was the reaction of 5-nitro-2-chlorobenzoic acid with diethyl-m-phenylenediamine which gave 4,4'-dinitrodiphenyl-2, 2'-dicarboxylic acid.
- 2. With piperidine these acids yielded chiefly unexpected products. 5-Nitro-2-chlorobenzoic acid alone reacted in the expected manner. o-Chlorobenzoic acid yielded salicylic acid and 3,5-dinitro-2-chlorobenzoic acid yielded 3,5-dinitrosalicylic acid.

THE CONDENSATION PRODUCTS OF METHYLETHYL KETONE¹

By John B. Ekeley and W. Warren Howe

Received February 21, 1923

Introduction

The action of various condensing agents upon acetone has been studied by numerous investigators.²

The most important of these condensation products of acetone are mesityl oxide, mesitylene, phorone, and isophorone. The following equations summarize the action of various reagents upon acetone.

In the light of the very interesting work that has been done on the condensation of acetone, it seemed important that corresponding investigations be made on methylethyl ketone, which is now available in large quantities.

 $4 (CH_3)_2CO - 3 H_2O = Xylitone.$ (Constitution unknown.)

A study of the literature shows that a compound assumed to be a homolog of mesityl oxide was first prepared by Pawlow² by the action of propionyl chloride upon zinc dimethyl and methylethyl ketone in the cold, and later by Schramm⁴ by the action of sodium on methylethyl ketone in benzene solution. The substance Schramm obtained was a nearly colorless liquid of peppermint-like odor, boiling at $163-165^{\circ}$ (729 mm.). The only derivative of this substance that Schramm attempted to obtain was a dark colored oil that easily decomposed, formed by the action of bromine. Schramm also obtained an impure ketone with a camphor-like odor, of the probable formula $C_{12}H_{20}O$, boiling at $248-253^{\circ}$, which he considered a trimethyl phorone. Descudé,⁵ working with zinc chloride upon a mixture of acetyl chloride and methylethyl ketone, obtained a liquid of peppermint-like odor boiling at $167-168^{\circ}$, evidently the same as that obtained by Schramm, and a second liquid boiling at $248-253^{\circ}$ which he considered to be a homolog of

¹ From a thesis submitted to the Faculty of the Graduate School of the University of Colorado by W. Warren Howe in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

phorone. This second liquid was also studied by Braun and Kittel⁶ who recorded a boiling point of 256° and found that, assuming a formula of $C_{12}H_{20}O$, it added 4 bromine atoms. They therefore concluded that the compound had two double bonds and arbitrarily assigned to it the formula $CH_3.CO.C(CH_3) = C(CH_3).C(CH_3) = C(CH_3).CH_2.CH_3.$

The present research was undertaken to study first, the action of hydrogen chloride and of sulfuric acid upon methylethyl ketone, and second, the action of sodium ethylate upon methylethyl ketone.

Theoretical Part

The theoretical possibilities are much greater for the formation of condensation products from methylethyl ketone than from acetone. From methylethyl ketone we derive for the homologs of mesityl oxide 2 different structural oxides, each of which may occur in a *cis* and a *trans* form.

Each of these 4 oxides in turn by condensing with a third molecule of methylethyl ketone may yield 2 different structural homologs of phorone. The cis and trans forms of these structural isomers are reciprocally identical. It is found, therefore, that there are 4 possible different isomers of the phorone thus obtained. The following tables show the structures of these isomes.

The isomeric homologs of phorone III, IV, V and VI may in turn suffer ring formation producing isomeric homologs of isophorone. A detailed study will show that 4 structurally different isomers, all homologs of isophorone, are possible. Their structures are indicated as follows.

⁶ Braun and Kittel, Monatsh., 27, 804 (1906).

Similarly, a great number of isomeric homologs of xylitone could be worked out from a theoretical standpoint.

In this paper, for the convenience of nomenclature, we shall give the name "homomesityl oxide" to the homologs of mesityl oxide, the name "homophorone" to the homologs of phorone, and the name "homo-isophorone" to the homologs of isophorone. On oxidation homomesityl oxide I should yield propionic acid, and homomesityl oxide II should yield acetic acid, and a mixture of I and II should yield a mixture of acetic and propionic acids.

Syntheses carried out in the manner of Knoevenagel^{2h} should throw light on the constitution of homo-isophorones, while molecular-refraction data should be valuable confirmatory evidence. If a homomesityl oxide has been shown to have the structure I, it should, when condensed with methyl aceto-acetic ester by Knoevenagel's method, yield homo-isophorones with structures corresponding to the isomers γ and δ , thus:

A study of the reactions, therefore, leads to the following.

	search or one remedicine, entereror	of reacts to our routo with 8.	
(1)	Homomesityl oxide I		
	+ methyl aceto-acetic ester ->	homo-isophorones γ and δ .	(7)
(2)	Homomesityl oxide II		
	+ methyl aceto-acetic ester ->	homo-isophorone α only.	(8)
(3)	Homomesityl oxide I		134
1	+ propionyl acetic ester ->	homo-isophorone β only.	(9)
(4)	Homomesityl oxide II		
	+ propionyl acetic ester ->	homo-isophorones γ and δ .	(10)

It will be shown in the experimental part of this paper that only one compound corresponding to a homomesityl oxide occurs among the condensation products obtained by using sulfuric acid or sodium ethylate as condensing agent, and that the homomesityl oxide yields only propionic acid on oxidation with permanganate. It must, therefore, be homomesityl oxide I. It will also be shown that 3 other condensation products gave analytical results and molecular weights such that they must have the empirical formula $C_{12}H_{20}O$, and must, therefore, be either homophorones or

homo-isophorones. Condensation of the experimentally obtained homo-mesityl oxide with methyl aceto-acetic ester after the method of Knoevenagel gave a mixture of 2 compounds which on fractionation under diminished pressure were found to be identical with two of the condensation products having the formula $C_{12}H_{20}O$. These two compounds boiling at $256-260^{\circ}$ and $280-285^{\circ}$, respectively, at 630 mm., must therefore have the structures γ and δ , or δ and γ (according to Equation 7 given above).

The non-occurrence of homomesityl oxide II among the condensation products from either acid or alkaline condensing agents shows that this homomesityl oxide must have been used up during the reactions to form homophorones by condensing with another molecule of methylethyl ketone.

If we assume the exaltation of the molecular refraction of homo-isophorone to be the same as that for isophorone, this compound should show a molecular refraction, M, of 56.08. Similarly, homophorone should show a molecular refraction of 59.7. The actually observed molecular refraction of the third product of condensation showing an empirical formula $C_{12}H_{20}O$ and boiling point 206–210°, was 57.72. This value, while not as high as that calculated above, is altogether too high for a homo-isophorone. Also, the fact that this compound shows the next higher boiling point in the series to homomesityl oxide would point to its being a homophorone. The following table shows the boiling points of the two series (acetone and methylethyl ketone).

Mesityl oxide	127-130°	Homomesityl oxide	156-160°
Phorone	197	Compound in question	206-210
Isophorone	213-215	Homo-isophorone γ or δ	256-260
		Homo-isophorone δ or γ	280-285

Moreover, acetone with hydrochloric acid acting as a condensing agent yields only mesityl oxide and phorone. Similarly, hydrochloric acid acting on methylethyl ketone yields only homomesityl oxide and the compound in question, as will be shown by the experimental results. It is evident that further work must be done on this compound to settle definitely whether or not it is a homophorone or a homo-isophorone. What evidence we have points to its being a homophorone.

Experimental Part

The methylethyl ketone was a very pure, water-white product containing traces of acetone. On distillation, all but a small fraction of the product passed over at 70-73° (625 mm.).

Condensation of Methylethyl Ketone under the Influence of Dry Hydrogen Chloride

Into 160 g. of methylethyl ketone, packed in ice, dry hydrogen chloride was passed not too rapidly until the liquid was completely saturated. The cork of the container was tied down so as to leave the liquid under a slight pressure. The mixture was allowed to stand for 30 days. The ketone was then washed with water to remove the excess of

acid, and poured into alcoholic potassium hydroxide; water was added, and an oily layer separated that was taken up with ether. The ether solution was dried over anhydrous sodium sulfate. After the ether was distilled an oily mixture remained that was fractionated, first at atmospheric pressure (625 mm.) up to 165°, and then under diminished pressure (15 mm.). Homomesityl oxide and homophorone only were obtained. The results are contained in Table I.

Condensation of Methylethyl Ketone under the Influence of Sulfuric Acid

Experiments were carried out with furning c. P. sulfuric acid containing, 20% excess of sulfur trioxide, and with a c. P. coned. acid, d. 1.84. It was found that the action of fuming acid on methylethyl ketone for 10 to 12 days was the same as that of the coned, acid during 16 to 20 days. Since an observation of the final effect of sulfuric acid on the ketone was desired the action was allowed to proceed over a long period. siderable amount of homomesityl oxide forms with the furning acid in 2 hours or with the coned, acid in 24 hours. The fuming acid will give a fair yield of homophorones in 4 days and the concd. acid in 7 days. In any case, the acid mixture was poured into two 2liter beakers half filled with snow or chipped ice, and a concd. solution of potassium hydroxide was added gradually until the black oil separated completely. The oil was not soluble in dil. sulfuric acid; therefore the dilute acid, colored with green to golden fluorescent sulfonic acids, was discarded. The black oil was dissolved in 5 times its volume of ether; the ether solution was then washed repeatedly with dil. sodium hydroxide solution and finally with water. This treatment changed the ether solution from a black to a beautiful golden-brown. After the ether had been dried with calcium chloride it was distilled and the oil fractionated, first at atmospheric pressure (625 mm.) and then under diminished pressure (15 mm.). Typical results are shown in Table I.

Many difficulties were encountered in using acid condensation agents with methylethyl ketone. In the experiments with both the hydrochloric and the sulfuric acids, addition products were formed that contaminated every fraction. After every precaution, traces of acid (hydrochloric or sulfurous) were found to come over during a distillation, and apparently pure fractions became dark colored on standing. The action of sodium ethylate, on the other hand, gave pure products.

Condensation of Methylethyl Ketone under the Influence of Sodium Ethylate

Pure sodium ethylate was prepared by the gradual addition of the calculated amount of absolute alcohol to sodium wire covered with a large volume of ether. Enough of the condensing agent was used to furnish sodium in the proportion 1 Na: 4 C₂H₅.CO.CH₅. The ethylate crystals were added in portions to the slightly cooled ketone. The mixture was then allowed to stand at ordinary temperatures protected from moisture for 3 or 4 weeks. When the sodium ethylate was not prepared pure, reddish, water-soluble waste products were obtained. The reaction mixture was then dissolved in 4 times its volume of ether and the ether solution washed 5 or 6 times with water until the wash water was neutral. The solution was dried over calcium chloride overnight, the ether distilled and the oil fractionated, first at atmospheric pressure until the homomesityl oxide was removed, and then at diminished pressure. Typical results are shown in Table I.

The results in this table are not "averages" but are from actual experiments selected from 20 to 30 such experiments.

Fractions 1, 2 and 3 were always obtained under normal pressure (625 mm. at Boulder).

Fractions 4 to 10, inclusive, were obtained at diminished pressure (15 mm.).

On repeated fractionation, Fraction 3 yielded pure homomesityl oxide; Fraction 4 yielded pure homophorone; Fractions 6 and 8 yielded the pure homo-isophorones.

TABLE I RESULTS HC1 Fuming Sodium H₂SO₄ ethylate G. Main Temperature C. H2SO4 gas G. It should be noted in connection with these tables of fractionation that the intermediate fractions, indicated in the table only by a temperature interval, many times represent nearly constant-boiling mixtures. These could be only partially separated even after repeated fractionation. The investigators' of the products of condensation of acetone encountered the same difficulty. That these fractions were truly "constant-boiling mixtures" was shown also by the fact that the refractive index varied, and that the combustion data on them varied.

Homomesityl Oxide

Physical Constants.—Homomesityl oxide, $C_8H_{14}O$, is a nearly colorless liquid with a peppermint-like odor and a camphor-like taste; b. p., $156-160^{\circ}(625 \text{ mm.})$; d_4^{20} , 0.8628; n_D^{20} , 1.4453; $M_D \longrightarrow 38.94$ (calc., 38.72); mol. wt. (from the vapor density), calc., 126.15; found, 132, 131.

Analysis. Calc. for C₈H₁₄O: C, 76.13; H, 11.18. Found: C, 76.35; H, 11.39.

Preparation of a Liquid Oxime.—The oxime was prepared by allowing the ketone to react with free hydroxylamine under the supposition that a crystalline oxime would in that way be formed as is the case with mesityl oxide; 20 g. of oil was dissolved in 70 cc. of alcohol and a saturated water solution of the calculated amount of hydroxylamine hydrochloride was added gradually. More alcohol was added to make the solution clear. The mixture was then refluxed for 2 hours, which caused a blackening of the product. A few drops were placed on a microscope slide and allowed to evaporate. No crystals appeared. The reaction mixture was, therefore, allowed to stand for 10 days. A saturated solution of potassium carbonate was then added gradually, causing the separation of an oily layer in which a few crystals were suspended. Since all attempts to cause further crystallization failed, the product was distilled at 17 mm. This

⁷ Ref. 2g, p. 212.

distillation gave 10 g. of the original oil and a fraction boiling at 120-140°. By repeated distillation a constant-boiling fraction was obtained of light greenish tinge, boiling at 132-137° (17 mm.).

Analysis. Calc. for C₈H₁₄NOH: N, 9.9. Found (Kjeldahl): 9.2.

An Attempt to Prepare a Semicarbazone.—Bodroux and Taboury⁸ report a semicarbazone of homomesityl oxide melting at 114–115°. We wish to call attention to the fact that, although we also obtained a crystalline precipitate of melting point 114–115° by the action of 1 molecule of homomesityl oxide on 1 molecule of semicarbazide in alcoholic solution using potassium acetate to neutralize the semicarbazide hydrochloride, this precipitate proved to be a mixture. The precipitate was dissolved in alcohol and diluted with an equal volume of water. A fraction of melting point 140° precipitated almost immediately. The remaining fraction melted at 108°. The authors believe the reaction to be more complex than indicated by the work of Bodroux and Taboury, and hope by further work to isolate the normal semicarbazone of homomesityl oxide and a pyrazoline derivative which seems to be formed.

The Semicarbazide-semicarbazone.—One molecule of homomesityl oxide was allowed to react with 2 molecules of semicarbazide hydrochloride in alcoholic solution. In an acid solution of this kind the semicarbazide-semicarbazone precipitated almost immediately. The crystals were insoluble in alcohol and water and ordinary organic solvents. They were soluble in hot dil. hydrochloric acid and were reprecipitated by neutralizing the acid with sodium hydroxide. By recrystallizing in this way they were obtained pure, appearing as microscopic prisms; m. p., 265–266° (decomp.).

Analysis. Calc. for C₁₀H₂₂N₆O₂: N, 32.55. Found (Kjeldahl): 32.6.

Oxidation with Potassium Permanganate.—Twenty-five g. of homomesityl oxide was shaken with 600 cc. of water, in 50g. portions. A 5% solution of potassium permanganate was added in small quantities and the mixture frequently and vigorously shaken until it retained the color after standing for 24 hours. The slight excess of permanganate was destroyed by heat. A little over 2 molecules of permanganate were required to 1 of homomesityl oxide. The large volume of solution thus obtained was evaporated to 400 cc. and the residue was then acidified with dil. sulfuric acid. Carbon dioxide was evolved in this step. The acid solution was extracted several times with ether. After being dried over anhydrous sodium sulfate, the ether solution was evaporated, leaving a brown liquid. This liquid was distilled at 15 mm. A study of the analytical results of the distillate shows that the liquid was a mixture of propionic acid and some lower-boiling substance, not acetic acid. Three fractions were obtained. The highest one on titration was shown to be propionic acid; 0.2801 g. required for neutralization 0.1485 g. of sodium hydroxide solution, a quantity which neutralizes 0.2784 g. of propionic acid.

The next lower fraction could not have been acetic acid and it could not have contained acetic acid, since 0.4926 g. required for neutralization 0.2454 g. of alkali solution, a quantity that neutralizes 0.4601 g. of propionic acid, and only 0.3681 g. of acetic acid. Moreover, the highest fraction, b. p., $45-50^{\circ}$ (15 mm.), gave a propionyl p-toluidine melting at 118° (the pure crystals should melt at 123°; not enough was obtained to be recrystallized); also, the boiling point of the fraction was 125-133° (622 mm.), identical with that of a known pure propionic acid at Boulder. A special effort was made to isolate acetic acid from these products; none was found. The presence of methylethyl ketone in the lowest distillate was indicated by the odor, but owing to the small yield of oxidation products, methylethyl ketone could not be isolated. The course of the reaction evidently is (C_2H_5) (CH₃)C=CH.CO.C₂H₅ + 4O = (C_2H_5) (CH₃)C=O + C_2H_5

⁸ Bodroux and Taboury, Compt. rend., 149, 422 (1909).

COOH + CO₂, and we must conclude that the homomesityl oxide here obtained has the constitution (C_2H_6) (CH₂) C=CH.CO.C₂H₅.

Homophorone

Physical Constants.—Homophorone, $C_{12}H_{20}O$, is a clear, slightly straw-colored liquid with a camphor-like odor and taste; b. p., $206-210^{\circ}$ (625 mm.); d_4^{20} , 0.8857; n_D^{20} , 1.4792, M_D , calc. (without exaltation), 56.71; + exaltation for phorone (+3) = 59.71; found; 57.72; mol. wt. (from vapor density), calc., 180.22; found, 185, 172.

Analysis. Calc. for C12H20O: C, 79.93; H, 11.18. Found: C, 79.59; H, 10.97.

The composition of this compound must be determined by further work as indicated in the discussion. Moreover, the data given above are from a fraction prepared by condensing methylethyl ketone with sulfuric acid. It is believed to be present among the products obtained by the action of sodium ethylate. An unexpected difficulty, however, was encountered in getting a pure fraction and none has been obtained so far. The authors propose to continue the work on this point.

The Homo-isophorones, C12H20O

Homo-isophorone, b. p. 256-260° (630 mm.).—This homo-isophorone is a clear yellow liquid with a weak odor and taste of terpene; $d_{\rm p}^{20}$, 0.9492; $n_{\rm p}^{20}$, 1.5045; $M_{\rm p}$, calc. (Eisenlohr), 54.98 + exaltation for isophorone, 54.98 + 1.1 = 56.08; found, 56.12; mol. wt. (from vapor density), calc., 180.22; found, 178,188.

Analysis. Calc. for C₁₂H₂₀O: C, 79.93; H, 11.18. Found: C, 80.08; H, 11.12.

An attempt was made to duplicate the work of Braun and Kittel⁶ who reported that this homo-isophorone adds 4 atoms of bromine. We were unable to verify their results since our investigations showed that hydrogen bromide was generated in large volume long before an amount of bromine corresponding to 2 atoms was added. The addition of hydrogen chloride was then investigated; 5 g. of the oil was dissolved in 20 cc. of dry liquid carbon disulfide, and hydrogen chloride, dried over phosphorus pentoxide, was passed through the solution. A heavy, black oil separated. It was carefully removed with a pipet and the solvent allowed to evaporate. A weighed amount was then refluxed with a standard solution of sodium hydroxide, and the excess alkali was titrated with 0.1 N acid; 0.3898 g. of substance contained 0.0641 g. of hydrogen chloride. This result indicates that this homo-isophorone contains but one double bond and not two as reported by Braun and Kittel.

Homo-isophorone, b. p. $280-285^{\circ}$ (630 mm.).—This homo-isophorone is a golden-brown, slightly viscous liquid. Its odor and taste are camphor-like; d_{2}^{40} , 0.9693; n_{D}^{20} , 1.5115; M_{D} , calc., 54.98 + exaltation for isophorone = 56.08; found, 55.74; mol. wt. from vapor density, calc., 180.22; found, 179, 168.

Analysis. Calc. for C12H20O: C, 79.93; H, 11.18. Found: C, 80.28; H, 10.81.

The Synthesis of the γ - and δ -Homo-isophorones

In this procedure the method of Knoevenagel^{2h} was followed. First, methyl aceto-acetic ester was prepared by the usual method; a pure product was obtained; b. p., 176-178° (630 mm.). Fifty g. of the experimentally obtained homomesityl oxide was mixed with the calculated amount (57 g.) of methyl aceto-acetic ester, and the mixture well cooled. A 25% solution of sodium ethylate in absolute alcohol was prepared and enough of the reagent used to furnish sodium in the proportion 1 Na: 1 CH₂COCHCH₃.-COOC₂H₅. The alcoholate solution was allowed to stand for 9 days at a temperature of 5-10°, then refluxed on the water-bath for 5 hours to complete the reaction, made acid with 20% sulfuric acid and refluxed for 6 hours to saponify the condensation

product. The solution was then cooled and washed 5 times with ether. The ether solution was made slightly alkaline by washing with dil. sodium hydroxide solution, and dried with anhydrous sodium sulfate. After the ether had been distilled, there remained about 50 g. of an oil. Much of the original homomesityl oxide was recovered from this product. The following fractions were obtained from the oil which bore every resemblance to the 2 homo-isophorones described above, in color, odor, taste and physical constants.

Fraction 1: b. p., $145-165^{\circ}$ (15 mm.); n_D^{20} , 1.4970. The corresponding pure homo-isophorone: b. p., $256-260^{\circ}$ (630 mm.); b. p., $150-157^{\circ}$ (15 mm.); n_D^{20} , 1.5045.

Fraction 2: b. p., $165-180^{\circ}$ (15 mm.); n_D^{20} , 1.5053. The corresponding pure homoisophorone: b. p., $280-285^{\circ}$ (630 mm.); b. p., $170-178^{\circ}$ (15 mm.); n_D^{20} , 1.5115.

It is evident, therefore, that the two higher-boiling compounds obtained by the condensation of methylethyl ketone have the constitutions γ and δ or δ and γ , as developed in the discussion.

Summary

- 1. The condensation products of methylethyl ketone under the influence of hydrogen chloride, of sulfuric acid, and of sodium ethylate have been studied. Hydrogen chloride yields 2 products, homomesityl oxide and homophorone. Both sulfuric acid and sodium ethylate yield homomesityl oxide, homophorone, and 2 homo-isophorones, besides other high-boiling products whose nature has not yet been determined.
- 2. Homomesityl oxide, prepared with the above reagents, has been shown to have the constitution $(C_2H_5)(CH_3)C=CH.CO.C_2H_5$.
 - 3. A liquid oxime of homomesityl oxide has been prepared.
- 4. The semicarbazone of homomesityl oxide reported by Bodroux and Taboury has been shown to be a mixture. The semicarbazide-semicarbazone of mesityl oxide has been prepared.
 - 5. The probable constitution of homophorone has been discussed.
- 6. Two homo-isophorones have been isolated, their important constants determined, and their structures shown to correspond to one of two possible constitutional formulas, γ and δ as shown above.

THE STRUCTURE OF PHENOLPHTHALEIN OXIME

By W. R. Orndorff and S. T. Yang

Received March 17, 1923

Two formulas (I and II) have been proposed for phenolphthalein oxime since it has been shown that Formula III proposed by Friedländer

is incorrect.

In order to explain the quantitative decomposition of the oxime by dil. sulfuric acid into p-hydroxybenzoyl-o-benzoic acid and p-aminophenol, Orndorff and Murray assume Formula I for the compound. They further assume that phenolphthalein oxime, like the oximes of the ketones, undergoes the Beckmann rearrangement giving an intermediate product which is the p-hydroxyanilide of p-hydroxybenzoyl-o-benzoic acid.

This intermediate product or its ketone form then hydrolyzes into *p*-hydroxybenzoyl-*o*-benzoic acid and *p*-aminophenol.

$$HOC_6H_4-C=O$$

 $C_6H_4CONHC_6H_4OH$
 $+ HOH =$
 $HO-C_6H_4-C=O$
 $+ H_2N-C_6H_4OH$

The fact that p-hydroxyphthalanil is obtained when an excess of hydroxylamine is used in the preparation of the oxime or as H. Meyer² found by heating the oxime with a solution of hydroxylamine hydrochloride is also

¹ See R. Meyer and Kissen, *Ber.*, **42**, 2825 (1909), and Orndorff and Murray, This Journal, **39**, 689 (1917).

² Meyer, Monaish., 20, 346 (1899).

explained by assuming the formation of the intermediate product which then breaks down into p-hydroxyphthalanil and phenol.

Intermediate product

p-Hydroxyphthalanil

Pheno1

The reduction product of phenolphthalein oxime which H. Meyer and R. Meyer have shown to have the structure

HOC₆H₄—C—H

C₆H₄—NC₆H₄OH(
$$p$$
)

is also formed according to Orndorff and Murray not from the oxime but from the intermediate product.

It will be seen from the foregoing that it would be highly desirable to prove that phenolphthalein oxime undergoes the Beckmann rearrangement like the ketoximes, to isolate the intermediate product and show that it undergoes the above changes. The present paper shows how this was accomplished.

Experimental Part

R. Meyer and Kissen¹ have prepared what they call a triacetate of the oxime by heating it with acetic anhydride and sodium acetate. As this substance is *colorless*, whereas the oxime is *yellow*, it was thought that it might be the triacetate of the intermediate product and that when the oxime is acetylated it undergoes the Beckmann rearrangement. If this is true then it seemed quite likely that on saponification the triacetate would give the intermediate product and not the oxime. Experiment showed that this idea was correct.

Triacetate of the p-Hydroxyanilide of p-Hydroxybenzoyl-o-benzoic Acid.—This was made from the oxime by the method given by R. Meyer and Kissen¹ and carefully purified by recrystallization from acetone. It crystallized in colorless needles that melted at 235°. R. Meyer and Kissen give the melting point of their product as 229–230°. Analyses on the product dried in a vacuum desiccator over concd. sulfuric acid gave the following results:

Analyses. Subs., 0.2388, 0.2238: CO_2 , 0.5939, 0.5568; H_2O , 0.1010, 0.0940. Calc. for $C_{26}H_{21}O_7N$: C, 67.95; H, 4.61. Found: C, 67.82, 67.85; H, 4.73, 4.70.

Subs., 1.0267, 1.0500: cc. of 0.1 N H_2SO_4 , 23.14, 23.53. Calc. for $C_{26}H_{21}O_7N$: N, 3.05. Found: 3.16, 3.14.

Subs., 0.5004: 32.62 cc. of 0.1 N NaOH. Calç. for $C_{26}H_{12}O_4N(COCH_3)_2$: CH_3CO , 28.11. Found: 28.10.

In view of the statement of H. Meyer³ that there are at least 3 triacetates of the oxime, all insoluble in alkali and that he had already obtained 2 of them in pure form and

³ H. Meyer, Monatsh., 17, 440 (1896).

had analyzed them, the crude acetate was subjected to careful fractional crystallization. Only the triacetate melting at 235° was obtained.

Saponification of the Triacetate by Sulfuric Acid. The Intermediate Product.—The triacetate is saponified in the cold by conc. sulfuric acid. A dark red, viscous solution was formed. This was gradually poured into crushed ice, the solution was vigorously stirred and finally diluted with a great amount of water, filtered and allowed to stand. A yellow crystalline powder settled. This was freed from sulfuric acid by dissolving it in a cold 4% solution of sodium hydroxide and reprecipitating it with a slight excess of very dilute hydrochloric acid. The colorless precipitate after being washed with water was boiled with water. It first melted, then solidified and finally all passed into solution on boiling with sufficient water. As the solution cooled, small colorless, flaky crystals formed that melted at 135° with decomposition. The substance loses very little weight in a vacuum desiccator. The substance dried in a desiccator gave the following results on analysis.

Analyses. Subs., 0.2908, 0.2995, 0.2961: CO₂, 0.7110, 0.7324, 0.7246. H₂O, 0.1334, 0.1366, 0.1358. Subs., 1.0010, 1.0007: cc. of 0.1 N H₂SO₄, 28.2, 28.0. Calc. for C₂₀H₁₂-ON(OH)₃ + 1¹/₂H₂O: C, 66.65; H, 5.04; N, 3.89. Found: C, 66.68, 66.69, 66.74; H, 5.13, 5.10, 5.13; N, 3.92, 3.92.

The above results show that the substance is the *p*-hydroxyanilide of *p*-hydroxybenzoyl-*o*-benzoic acid with 1.5 molecules of water of crystallization. An attempt was made to determine the water of crystallization by heating the substance in an atmosphere of carbon dioxide at 95°. Water vapor was given off and the substance melted to a dark red liquid which solidified on cooling to a dark red glass; 0.4892 g. of substance lost 0.0639 g. of water after 6 hours' heating; the calculated loss for 2.5 molecules of water is 0.0640 g. Thus, the intermediate product when heated not only loses all its water of crystallization but also an additional molecule of water of constitution as shown in the following equation.

$$C_6H_4OH$$
 $C=C_6H_4=O$
 $C=C_6H_4=O$
 $C=C_6H_4=O$
 $C=C_6H_4=O$
 $C=C_6H_4OH + 2^1/2H_2O$
 $C=C_6H_4OH + 2^1/2H_2O$

An attempt made to convert the red glass into the intermediate product by boiling it with water was unsuccessful. The red compound is very difficultly soluble in hot water and only after prolonged boiling with water imparts a faint pink color to it. It is very soluble in dilute solutions of alkalies, giving a dark green solution. When this alkaline solution is acidified a yellow amorphous precipitate is formed. An attempt was also made to get the intermediate product in the anhydrous form by recrystallizing it from boiling water. The product, however, had the same melting point and on heating lost the same amount of water (i. e., 2.5 molecular equivalents) as before.

The action of organic solvents on the intermediate product is very remarkable. Acetone, ethyl alcohol, methyl alcohol, or ethyl acetate dis-

solves it readily and the recrystallized product from each of these solvents has a different melting point. That from acetone melts at $94-95^{\circ}$, from methyl alcohol at 125° , from ethyl alcohol at 130° and from ethyl acetate at $195-198^{\circ}$. The intermediate product is slightly soluble in hot benzene or in hot toluene and insoluble in ether, ligroin, chloroform or carbon tetrachloride. The product crystallized from ethyl acetate seems to have the formula $C_{20}H_{12}ON(OH)_3 + \frac{1}{2}CH_3COOC_2H_5$ from the analysis.

Analysis. Subs., 0.6675: 19.11 cc. of 0.1 N H₂SO₄. Calc. for $C_{20}H_{12}ON(OH)_3 + \frac{1}{2}CH_3COOC_2H_5$: N, 3.92. Found: 4.01.

Subs., 0.3230. Calc. loss for $H_2O+{}^1/_2CH_3COOC_2H_5$: 0.0543 g. Loss after heating for 5 hours at 95°, 0.0540 g.

The odor of ethyl acetate was detected during the heating and a red glass was left in the boat.

Saponification of the Triacetate by Alkali.-Twenty g. of the triacetate, made from the oxime, was treated with 200 cc. of a 4% solution of sodium hydroxide. All of it dissolved in the cold after the solution stood a few hours and was shaken occasionally. The solution was colored yellow. If allowed to stand for a few days, it becomes green. The yellow solution was acidified with dil. hydrochloric acid and a white flocculent precipitate was obtained. This was collected on a filter, washed and boiled with a large amount of water. It acted exactly like the intermediate product obtained from the triacetate by saponification with conc. sulfuric acid. It first melted under the water, then solidified and finally all went into solution on boiling it with sufficient water. The crystals obtained from this solution on cooling were identical with those of the intermediate product made by saponification of the triacetate with concd. sulfuric acid and had the same m. p. The substance also gave the same reduction product, the same p-hydroxyphthalanil, the same dibenzoate, the same triacetate and the same trimethyl ether as the intermediate product made from the triacetate by saponification with concd. sulfuric acid. There is no doubt of the identity of the 2 products. This method of saponification of the triacetate gives a quantitative yield of the intermediate product and is better than the one with concd. sulfuric acid. The intermediate product made in this way also lost the same amount of water when heated and gave a red glass $(0.4832 \text{ g. lost } 0.0606 \text{ g. after 6 hours at } 92^{\circ}; \text{ calc. for } 2^{1}/_{2} \text{ mols. of } H_{2}O, 0.0603 \text{ g.}).$

Hydrolysis of the Intermediate Product with Dilute Sulfuric Acid.—On boiling the intermediate product with dil. sulfuric acid (1:8), it is hydrolyzed to p-hydroxy-benzoyl-o-benzoic acid and p-aminophenol just as the oxime is. A quantitative determination resulted as follows: 1.0037 g. of substance gave 0.5759 g. of p-hydroxybenzoyl-o-benzoic acid and 0.2883 g. of p-aminophenol. The calculated amounts are p-hydroxybenzoyl-o-benzoic acid, 0.6187 g.; p-aminophenol, 0.3039 g.

Decomposition of the Intermediate Product with Hydroxylamine Hydroxylamine Hydroxylamine hydroxylamine hydrochloride. After a short time, long colorless needles separated. These were recrystallized from dil. alcohol and found to melt at 288° with decomposition—as in the case of p-hydroxyphthalanil obtained from the oxime by the same treatment. A qualitative test for phenol, the other product of the decomposition, was also obtained. A Kjeldahl analysis of the product melting at 288° showed that it was p-hydroxyphthalanil.

Analysis. Subs., 0.3370: cc. of 0.1 N H₂SO₄, 14.14. Calc. for C₂₄H₉O₂N: N, 5.86. Found: 5.88.

Reduction of the Intermediate Product.—Five g. of the intermediate product was dissolved in about 60 cc. of dil. alcohol and 5 cc. of coned. sulfuric acid. Zinc dust was

then added and the mixture carefully heated. The red color of the solution gradually faded to a light yellow. The zinc was then filtered off and the filtrate poured into water. The white precipitate obtained was recrystallized from dil. alcohol and found to melt at 256°—the same melting point as that of the reduction product made from the oxime by the same method. A mixture of the two products melted sharply at the same temperature. An acetyl derivative of the reduction product was also made, m. p., 205–208°, the melting point given by Herzig and H. Meyer for the diacetate of the reduction product.

Acetylation of the Intermediate Product.—Acetylation of the intermediate product with acetic anhydride and sodium acetate gave the same triacetate as was obtained from the oxime.

The product crystallized from acetone had the same melting point, and the same chemical and physical properties as the triacetate made from the oxime. Kjeldahl analyses on the substance dried in a desiccator also showed that it was identical with the triacetate made from the oxime.

Analyses. Subs., 0.9522, 0.9647: cc. of 0.1 N H_2SO_4 , 20.86, 21.30. Calc. for $C_{26}H_{21}O_7N$: N, 3.05. Found: 3.07, 3.09.

Benzoylation of the Intermediate Product.—R. Meyer and Kissen¹ made what they call a tribenzoate of the oxime by benzoylating the oxime by the Schotten-Baumann reaction. It was thought that this benzoate might be the benzoate of the intermediate product, as in the case of the triacetate made from the oxime.

Ten g. of the intermediate product was dissolved in 150 cc. of 20% sodium hydroxide solution and an excess of benzoyl chloride was added, a little at a time while the mixture was shaken vigorously. A white precipitate was formed. It was washed with a dilute solution of sodium hydroxide, boiled with water to remove benzoic acid and then recrystallized from methyl alcohol. It melted at 227° and the melting point did not change when the substance was recrystallized from ethyl alcohol and from acetone. R. Meyer and Kissen give the melting point of their tribenzoate as 175°. Kjeldahl determinations of the substance dried in a desiccator gave the following results.

Analyses. Subs., 0.7828, 0.7815: cc. of 0.1 N H_2SO_4 , 14.70, 15.09. Calc. for $C_{20}H_{13}O_4N(COC_6H_5)_2$: N, 2.59. Found: 2.63, 2.70.

This indicates that the substance is a dibenzoate instead of a tribenzoate. Further evidence of this was secured from the results of combustion analyses.

Analyses. Subs., 0.2994, 0.3095: CO₂, 0.8259, 0.8536; H₂O, 0.1158, 0.1228. Calc. for $C_{20}H_{18}O_4N(COC_6H_6)_2$: C, 75.39; H, 4.28. Found: C, 75.23, 75.21. H, 4.33, 4.44.

An attempt was made to obtain a mono-acetate of this dibenzoate by boiling it with acetic anhydride but the product was the triacetate of the intermediate product.

Benzoylation of Phenolphthalein Oxime.—Meyer and Kissen's experiment was repeated using exactly the same quantity of materials that they specify. The same dibenzoate was obtained as in benzoylating the intermediate product. It melted at 227° and gave the following results on analysis.

Analyses. Subs., 0.4112, 0.4042: cc. of 0.1 N H_2SO_4 , 7.45, 7.64. Calc. for $C_{20}H_{13}$ - $O_4N(COC_6H_6)_2$: N, 2.59. Found: 2.54, 2.65.

Subs., 0.3143: CO₂, 0.8679; H_2O , 0.1208. Calc. for $C_{20}H_{13}O_4N(COC_6H_6)_2$: C, 75.39; H, 4.28. Found: C, 75.31; H, 4.30.

Repeated attempts to make the tribenzoate described by Meyer and Kissen were unsuccessful.

It will be seen from these results that when the oxime is acetylated and benzoylated, it undergoes the Beckmann rearrangement and gives the triacetate and the dibenzoate of the intermediate product. These have the following structural formulas.

$$\begin{array}{cccc} CH_{\circ}COOC_{\circ}H_{4}-C-OCOCH_{\circ} & C_{\circ}H_{\circ}COOC_{\circ}H_{4}-C-OH \\ C_{\circ}H_{4} & NC_{\circ}H_{4}OCOCH_{\circ} & C_{\circ}H_{\bullet} & NC_{\circ}H_{4}OCOC_{\circ}H_{4} \\ \hline C=O & C=O & Dibenzoate \\ \end{array}$$

Methylation of the Intermediate Product.—R. Meyer and Spengler⁴ have made the trimethyl ether of phenolphthalein oxime by methylating it in alkaline solution with dimethyl sulfate. As they describe this ether as almost colorless, it was thought that it might be the trimethyl ether of the intermediate product.

Five g. of the intermediate product was dissolved in 60 cc. of 30% of sodium hydroxide solution in a stoppered flask and an excess of dimethyl sulfate gradually added with vigorous shaking. The reaction soon took place with the evolution of heat and a white solid separated. This was collected, washed with water and recrystallized from methyl alcohol. The melting point of the recrystallized product was found to be 131–133°. Meyer and Spengler give the melting point of the trimethyl ether of the oxime as 145–146°. Phenolphthalein oxime was therefore methylated with dimethyl sulfate by the method given by Meyer and Spengler. The melting point of the ether recrystallized from both methyl alcohol and acetone was 145–146°; but the crystals are distinctly yellow, while those of the ether made from the intermediate product are colorless. Kjeldahl analyses were made on both substances and the results show that both are trimethyl ethers.

Analyses. (1) Trimethyl ether of the intermediate product. Subs., 0.5182, 0.5154: cc. of 0.1 N H₂SO₄, 13.33, 13.62. Calc. for C₂₀H₁₂ON(OCH₃)₃: N, 3.73. Found: 3.60, 3.70.

(2) Trimethyl ether of the oxime (yellow). Subs., 0.5150: cc. of 0.1 N $\rm H_2SO_4$, 13.91. Calc. for $\rm C_{20}H_{12}ON(OCH_3)_3$: N, 3.73. Found: 3.78.

It will be seen from these results that the 2 ethers are isomeric and that the oxime does not undergo the Beckmann rearrangement when methylated in alkaline solution with dimethyl sulfate. The structures of the two compounds are represented as follows.

Trimethyl ether of the oxime Trimethyl ether of the intermediate product

Synthesis of the Intermediate Product.—H. Meyer and R. Meyer have both made the reduction product of the oxime synthetically by heating p-hydroxy-phenylphthalide with p-aminophenol.

⁴ R. Meyer and Spengler, Ber., 36, 2964 (1903).

It was thought that p-hydroxybenzoyl-o-benzoic acid and p-aminophenol might react in a similar manner.

Eleven g. of p-hydroxybenzoyl-o-benzoic acid and 5 g. of p-aminophenol were melted together. Instead of obtaining the intermediate product, a dark purple solid resulted. It was very sparingly soluble in hot water, and colored the solution pink only after prolonged boiling. It is readily soluble in solutions of the alkalies giving a deep purple solution from which it is precipitated by acids. It is probably a mixed phthalein.

The results given in this paper can only be explained by assuming that phenolphthalein oxime has a structure similar to that of phenolphthalein imide and phenolphthalein anilide, substances formed from phenolphthalein and ammonia or from phenolphthalein and aniline, just as the oxime is formed from phenolphthalein and hydroxylamine.

That these two substances do not undergo reduction or hydrolysis as readily as the oxime is easily explained because they do not undergo the Beckmann rearrangement as the oxime does. It is the intermediate product formed by the Beckmann rearrangement of the oxime that in reality undergoes the reduction and the hydrolysis. The objection that has been made to this formula by R. Meyer that it does not explain the color of the compound may be answered by calling attention to the fact that although phenolphthalein is a colorless substance to the naked eye, it has two absorption bands in the ultraviolet. Phenolphthalein oxime also has two absorption bands in the ultraviolet and apparently the effect of substituting the <NOH group for oxygen is the shifting of one of these bands towards the visible part of the spectrum. A small part of the blue is cut out and hence the solution appears yellow to the eye. Attention should also be called to the fact that phenolphthalein oxime, like the imide and anilide of phenolphthalein, dissolves in solutions of alkalies without under-

going the change into the quinoid condition so characteristic of phenol-phthalein.

Summary

The results obtained in this work may be briefly summarized as follows.

- 1. It has been shown that phenolphthalein oxime undergoes the Beckmann rearrangement when acetylated or benzoylated. The triacetate and dibenzoate formed are derivatives of the *p*-hydroxyanilide of *p*-hydroxybenzoyl-*o*-benzoic acid and not of the oxime.
- 2. The intermediate product (p-hydroxyanilide of p-hydroxybenzoyl-o-benzoic acid) has been isolated by saponification of its triacetate made from the oxime both with sulfuric acid and with dilute solutions of the alkalies.
- 3. It has been shown that the intermediate product undergoes hydrolysis when heated with dil. sulfuric acid, just as the oxime does, into p-hydroxybenzoyl-o-benzoic acid and p-aminophenol and the yield of both products is practically quantitative.
- 4. When reduced with zinc dust and dil. sulfuric acid the intermediate product gives the same reduction product that the oxime does.
- 5. When heated with a solution of hydroxylamine hydrochloride the intermediate product gives p-hydroxyphthalanil and phenol just as the oxime does.
- 6. When acetylated the intermediate product gives the same triacetate that is formed when the oxime is acetylated.
- 7. When benzoylated by the Schotten-Baumann reaction the intermediate product gives a dibenzoate, identical with that obtained from the oxime by the same treatment. Attempts to make the tribenzoate of the oxime described by R. Meyer and Kissen were unsuccessful.
- 8. The intermediate product gives a *colorless* trimethyl ether, when methylated in alkaline solution with dimethyl sulfate, isomeric with the *yellow* trimethyl ether obtained from the oxime by the same treatment.
- 9. Attempts to make the intermediate product synthetically from p-hydroxybenzoyl-o-benzoic acid and p-aminophenol were unsuccessful. A mixed phthalein was obtained instead.

CHARACTERISTICS OF THE TWO CRYSTALLINE FORMS OF GLYCINE

By C. A. Brautlecht and N. F. Eberman Received April 9, 1923

Emil Fischer¹ observed that the needle-shaped form of glycine, precipitated from water solution by absolute alcohol, reacts smoothly with phosphorus pentachloride in presence of acetyl chloride to form the hydrochloride of glycyl chloride (amino-acetyl chloride). The plate form, prepared by evaporating the water solution and drying at 100°, did not react in the same manner. Fischer believed that this behavior had to do with isomerism. There are only two structures for glycine theoretically possible, the straight chain (NH₂CH₂COOH) and the inner salt NH₃CH₂COO. There is much controversy concerning the correct form

and much additional experimentation is needed before a satisfactory conclusion can be reached.

Falk and Sugiura² studied the two forms of glycine and observed that the needle form began to decompose at a slightly higher temperature than the plate; that the time interval after solution of the plate form caused a slight difference in amino nitrogen content by the Van Slyke method, whereas the needle form underwent no change; and that the plate form took up about one atomic proportion of bromine while the needle form took up about two, the bromine, however, leaving the glycine readily. Their conclusion was that a difference existed between the two forms.

H. Biltz and H. Paetzold³ observed that the two forms of glycine did not react with diazomethane in the absence of moisture. When moisture was present, both forms acted exactly alike, yielding betaine hydrochloride. When the two forms were pulverized and dried at 130° both plates and needles decomposed at the same temperature and in the same manner. They believed that the difference noted by Falk and Sugiura in decomposition temperature for the two forms, a fact confirmed by them when the crystals were dried at 100–103°, was due to the plates occluding mother liquor which depressed the decomposition temperature. Biltz and Paetzold then repeated the bromination experiments of Falk and Sugiura and observed that bromine taken up by both forms was lost on standing in a vacuum desiccator over moist potassium hydroxide; that each form took up about the same quantity of bromine which was adsorbed or loosely attached and variable in quantity in different experiments and was not affected whether the glycine was strongly dried or not. In repeating E.

¹ Fischer, Ber., 38, 2914 (1905).

² Falk and Sugiura, J. Biol. Chem., 34, 29 (1918).

³ Biltz and Paetzold, Ber., 55, 1066 (1922).

Fischer's acetylation experiments,¹ they obtained similar results with both forms when dried at 130°, whereas when the substances were dried at 100° the results agreed with those of Fischer, the needles reacting to form the glycyl chloride hydrochloride in about 50% yield, whereas the plates reacted only to a slight extent. It thus becomes possible to obtain this acid chloride from glycine in plate form, prepared by evaporation of the water solution, by heating to 130° for 9 hours or possibly less. The questions then arise, since the supposition can be made that the needle form has the open structure, (1) does the action of heat at 130° effect a transformation of the plate form into the needle form; (2) does solution or drying at 130° effect an equilibrium between the two forms; (3) does glycine in crystalline forms and in the presence of water have a different structure? We hope to furnish a little evidence from the following experiments to aid in answering these questions.

Experimental Part

The two forms of glycine were prepared as described by Fischer¹ from imported glycine and glycine prepared according to the method of Klages, ⁴ T. Curtius and E. Welde⁵ and K. Kraut.⁶ The material was pulverized, sifted, and dried at 100–103°. Photomicrographs of the plate and needle forms before pulverization indicated that there was water of occlusion in the plates at times. The processes of pulverizing and drying at 100–103° and sifting to 0.3 mm. mesh apparently remove this water.

Decomposition Temperature of the Two Forms

From the following and similar results, using a long thermometer, it appears that there is no difference in decomposition temperature between the two forms.

Appearance	•	Needl		ecomposi ate form °C.	Ne and	edle plates	Ne	edle olate	form form form 90 rat	and

Decomp., gas formed		2	33	233	2	33			233	

Content of Moisture or Alcohol

Although Fischer¹ in his experiments on the action of phosphorus pentachloride and acetyl chloride, carefully dried each form similarly at 103° and although Falk and Sugiura² also first dried the 2 forms of glycine, it appeared desirable to determine the amounts of moisture present in the airdry material since, as will be shown, the presence of moisture has an effect upon the degree and intensity of the reaction.

- ⁴ Klages, Ber., 36, 1507 (1903).
- ⁵ Curtius and Welde, ibid., 43, 868 (1910).
- ⁶ Kraut, Ann., 266, 295 (1891).

The two forms were prepared as usual, ground uniformly, in dried air and the moisture was determined by heating at 100°, and cooling in a desiccator.

	Needles		Plates			
Sample G.	Loss in weight G.	%	Sample G.	Loss i G.	n weigh	ıt %

In one experiment, after pulverized plates and needles had been dried over phosphorus pentoxide for 24 hours, the plates lost 0.05% in weight at 100° in 24 hours, and the needles lost 0.20% under the same conditions. From these results it appears that the small quantity of moisture or alcohol held by the air-dry glycine is the same for both forms.

Action of Hydrogen Chloride

Dry hydrogen chloride was passed over each of the two powdered forms of glycine after it had been sieved to 0.3 mm. mesh, and dried at 100°. Bell jars were used with a tray of fused calcium chloride at the bottom. Before removing the samples for weighing, the bell jar was first swept out with dry air, or the treated glycine was placed in a vacuum desiccator.

[&]quot;In this experiment the dried gas was conducted over the powdered crystals in fractions, allowed to remain in contact during the intervals and then the excess removed in a vacuum desiccator. The results of this series show that dry hydrogen chloride acts slowly on dry glycine in either form.

In the presence of moisture, for instance, when glycine was treated with hydrogen chloride in a bell jar with a dish of water present the hydrochloride was more easily and completely formed. The samples were dried at 100° after the reaction, before weighing.

The results expressed in the last tabulation show that moisture permits hydrogen chloride to react quantitatively with glycine in 6 days. It is

.1305	.1907	. 1932	98.60

also apparent that no difference exists between the two forms chemically, in the presence of moisture.

Action of Sulfur Dioxide

Sulfur dioxide was allowed to react with the two forms. They were first exposed in a jar under ordinary moisture, temperature and pressure conditions. Here the reaction proceeds according to the equation: $2CH_2(NH_2)COOH + H_2SO_3 \longrightarrow (CH_2.NH_2.COOH)_2H_2SO_3$ and goes practically to completion with both forms.

	Ne	edles			Plates	3

.1127	.1709	.1736	98.45	.0894	.1197	.1377	86.93	

When dry gas and powdered crystals were employed, practically no sulfur dioxide was taken up, the action at best being only very slight, less than one part per hundred in the case of the needle form, and none at all with the plates.

Action of Bromine

Even after 6 days, not enough bromine (an average of 67%) added to the dry powdered crystals to form a monobromo addition product. The needle form, however, was observed to react somewhat more readily than the plates.

Under atmospheric moisture conditions bromine acted upon the two forms as follows.

		Needles		
Sample G.	Wei After 3 days	ght After 6 days	Cale. wt. for glycine monobromide	Calc. wt. for glycine dibromide
0.1166	0.4420		0.2390	0.3653
.1206(b)	.2000	0.2480	.2473	.3780
. 1167	.2044	. 2244	.2394	.3656
		Plates		
.1260	.3800		.2587	.3950
.1066	.3305	.4055	.2187	.3340
.1007	.2947	.3417	.2064	.3160

In this series of experiments, the results are irregular. Sometimes the needle form or the plate form takes up more bromine than the theoretical quantity for a dibromo addition product. In (b) the quantity taken up approximated the monobromo product. According to Falk and Sugiura² the needles form the dibromo and the plates the monobromo product. These investigators state, however, that at times when conditions were apparently suitable for the one form the other was obtained.

When moist bromine was allowed to come in contact with glycine, enough bromine was taken up by both forms in 45 minutes to form about 67% of the monobromo product. After 5 hours, a dark red, liquid mass was obtained. When this was dried, colorless glycine was recovered.

In view of the facts that relatively little bromine adds to glycine in dry form, that varying quantities of moisture change the speed and quantity of bromine addition or absorption, or adsorption, and that the bromine is immediately given off when the compound is allowed to stand in the air, it seems probable that bromine forms no definite chemical compound with either variety of glycine. If all moisture were to be excluded from the apparatus, the glycine and the bromine, it is probable that no bromine would adsorb or add to the glycine at all. Various inorganic salts containing water of crystallization or hydration also add bromine temporarily. Crystallized borax, for instance, adds bromine when exposed under ordinary conditions to bromine vapors in a bell jar. In one experiment 30.2305 g. of borax (weight with container) added 0.0138 g. of bromine in 3 days and 0.0820 g. in 6 days.

Formation of Amino-acetyl Chloride

Attempts were next made to investigate the nature of the compounds formed in Fischer's original experiment with phosphorus pentachloride and acetyl chloride. When 2 g. of glycine was treated with phosphorus pentachloride and acetyl chloride according to Fischer's procedure, the needle form yielded 0.353 g. of the hydrochloride of glycyl chloride, while the plate form yielded 0.345 g., amounting to about 10%. These results indicate that one form might have reverted to the other upon standing after pulverization. The filtrates from the solid residues were distilled under 170 mm. pressure and at from 20–25°. The distillates in both cases contained no nitrogen and consisted chiefly of acetyl chloride. A red oily substance remained in the flasks. When alcohol was added to the oil, that from the needle form warmed but deposited no crystalline substance, while that from the plate form warmed to a greater degree and yielded some crystals of glycine ethyl ester hydrochloride. H. T. Clark' states that acetyl chloride reacts with glycine to form acetyl-glycine.

⁷ Clark, "An Introduction to the Study of Organic Chemistry," Longmans, Green and Co., 1914, p. 290.

The second set of experiments was carried out with 10 g. of the freshly prepared forms without intermission. In these experiments Fischer's results were duplicated, that is, 8.5 g. of the acid chloride was separated from the reaction mixture from needle glycine, corresponding to 49.2% of that calculated for glycyl chloride hydrochloride. The plate form gave a solid residue which when dried weighed 3.0 g., corresponding to 17.3% of the hydrochloride of glycyl chloride. Aniline, water and alcohol all reacted violently and exothermically with the hydrochloride of glycyl chloride from needle glycine.

The 3 g. of substance separated from the reaction mixture from the plate form did not react with aniline or alcohol and dissolved in water without rise in temperature. Its melting temperature was 202°, it contained chlorine and was probably glycine hydrochloride. Analogous to ammonium chloride, its heat of solution was negative. When dissolved in water, treated with silver oxide and hydrogen sulfide, filtered, the filtrate evaporated and the residue crystallized, glycine was obtained. It thus appears that the plate form did not react to form an acid chloride and that the substance that was formed dissolved in the acetyl chloride.

The filtrates were examined as before. They were distilled under reduced pressure at 30°, the residual oil was washed in petroleum ether and was then found to contain phosphorus and chlorine. It was soluble in acetone and ethyl acetate but could not be purified.

In order to study the influence of one constituent at a time, the action of phosphorus trichloride alone on glycine was examined. Even prolonged action or treatment of a suspension of the pulverized needle or plate glycine in phosphorus trichloride yielded no new product, the glycine being recovered unchanged.

Phosphorus pentachloride was next dissolved in carbon disulfide and treated with glycine. No action was observed. Ten g. of each form was mixed with 200 cc. of carbon disulfide and 31.5 g. of phosphorus pentachloride and the mixture stirred for 4 hours. The plate form yielded 11 g. of a white crystalline salt which fumed strongly in the air (due to the presence of hydrogen chloride) even after being washed with carbon disulfide and petroleum ether. After the mass had stood in a vacuum desiccator over phosphorus pentoxide for 12 hours it darkened and became oily and resinous. This action was probably the effect of some phosphorus pentachloride that had not been washed out, as a positive test for phosphorus was obtained. When phosphorus pentachloride and glycine were mixed dry and allowed to stand in a desiccator, an oily mass was formed, similar to that obtained in the experiment with acetyl chloride when phosphorus pentachloride was present.

In the next trial, 10 g. of the plate form of glycine was treated with a larger quantity of carbon disulfide (400 cc.) and much effort was made to

wash out all phosphorus pentachloride with carbon disulfide and petroleum ether. In this manner 7 g. of a white crystalline solid was obtained. This did not fume in moist air, contained only a slight trace of chlorine, melted at 210° and was soluble in carbon disulfide. It was, therefore, not an acid chloride. Upon purification, it proved to be glycine. The needle form under exactly the same conditions yielded 10.4 g. of a white crystalline solid that was soluble in carbon disulfide, insoluble in alcohol and melted at 210°.

From these experiments, we conclude that phosphorus trichloride and phosphorus pentachloride in carbon disulfide solution have no action on either form of glycine. This would indicate that the substance causing the reaction in the Fischer experiment, yielding a chlorine derivative was the acetyl chloride, although the phosphorus pentachloride may have had some influence.

An attempt was made to determine whether any difference existed between the 2 forms of glycine in their action toward esterification reagents; 5 g. of each was boiled under a reflux condenser for 2 days with ethyl iodide and absolute alcohol. There was no evidence of reaction in either case, the glycine separating unchanged after removal of heat. After filtration, the filtrates were extracted with ether and when the ether extract was evaporated only a small quantity of resinous material was obtained. Evaporated with strong hydrochloric acid solution, no crystals were obtained. According to Beilstein, the plate form yields the ethyl ester when treated with absolute alcohol and ethyl iodide in a closed tube.

Summary

- 1. The action of hydrogen chloride, bromine vapor, and sulfur dioxide, with and without moisture, shows that moisture rapidly brings about an equilibrium between the plate and needle forms of glycine, and that any difference to be definitely established must be determined in the absence of water or even atmospheric moisture. The dry crystals do not differ chemically when dried at 103° and pulverized to pass a 0.3 mm.-mesh sieve; neither is there a difference in their moisture content when air-dried and pulverized, or in their decomposition temperatures.
- 2. Bromine did not form a chemical compound with glycine. By varying the quantity of moisture and length of time of contact, varying quantities of bromine can be taken up. The addition, absorption, or adsorption, however, is only temporary.
- 3. It is probable in the Fischer experiment that phosphorus pentachloride does not act directly on glycine to form any acid chloride. From the results obtained with phosphorus trichloride and phosphorus pentachloride, both dissolved in carbon disulfide, it appears that acetyl chloride itself reacted with glycine in the presence of the phosphorus halide to form glycyl

chloride indirectly, together with a number of other substances, some containing phosphorus.

This study of the characteristics of glycine is being continued.

NEW SOURCES OF SANTONIN¹

By Arno Viehoever and Ruth G. Capen Received April 9, 1923

The discovery of a new source of santonin should attract attention, especially because it is now almost impossible to obtain the plant material, wormseed, as well as santonin itself, owing to the unsettled conditions in Russia. Both are now marketed at prices unusually high. Levant wormseed is quoted at \$3.25 to \$3.50 per pound, and santonin at \$172 to \$175 per pound.²

Supplies other than the normal source of santonin, Artemisia cina Bg. (Artemisia maritima var. stechmanniana Bees.), which grows exclusively in the region of Turkestan and Siberia, have been utilized by manufacturers of santonin. It is reported that the plant species Artemisia gallica Willdenow, which is indigenous to France, and Artemisia brevifolia Wallich contain santonin. No definite quantities of santonin are reported in the investigations of Heckel and Schlagdenhauffen³ and, as far as is known, this plant (Artemisia gallica) was never utilized in the manufacture of santonin. Artemisia brevifolia, a form very closely related to Artemisia maritima Linné, growing abundantly in Thibet, has more recently been mentioned as a possible commercial source. In 1921 Greenish and Pearson4 called attention to this source in which they found 0.85% of santonin. Another sample of the same plant, collected at Gurez, yielded 1.09% in the leaves dried at 100°, or 0.76%, calculated upon the air-dry leaves and stems as received.⁵ Whether this material can be utilized as a commercial source is still undecided.

In 19206 a German firm patented a process to isolate santonin from the

whole herb of Artemisia maritima L., growing in Germany on the North Sea and the Baltic Sea.

Survey of Domestic Species of Santonin

Because of the scarcity of a needed drug, a survey of the domestic forms of Artemisia, as a possible source of santonin, was undertaken by the Bureau of Chemistry. This investigation, not fully completed, has yielded very interesting and promising results.

Procedure

A few of the flower heads of the Artemisia species to be examined were placed in a sublimation apparatus. The apparatus, consisting of a small beaker-like container with a cup extending from the bottom, was immersed in an oil-bath kept at a temperature ranging from 150° to 170°. A cover slip (upon which the sublimate was received) was placed over the opening of the cup. A cooling device and vacuum were also used.

The sublimed santonin was deposited on the cover slip in oily drops, which, upon standing, crystallized in large prismatic plates. By treating the sublimate with ether the formation of santonin crystals was appreciably hastened. Santonin was identified by four tests as follows.

Crystalline Structure.—Santonin forms very characteristic rhombic plates. On account of the solubility of santonin in most solvents having a high index of refraction, only an approximate value for its refractive index, namely, about 1.6, was established.⁸

Melting Point.—Purified santonin melts at 170°. The melting is preceded by a loss of the polarizing power, at 1° or 2° below 170°. The melting point can be readily observed under the microscope when the material is heated in a special heating chamber (micro-melting-point apparatus).

Furfural Reaction.—The sublimate is dissolved in a small quantity of alcohol to which 1 to 2 drops of 2% furfural solution and 1 to 2 cc. of sulfuric acid are added. Upon evaporation of the alcohol the liquid is purplish-red, carmine-red, changing to bluish-violet, and finally shows a black precipitate. Furfural alone with sulfuric acid gives a red.

Formation of Santonin Per-iodide.—This has already been described. ¹⁰ The species examined, the locality from which they were obtained, and the results of the examination are given in Table I.

⁷ This apparatus, as well as a new sublimation flask suitable for this work, is fully described in a paper entitled "Sublimation of Plant and Animal Products, Third Report," by Arno Viehoever, *J. Assoc. Official Agr. Chem.*, 6, 473 (1923).

⁸ Determined by J. F. Clevenger of the Bureau of Chemistry.

The survey of 56 species of Artemisia showed that santonin can be obtained from Artemisia mexicana Willd., from Artemisia neo-mexicana

Wooton, and probably from Artemisia Wrightii, all of which grow in the region of New Mexico and Mexico.¹¹

Only very small quantities of material were available for experimental work. Attempts to obtain fresh and larger supplies of Artemisia mexicana and Artemisia neo-mexicana have thus far been unsuccessful. Sufficient plants could not be collected in time, and the seeds obtained failed to grow. The closed flower heads, which in the case of Artemisia cina, contain the largest quantities of santonin, were used in the survey whenever possible. In many cases the open flower heads of old plants of various species had to be examined. The negative results, therefore, are not absolute proof of the absence of santonin in the species mentioned.

The results indicate a distinct possibility of utilizing domestic plants, growing as weeds in barren fields, for the manufacture of santonin.

Summary

Of 56 species of domestic Artemisia pronounced tests for santonin were obtained from A. mexicana Willd., from A. neo-mexicana Wooton and probably from A. Wrightii, all of which grew in the region of New Mexico and Mexico.

The results indicate a distinct possibility of utilizing domestic plants, growing as weeds in barren fields, for the manufacture of santonin.

[Contribution from the Biochemical Laboratory, New York Agricultural Experiment Station]

A STUDY OF THE PHYTOSTEROLS OF CORN OIL, COTTONSEED OIL AND LINSEED OIL¹

By R. J. Anderson with M. G. Moore Received May 7, 1923

Introduction

The present investigation was undertaken in connection with the work on the phytosterols in the fat from corn pollen.² The properties of the phytosterols from corn pollen differed so markedly from other plant phytosterols that we desired to extend the investigation in the hope of finding similar substances in other plant products. But the materials which we examined, corn oil, cotton seed oil and linseed oil, did not yield any phytosterols similar to those found in corn pollen.

The first substance to be investigated was corn oil. The unsaponifiable matter in corn oil was called cholesterol by Hoppe-Seyler,³ but no data were

- 11 Copies of the illustrations of the plants may be obtained from the author.
- ¹ Read at the meeting of the American Chemical Society, New Haven, Conn., April, 1923.

 - * Hoppe-Seyler, "Med. Chem. Unters.," 1866, p. 162.

given regarding the physical or chemical properties of this substance. Hopkins⁴ reported that the "cholesterol" of maize oil melted at 137° to 137.5°, and gave the color reactions of cholesterol. Gill and Tufts⁵ questioned the correctness of the term "cholesterol" as applied to the unsaponifiable matter in maize oil. These authors found that the purified substance melted at 137.5° to 138°, and the acetyl derivative melted at 127.1°, and they concluded that "the above results seem sufficient to prove that the alcohol of maize oil is not cholesterol....the compound studied is undoubtedly identical with the compound found in wheat and rye and described by Burian⁶ under the name of 'Sitosterol'." König and Schluckebier⁷ report the isolation of a phytosterol from corn oil which melted after the seventh recrystallization at 140.4°, and the acetate melted at 137°. The high melting point of this substance must have been due to imperfect or partial acetylation.

Our results agree with those reported by Gill and Tufts. The phytosterol which we isolated from corn oil appeared to be homogeneous. We believe that it is identical with sitosterol and we could not find any evidence of the presence of stigmasterol. Upon bromination of the acetyl derivative by the method of Windaus and Hauth⁸ only a dibromo compound was obtained. Ritter⁹ reported for sitosterol in chloroform solution a specific rotation of —33.91°, while our preparation dissolved in chloroform gave a specific rotation of —34.38°.

Several investigators have reported upon the unsaponifiable matter in cottonseed oil. Bömer and Winter isolated a preparation which melted at 136° to 137°. Siegfeld obtained 3 different crystalline substances from the unsaponifiable matter of cottonseed oil. A phytosterol preparation was finally obtained from the mother liquors which melted at 138.8° to 139.8°, and its acetate melted at 131.5° to 132.5°. König and Schluckebier found a phytosterol which melted at 137° to 138° and the acetate melted at 125.8°, after the fifth recrystallization. Heiduschka and Gloth were unable to find any stigmasterol in the phytosterol from cottonseed oil by the method of Windaus and Hauth. They obtained a dibromo-acetate that melted at 127°, and that upon reduction with zinc

dust and saponification gave the original phytosterol which melted at 136°. In an investigation of the "Soapstock" residues from cottonseed oil, Wagner and Clement¹⁴ isolated a phytosterol which after 3 or 4 recrystallizations melted at 137.5° to 138°. The above-mentioned authors were unable to separate any stigmasterol from the preparation by the method of Windaus and Hauth,⁸ thus confirming the results of Heiduschka and Gloth.¹³ They were able, however, by repeated recrystallization to separate this phytosterol into 2 fractions. One melted at 139°, and gave an acetate melting at 125°; the other melted at 130–131°, and its acetate melted at 120°. Although both of these fractions gave the usual phytosterol reactions, these authors believed that the phytosterol of cottonseed oil was not homogeneous, but consisted of two different substances.

Matthes and Heintz¹⁵ separated the unsaponifiable matter obtained from cottonseed oil into a solid and a liquid portion. The liquid portion was further separated by distillation under reduced pressure into several fractions from which, however, no definite compounds could be obtained.

The solid portion consisted of phytosterol which melted at 139°. Its optical rotation was —23.14° which is much lower than has usually been reported for phytosterol. The acetyl derivative gave only a dibromo derivative melting at 125°, which upon reduction with zinc dust gave the original phytosterol melting at 139°.

Our results confirm the findings of Wagner and Clement. By fractional crystallization we were able to separate the phytosterol of cottonseed oil into 2 fractions that differed slightly in their melting points and also in optical rotation.

The phytosterol of linseed oil was investigated by Bömer and Winter¹¹ who isolated a preparation which melted at 137° to 138°, and the acetate melted at 128° to 129°.

We were able to separate the phytosterol of linseed oil by fractional crystallization into 2 fractions that were very similar to those we obtained from cottonseed oil. We believe, therefore, that cottonseed oil and linseed oil contain at least 2 phytosterols that differ in their melting points and also in their optical rotation. These substances, however, so far as one can determine by chemical analysis, are identical in composition and they give identical color reactions. The differences in physical properties which we have noted must depend upon slight variations in constitution.

It is very evident that the phytosterol occurring in plants is not a single homogeneous substance but may consist of 2 or more fractions that differ slightly in physical properties and sometimes in chemical composition, particularly stigmasterol. Occasionally these fractions may be separated with ease and in great purity as shown by Windaus and Hauth.⁸ However,

¹⁴ Wagner and Clement, Z. Nahr. Genussm., 17, 266 (1909).

¹⁵ Matthes and Heintz, Arch. Pharm., 247, 161 (1909).

in some mixtures of phytosterols this method is not applicable as shown by Wagner and Clement¹⁴ in the case of the phytosterols from cottonseed oil.

Phytosterols occur in all parts of the plants¹⁶ but the function of these substances in the metabolism of the plant is not known. The fact that phytosterols are largely deposited with the fats in seeds and pollen grains would seem to justify the assumption that these substances play an important role in the life of the plant cells.

An important relation must undoubtedly exist between the phytosterols and the corresponding alcohol which occurs in animal cells and tissues, namely cholesterol, the phytosterols contained in vegetable foods being the source of the cholesterol found in animal tissues.

Experimental Part

Crude corn oil¹⁷ was saponified in lots of 300 g. by boiling it with 600 cc. of alcoholic potassium hydroxide. Two kg. of the oil was saponified in this way. The soap solution was largely diluted with water and extracted with 3 portions of ether. The ethereal solution was washed with dilute potassium hydroxide and with water, filtered and evaporated. The residue was yellowish-brown in color and it contained some oily substance. It was again boiled with 300 cc. of alcoholic potassium hydroxide for ¹/₂ hour. As the solution cooled, the greater part of the substance crystallized. This was filtered off, washed in dil. alcohol until free from alkali, and dried in a vacuum over sulfuric acid.

A smaller amount of material was recovered from the filtrate after diluting it with water and extracting with ether. After the ether had evaporated an oily residue remained that was dissolved in hot alcohol. A mixture of crystals and a yellow oil separated as the solution cooled. The oil was eliminated by repeated crystallization from alcohol, and we obtained finally a pure snow-white product that crystallized in plates. The dry substance melted 18 at 137.5°.

The first crystalline product mentioned above weighed 16.8 g. It was recrystallized thrice from 300 cc. of 95% alcohol and was then snow-white in color. It crystallized in 2 forms, either as compact elongated plates when the solution was cooled slowly, or in very large thin plates when the solution was cooled rapidly. The purified substance weighed 12.6 g. Heated in a capillary tube it melted at 137.5°. Drying in a vacuum at 105° did not change its melting point. It gave the Liebermann-Burchard reaction and it readily absorbed bromine in chloroform solution. For analysis it was dried at 105°, in a high vacuum over phosphorus pentoxide.

Analyses. Subs., 0.1434: H_2O , 0.1578; CO_2 , 0.4437. Calc. for $C_{27}H_{45}OH$ (386): C, 83.93; H, 11.91. Found: C, 84.38; H, 12.31.

¹⁶ Czapek, "Biochemie der Pflanzen," Gustav Fischer, Jena, 2nd ed., 1905, vol. I, p. 163.

¹⁷ The crude and refined corn oils used in this investigation were kindly furnished by Mr. Lloyd Bosworth of the Patent Cereals Company, Geneva, N. Y.

¹⁸ Unless otherwise specified, the melting points given in this paper are uncorrected.

The substance was again recrystallized four times from absolute alcohol and analyzed after it was dried as described above.

Analysis. Found: C, 83.72; H, 12.41.

The substance again melted at 137.5° . It was then recrystallized from 80% alcohol. The melting point did not change. After it had been dried as described above it was analyzed.

Analysis. Found: C, 83.78; H, 12.12.

In chloroform solution its specific rotation was $[\alpha]_{\rm D}^{20} = -34.38^{\circ}$.

The analyses agree closely with the calculated composition of phytosterol, $C_{27}H_{45}\mathrm{OH}$, and the melting point is identical with that of sitosterol.

Water of Crystallization.—The various preparations that we analyzed contained some water of crystallization.

Analyses. Subs., 0.1532, 0.1384, 0.1093: loss on drying at 105° , 0.0063, 0.0054, 0.0036. Cale. for $C_{27}H_{45}OH + H_2O$: H_2O , 4.45. Found: 4.11, 3.90, 3.29.

The first sample had been crystallized from 95% alcohol and dried in a vacuum over sulfuric acid. The second had been crystallized from absolute alcohol and dried in the air. The third had been crystallized from 80% alcohol and dried in the air.

It is evident from the above data that all of our preparations contained less water of crystallization than is required for $1~\rm{H}_2O$.

Acetyl Derivative.—The acetyl derivative was prepared by boiling 1 g. of phytosterol with 35 cc. of acetic anhydride. The acetic anhydride was distilled in a vacuum and the residue purified by recrystallizations from absolute alcohol. The substance was obtained as snow-white crystals that melted at 127°. It did not lose in weight on drying in a vacuum over phosphorus pentoxide.

Analysis. Subs., 0.1410: H_2O , 0.1435; CO_2 , 0.4207. Calc. for $C_{27}H_{45}O$.OC.CH₃ (428): C, 81.31; H, 11.21. Found: C, 81.37; H, 11.38.

Bromination of Phytosterol.—The direct bromination of phytosterol did not lead to a satisfactory product. To a solution of 1 g. of dry phytosterol in 10 cc. of ether was added 0.85 g. of bromine dissolved in 10 cc. of glacial acetic acid. Nothing crystallized from this solution even after it had stood in a freezing mixture for some time. The substance was therefore extracted with ether, the ethereal solution was washed with dil. alkali and water, filtered and the ether evaporated. The yellowish crusts that remained weighed 1.4 g. after they had dried in a vacuum over sulfuric acid. This indicates that 2 atoms of bromine had been absorbed. The substance could not be obtained in crystal-line form from any of the usual solvents. It separated more readily from methyl alcohol than from any other solvent but the product was amorphous.

The bromination of the acetyl derivative was more successful. A solution of 5.1 g. of the acetyl derivative in 30 cc. of ether was brominated by the method of Windaus and Hauth.⁸ After it had stood for about ¹/₂ hour at room temperature a small amount of substance without any distinct crystal form separated from the bromination mixture. When the flask was placed in a freezing mixture the amount of this substance was greatly increased. It was filtered, washed thoroughly in cold glacial acetic acid and dried in a vacuum over sulfuric acid and potassium hydroxide. The dry substance showed only a faint yellowish color, and it weighed 3.3 g.

The remainder of the bromine derivative was obtained when the filtrate from the precipitate described above was diluted with water after the ether had been distilled under reduced pressure. It separated as a voluminous, amorphous precipitate. This was filtered off, washed with water and dried in a vacuum over sulfuric acid. The dry substance was brownish and weighed 3.7 g.

The total weight of the bromine derivatives was 7 g., which represents a quantitative yield provided 2 atoms of bromine had been absorbed.

These fractions were purified separately. The first fraction separated from absolute alcohol in the form of microscopic granules that showed no definite crystalline structure. The product was snow-white. It was impossible to obtain the substance in definite crystals from any of the usual solvents. When heated in a capillary tube the substance melted at 120° to 120.5°. It did not give the Liebermann-Burchard reaction. Evidently the development of the color in this reaction depends upon the double bond.

It did not lose in weight on drying at 105° in a high vacuum over phosphorus pentoxide.

Analyses. Subs., 0.2075: H_2O , 0.1569; CO_2 , 0.4500. Subs., 0.1780: AgBr, 0.1182. Calc. for $C_{27}H_{46}O$.CO.CH₂Br₂ (587.84): C, 59.20; H, 8.16; Br, 27.19. Found: C, 59.14; H, 8.46; Br, 28.25.

The bromine found was about 1% too high but it is evident that the substance was essentially a dibromo-phytosterol acetate.

The second preparation was purified in the same way and gave an identical product that melted at 120° to 120.5° .

It is evident from the above results that the phytosterol of corn oil does not contain any stigmasterol.

Regeneration of Phytosterol from the Bromo-acetyl Derivative.—To 3 g. of the bromo-acetyl derivative dissolved in 200 cc. of alcohol was added 10 cc. of glacial acetic acid and the solution was boiled for 3 hours with 15 g. of zinc dust under a reflux condenser. More zinc dust was added in small portions from time to time. The excess of zinc was then filtered off and the filtrate boiled with 40 g. of potassium hydroxide for 1 hour. The phytosterol was extracted with ether and purified by recrystallization several times from absolute alcohol. So far as one could judge by crystal form, solubilities and reactions, the substance was identical with the original phytosterol and melted at 137.5°.

Quantitative Determination of the Unsaponifiable Matter in Corn Oil.—We followed the method outlined by Bömer¹⁹ in determining the unsaponifiable matter in corn oil. It was found necessary, however, to extract the soap solution 7 times with ether before all of the crystallizable phytosterol had been removed. On evaporation of the ether after the sixth extraction there was a slight but distinct crystalline residue. Even the seventh extraction left a slight residue on evaporation of the ether but this was a yellow oily substance that did not show any crystals of phytosterol.

The total residue after the evaporation of the ether was again boiled with alcoholic potassium hydroxide, diluted with water, and extracted thrice with ether. After the ethereal solution had been washed and filtered, it was evaporated and the residue dried to constant weight at 100° and weighed.

The crude phytosterol thus obtained was mixed with some yellow oil and the residues from the crude corn oil contained a larger amount of this oily substance than those from the refined oil. We did not determine the nature of this unsaponifiable oily substance but it would seem worthy of further investigation.

¹⁹ Börner, Z. Nahr. Genussm., 1, 21 (1898).

In each determination 50 g. of oil was saponified and the following results were obtained.

Cruc	Crude corn oil Unsaponifiable		Refined edible corn oil Unsaponifiable			
	G.	%	G.	%		
1	.0740	2.15	0.8346	1.67		
1	.0018	2.00	.8260	1.65		
. 0	.9711	1.94	.8654	1.73		
0	.9813	1.96				
, -		#	***************************************			
Av. 1	.0070	2.01	Av. 0.8420	1.68		

It is evident from the above figures that corn oil contains a high percentage of unsaponifiable matter and that in the process of refining less than 0.5% of the unsaponifiable material is removed.

The Phytosterol of Cottonseed Oil

About 2 kg. of cottonseed oil²⁰ was saponified and the phytosterol isolated as described under corn oil.

The unsaponifiable residue left on evaporation of the ether was dark brown, largely due to the admixture of a dark oil. The substance was dissolved in 500 cc. of methyl alcohol and the solution boiled with norite, filtered and allowed to cool. It was still dark in color and the product that separated in large thin plates was yellowish-brown. It was recrystallized thrice from methyl alcohol and 4 times from ethyl alcohol. The dry substance weighed 2 g. and was slightly yellowish; m. p., 135°. The mother liquors were saved and examined, as will be described later.

Acetyl Derivative.—For further purification the phytosterol was acetylated and the acetyl derivative recrystallized twice from methyl alcohol, from which it crystallized in rosets of fine needles, and twice from ethyl alcohol from which it crystallized in thin plates. After the final filtration, washing the substance in cold alcohol and drying it in a vacuum over sulfuric acid, it weighed 1.7 g. It was snow-white; m. p., 119°. It did not lose in weight on drying at 105°, in a high vacuum over phosphorus pentoxide.

Analyses. Subs., 0.1103: H_2O , 0.1151; CO_2 , 0.3288. Calc. for $C_{27}H_{45}O$.CO.CH₃ (428): C, 81.31; H, 11.21. Found: C, 81.30; H, 11.67.

Saponification of Acetyl Derivative.—The remainder of the purified acetyl derivative was saponified with alcoholic potassium hydroxide and the phytosterol extracted with ether in the usual way. It was crystallized from methyl alcohol and recrystallized from ethyl alcohol from which it separated in thin colorless plates. The dry product was snow-white and it weighed 1.1 g. Heated in a capillary tube it melted at 134-135°. Drying it at 105° in a vacuum over phosphorus pentoxide did not change the melting point. The substance was again recrystallized from 95% ethyl alcohol, but the melting point was still 134° to 135°.

Water of Crystallization.—The purified phytosterol suffered some loss in weight when dried at 105° in a vacuum over phosphorus pentoxide, corresponding to about 0.5 H₂O.

Analyses. Subs., 0.1201, 0.8760: loss, 0.0033, 0.0185. Calc. for $C_{27}H_{48}OH.H_2O$: H_2O , 4.45. Calc. for $C_{27}H_{45}OH.^1/_2H_2O$; H_2O , 2.27. Found: 2.74, 2.11; av., 2.42.

²⁰ The oil was bought in the open market in sealed tin cans which were marked "Wesson Oil. The Southern Cotton Oil Company."

The purified and dried phytosterol in chloroform solution gave $[\alpha]_{\rm p}^{20}$, —33.61°. After drying in a vacuum at 105°, over phosphorus pentoxide the substance was analyzed.

Analysis. Subs., 0.1168: H_2O , 0.1277; CO_2 , 0.3588. Calc. for $C_{27}H_{45}OH$: C, 83.93; H, 11.91. Found: C, 83.78; H, 12.23.

Phytosterol from the Mother Liquors.—The total mother liquors from which the phytosterol preparation described above had been crystallized, were evaporated in a vacuum. The residue was crystallized several times from methyl alcohol until it was snow-white. It was then acetylated and the acetyl derivative purified by recrystallization from ethyl alcohol. It was saponified by alcoholic potassium hydroxide, extracted with ether, and the product was recrystallized many times from methyl alcohol. It was snow-white and crystallized in large thin plates. After drying in the air it weighed about 1 g.; m. p., $138-139^{\circ}$. After the substance was again recrystallized from methyl alcohol the melting point was still the same; in chloroform $[\alpha]_{D}^{20}$, -34.19° .

When dried at 105° in a vacuum over phosphorus pentoxide the substance was found to contain about the same amount of water of crystallization as the first preparation.

Analyses. Subs., 0.1192, 0.7807: loss, 0.0036, 0.0212. Found: H_2O , 3.02, 2.71; av., 2.86.

The dried preparation was analyzed.

Analysis. Subs., 0.1156: H₂O, 0.1257; CO₂, 0.3546. Calc. for C₂₇H₄₅OH (386): C, 83.93; H, 11.91. Found: C, 83.65; H, 12.16.

Acetyl Derivative.—The acetyl derivative prepared from this fraction and recrystallized from methyl alcohol melted at 124°. It was recrystallized several times without change in the melting point.

The 2 phytosterol preparations described above gave identical colors in the Liebermann-Burchard reaction and both preparations absorbed bromine in chloroform solution.

It is evident from the data obtained that the phytosterol contained in cottonseed oil is not homogeneous but consists of at least 2 fractions which differ in melting point and probably in optical rotation since the rotation was slightly greater in the fraction having the higher melting point. If there are 2 phytosterols in cottonseed oil they have apparently the same chemical composition. The differences in physical properties must depend upon slight differences in constitution. It seems doubtful whether these products can ever be separated into homogeneous substances by simple recrystallization.

The Phytosterol of Linseed Oil

The crude phytosterol was isolated from 2 kg. of saponified raw linseed oil in the manner described under corn oil.

The residue obtained on the final evaporation of the ether contained a considerable amount of dark brown oil. This oil was eliminated by recrystallizing the substance several times from ethyl alcohol and then from methyl alcohol but the crystals retained a brownish color. The alcoholic solution was finally decolorized with norite and the phytosterol was obtained pure white in color. The substance was now recrystallized 5 times from methyl alcohol from which it separated in colorless plates. The dry product was snow-white and it weighed 2.8 g. Heated in a capillary tube it began to soften at 132° and to melt at 134°, but it was not completely fluid until heated to 136°. The mother liquors were examined, as will be described later.

Acetyl Derivative.—The whole substance was acetylated and the product crystallized from acetic anhydride. It was then twice recrystallized from 95% alcohol from which it separated in small plate-shaped crystals. It was snow-white and weighed 2.4 g. It softened at 122° and melted at 124°. It did not lose in weight when dried at 105° over phosphorus pentoxide.

Analysis. Subs., 0.1246: H_2O , 0.1299; CO_2 , 0.3709. Calc. for $C_{27}H_{48}O$.CO.CH₃ (428): C, 81.31; H, 11.21. Found: C, 81.18; H, 11.66.

Saponification of Acetyl Derivative.—The balance of the acetyl derivative was saponified with alcoholic potassium hydroxide and the phytosterol was isolated in the usual way. After it had been recrystallized several times from alcohol it was obtained as snow-white, plate-shaped crystals which weighed 1.9 g. It began to soften at 130° but it was not melted to a clear fluid until heated to 134°. When dried at 105° in a high vacuum over phosphorus pentoxide it lost 2.37% in weight, corresponding to 1/2 mol. of water; in chloroform solution $[\alpha]_{D}^{20}$, —31.16°. The dry substance was analyzed.

Analysis. Calc. for C₂₇H₄₅OH(386): C, 83.93; H, 11.91. Found: C, 83.88; H, 12.34.

Phytosterol from the Mother Liquors.—The mother liquors left on crystallizing the above preparations were saved, concentrated in vacuum and the material that crystallized as the solution cooled was purified by recrystallization from methyl alcohol until it was snow-white. This fraction weighed 1.4 g.; m. p., 138°; in chloroform solution, $[\alpha]_{D}^{20}$, —34.22°.

Water of Crystallization.—The loss in weight when the substance was dried at 105° in a high vacuum over phosphorus pentoxide corresponded to $^{1}/_{2}$ H₂O.

Analyses. Subs., 0.1045, 1.0131: loss, 0.0028, 0.0186. Calc. for $C_{27}H_{45}OH^{1/2}H_{2}O$: $H_{2}O$, 2.27. Found: 2.67, 1.83; av., 2.25.

The dried preparation was analyzed.

Analysis. Subs., 0.1017: H_2O , 0.1125; CO_2 , 0.3130. Calc. for $C_{27}H_{48}OH$ (386): C, 83.93; H, 11.91. Found: C, 83.93; H, 12.37.

Acetyl Derivative.—The acetyl derivative was prepared in the usual way and allowed to crystallize from acetic anhydride. It was recrystallized from methyl alcohol from which it separated in tufts of needles. The product was snow-white; m. p., 129-130°. Both fractions gave identical colors with the Liebermann-Burchard reaction.

The data obtained indicate that the phytosterol contained in raw linseed oil is very similar to the phytosterol of cottonseed oil. From both oils 2 fractions of phytosterol were isolated one of which melted at 134°, and the other at 138°. The higher-melting fraction showed a slightly higher specific rotation. However, the acetyl derivatives of the phytosterol from linseed oil melted 5° higher than the corresponding products derived from cottonseed oil.

It is an interesting point that the higher-melting fractions of phytosterol were always obtained from the mother liquors.

Summary

- 1. Corn oil contains a relatively high percentage of unsaponifiable matter, amounting in the crude oil to 2.01% and in the refined edible oil to 1.68%. This unsaponifiable matter consists largely of phytosterol which is identical with sitosterol. Its melting point was 137.5° , and the optical rotation of the dry phytosterol was -34.38° . The acetate melted at 127° . The phytosterol of corn oil does not contain any stigmasterol.
- 2. Cottonseed oil contains at least two phytosterols which differ in melting points and probably in optical rotation. Two fractions of phytosterol were separated by fractional crystallization: (a) m. p., 138-139°;

 $[\alpha]_D^{20}$, —34.19°; the acetate melted at 124°; (b) m. p., 134-135°; $[\alpha]_D^{20}$, —33.61°; the acetate melted at 119°.

The complete separation of these fractions by crystallization is very difficult, if not impossible, and we do not believe that either of the above preparations was homogeneous.

3. Linseed oil contains at least two phytosterols which differ in melting point and optical rotation. As in the case of cotton seed oil 2 fractions of phytosterol were separated by fractional crystallization: (a) m. p., 138° ; $[\alpha]_D^{20}, -34.22^{\circ}$; the acetate melted at $129-130^{\circ}$; (b) m. p., not sharp, 134° ; $[\alpha]_D^{20}, -31.16^{\circ}$; the acetate melted at 124° .

None of the phytosterol preparations that we isolated contained 1 molecule of water of crystallization. The loss in weight on drying was somewhat irregular but corresponded more nearly to 1/2 molecule of water of crystallization.

Mixtures of phytosterols such as are obtained from cottonseed oil and linseed oil are so nearly alike in solubility in the usual solvents that it is practically impossible to effect a complete separation by simple fractional crystallization.

A QUANTITATIVE METHOD FOR THE DETERMINATION OF TOTAL SULFUR IN BIOLOGICAL MATERIAL¹

By Mabel Stockholm and Fred C. Koch

Received May 11, 1923

The estimation of total sulfur in biological materials has been the subject of many investigations. The most generally recognized source of error, the difficulty of forming a pure barium sulfate, has been largely eliminated by the now well-known modifications introduced as a result of the careful studies by Folin,² Allen and Johnston,³ Johnston and Adams⁴ and Krieble and Mangum.⁵ There are, however, several other factors which have not been sufficiently emphasized. These are complete retention of the sulfur, complete oxidation to sulfate and complete precipitation of sulfate in blanks and in materials low in sulfur. The first two factors appear to be well controlled in the special methods for total sulfur in urine as developed by

- ¹ The greater part of the experimental work of this paper was carried out by Miss Mabel Stockholm in 1918 as part of the requirement for the degree of Master of Science.

Folin,² Benedict,⁶ Denis⁷ and Modrakowski.⁸ Urine, however, is a very special case in which by far the greater part of the sulfur is already in the sulfate form and, in which we are dealing with relatively large amounts of sulfur as compared with the amount of organic matter to be oxidized. It is a very different matter when it is necessary to oxidize several g. of dry tissue in order to obtain a weighable amount of barium sulfate. This at once introduces the three difficulties referred to.

The incomplete retention of the total sulfur, due either to a loss by volatilization or to incomplete oxidation or both appears to be the most logical source of error in the usual fusion methods with dry sodium carbonate and potassium nitrate or dry sodium peroxide. The same is true for the wet, acid combustion methods. These predictions have been confirmed in this study and in part by earlier studies. Not until after the completion of this work did the authors come across the excellent and almost completely ignored work of Barlow9 who showed the loss of sulfur in the usual dry fusion and wet, acid combustion methods to be due to volatilization. The method which Barlow finally developed is no doubt a reliable one, but it is too cumbersome for general biological application. In view of the impossibility of retaining all sulfur in the usual methods here considered the only alternative is one of two procedures. It is either a complete oxidation of the material by fusion in the presence of an excess of base in a closed vessel or the oxidation of the sulfur in an aqueous alkaline solution to a less volatile form, with the subsequent oxidation of the organic matter by fusion or by a wet, acid oxidizing method. The former involves the use of a specially devised Parr bomb as now employed by the Association of Agricultural Chemists. 10 By the use of this modification investigators working on sulfur problems in plants have found that seeds and plants contain much more sulfur than had previously been reported. This method is not likely to be generally adopted on account of the necessity of the special bomb.

The difficulties of the second alternative, that of wet oxidation in an alkaline solution, we overcame by the use of hydrogen peroxide in concentrated form. Here, also, we later found numerous confirmations as to the value of this reagent for oxidizing reduced sulfur. Thus, as early as 1884 Classen and Bauer¹¹ used hydrogen peroxide for the complete oxidation of sulfides and sulfites. This was confirmed by many other studies and especially by Klemmer¹² and Petersen.¹³ The former uses it for the

complete oxidation of sulfur in gas and Petersen reports the quantitative oxidation of sulfur in the forms of sulfides, thio-urea, thiocarbanilide and of carbon disulfide by hydrogen peroxide in alkaline solutions. Folin.2 in fact, uses essentially the same principle in evaporating the urine after the addition of several g. of sodium peroxide and subsequently oxidizes other constituents by fusion with the addition of more sodium peroxide. As stated before, this method is reliable for urine, but the subsequent peroxide fusions are not applicable to tissues in general unless conducted in a homb. Unless this precaution is taken the chances are that the analyst will lose many estimations due to the explosive combustion, especially when the material contains considerable carbohydrate. We therefore devised our method so as to follow the oxidation by hydrogen peroxide by a second process of acid oxidation with nitric acid and bromine. The results are very satisfactory, as indicated in the table, and as found by experience in the use of the method in other studies. The presence of nitrate in sulfate precipitations has been severely criticized, but the very high results reported as due to the presence of nitrates have been obtained under conditions where the precipitations were carried out in small volumes with relatively high concentrations of nitrates. Under the conditions employed here, that is, of precipitating from a volume of 500 to 600 cc. and digesting on the steam-bath for 10 to 12 hours before filtering and washing, the error is a very slight one. In fact the slight difference of 0.5 to 1.0 mg. of barium sulfate in a total of 0.1125 g. may easily be due to a trace of sulfate in the relatively large amounts of reagents employed. Furthermore, this is corrected by the introduction of a true blank estimation as practiced in this Laboratory for the last 8 or 10 years.

The basis of this true blank test is as follows. It is a very common experience to find no sulfate precipitated in the usual length of time in blank estimations and in other cases where it is known that small amounts of sulfur must be present. If the solution is permitted to stand several days these traces of sulfate may be precipitated. This is especially true when such small amounts of sulfate are to be precipitated from a 500 to 600cc. volume containing 25 to 30 g. of soluble salts. When, however, a known amount of sulfuric acid is added to such solutions, the usual rapid and complete precipitation of barium sulfate is observed. In view of the very satisfactory results obtained in this and other laboratories by the use of this procedure, we have adopted the plan of consistently adding 10 cc. of 0.1 N sulfuric acid to every sulfur estimation including the blank tests. The value obtained in the blank tests is, of course, subtracted from the unknowns and the differences give values truly corrected for blank sulfur in the reagents and procedure.

Experimental Part

In view of the nitric acid oxidation methods suggested by Wolf and Oster-

berg, ¹⁴ by Konschegg¹⁵ and by Halverson, ¹⁶ we tried various modifications of these acid oxidation methods on pure cystine and in no case could we obtain theoretical values. In all estimations careful blank tests were made. Oxidation by bromine in alkaline solution with subsequent oxidation by nitric acid gave the highest results, that is 22.26 to 25.06% of sulfur as compared with the calculated value of 26.69%.

A few preliminary trials in which we attempted first to oxidize cystine in an alkaline solution by means of hydrogen peroxide and later complete the oxidation by nitric acid indicated possibilities by this method of oxidation. After a number of attempts with various modifications we finally devised the new Perhydrol-nitric acid method by means of which we obtained theoretical values for cystine after the proper correction for carefully run blank estimations. The method thus developed was then applied in parallel with the ordinary sodium carbonate-potassium nitrate fusion method to various types of biological material containing different forms of organically combined sulfur. The ordinary fusion method and the new Perhydrol-nitric acid method as used in these studies are given in detail below, and the results obtained after proper corrections for blanks are given in Table I.

Fusion Method

Reagents.—The fusion mixture was prepared by thoroughly grinding and mixing 225 g. of potassium nitrate with 750 g. of anhydrous sodium carbonate. 0.1 N Sulfuric acid and 10% barium chloride solution were used.

Procedure.—A sample of 0.5 to 2.0 g. is thoroughly mixed with 15 g. of the fusion mixture in a 50×70 mm. nickel crucible. Over this mixture is placed a cover of 10 g. of fusion mixture. The crucible is covered and heated very gradually over an alcohol lamp. If smoke escapes from the crucible the flame is lowered and the heating is continued and gradually increased until, with the flame almost touching the crucible, very little or no smoke is developed after heat has been applied for an additional hour at that temperature. When thus thoroughly charred, without loss due to visible "smoking," the contents of the crucible are thoroughly mixed, the crucible is covered and then heated for 10 minutes in a medium sized flame on a Roger's burner.

After the fusion mass has cooled, it is dissolved in about 400 cc. of water in a flask and 40 cc. of coned. hydrochloric acid is added. This is boiled in a flask to remove the carbon dioxide and then evaporated to dryness in a disk on the steam-bath. When completely dry, the mass is moistened with 20–25 cc. of coned. hydrochloric acid and again evaporated to dryness. This same treatment is repeated once more.

The mass of salts is next dissolved in 300 to 400 cc. of distilled water,

¹⁴ Wolf and Osterberg, Biochem. Z., 29, 429 (1910).

¹⁵ Konschegg, Arch. ges. Physiol. (Pflüger's), 123, 274 (1908).

¹⁶ Halverson, This Journal, 41, 1494 (1919).

10 cc. of concd. hydrochloric acid added, and the whole transferred to a 500cc. volumetric flask and accurately made up to 510 cc. The well-mixed solution is then filtered through a dry filter into a dry 500cc. volumetric flask and, after exactly 500 cc. has been collected, it is transferred to a liter beaker together with 100-200 cc. of rinsing water. To this is now added 10 cc. of 0.1 N sulfuric acid solution and after the mixture has been heated to boiling, the 10 cc. of a 10% barium chloride solution is added, drop by drop. The boiling is continued for 10 to 15 minutes and then the mixture is heated for 10 to 12 hours before it is filtered and washed as usual. The filter paper and precipitate are cautiously burned and weighed. Blank estimations are made in exactly the same way. After the value found in the blank has been subtracted from the total weight the difference represents, of course, only 500/510 of the original sample.

Perhydrol-Nitric Acid Method

- (1) Reagents.—(a) A 25% solution of sodium hydroxide by volume; (b) Perhydrol or Superoxol, a 30% solution of hydrogen peroxide; (c) furning nitric acid; (d) bromine; (e) 0.1 N sulfuric acid; (f) a 10% solution of barium chloride.
- (2) Procedure.—Into a 100cc, nickel crucible (50×70 mm.) containing 10 cc. of the 25% sodium hydroxide solution is transferred 0.5 to 2.0 g. of the substance. The covered crucible is then heated on the steam-bath until the mass is almost dry. This requires several hours, but causes considerable decomposition of the complex substances present, so that the sulfur in particular can later be easily oxidized. In case the evaporation has proceeded too rapidly it is best to add again about 10 cc. of water and to repeat the slow evaporation. To the slightly moist material 5 cc. of Perhydrol is added very gradually. In some cases it is necessary to stir the mass with a glass rod or to add a few drops of water so as to distribute the reagent properly. During this treatment the heating is continued on the steam-bath.

The material thus partially oxidized is next transferred to a 300cc. Kjeldahl flask, acidified with nitric acid and concentrated over a free flame until salts begin to separate. This concentrated solution is then oxidized, while boiling, by the gradual addition of fuming nitric acid and bromine until 10 cc. of acid and 40 to 50 drops of bromine have been used. With material low in, or free from, fat this treatment is usually sufficient to bring about complete oxidation of the organic matter. The solution is next evaporated almost to dryness and after water has again been added evaporation is repeated to remove most of the nitric acid. When the water solution of this material is not absolutely clear it is filtered and after it has been neutralized with sodium hydroxide and diluted to about 600 cc. it is acidified by the addition of 10 cc. of concd. hydrochloric acid. The 10 cc. of 0.1 N sulfuric acid is added and the precipitation and estimation are con-

ducted as usual and as described for the fusion method. Blank estimations must be made in exactly the same way with the same amounts of reagents.

In case considerable lipin material is present, such as in nerve tissue, egg yolk, etc., drops of lipin or fatty acid remain unoxidized by the above procedure. These, we find, can be filtered off after the mass has cooled without any loss of sulfur, but we consider it safer to modify the method so as to make the oxidation more efficient and prolonged. By conducting the oxidation by nitric acid and bromine in a flask provided with a glass-stoppered reflux condenser and continuing the boiling for 24 hours on an electric plate we were able to decompose completely egg yolk and a sulfo-lipin preparation from brain tissue.

^a Corrected for the sulfuric acid added and the trace in the reagents introduced in the process.

The results in Table I clearly show that the fusion method tends to give low and irregular results. For cystine the values are distinctly low by the fusion method, but the Perhydrol method gives theoretical values and excellent checks. That the low results in the fusion method are due to the loss of sulfur by volatilization is shown by a combustion of a proper mixture of cystine and fusion mixture in a combustion tube with a slow, well-regulated and well-washed current of air passing over the material, and a final washing of the air through 2 wash bottles containing $0.5\,N$ sodium hydroxide solution. The latter solution was next evaporated almost to dryness and analyzed for sulfur by the Perhydrol method. Blank estimations were made in the same way with fusion mixture alone, in the combustion tube instead. By thus heating 2 g. of cystine with 75 g. of fusion mixture and

gradually raising the temperature in the course of $2^{1}/_{2}$ hours, we obtained 2.8% of the cystine sulfur in the washing solution, after due allowance had been made for a careful blank test. This, to be sure, is a rapid heating but repetition of the same experiment with a very gradual heating over a period of 6 hours gave 1.3% of the cystine sulfur in the washing solution. Furthermore, when the gases from the tube at the close of this period were passed into a lead acetate solution, a precipitate of lead sulfide was obtained at once.

The completeness of oxidation of cystine sulfur is easily shown by observation of the rapid loss of reduced sulfur in an alkaline solution of cystine when it is treated with hydrogen peroxide. Such solutions can no longer be reduced to cysteine by sodium sulfite as suggested by Folin and Looney¹⁷ in their recent method for the estimation of cystine. However, such oxidized solutions do not yield calculated values for sulfate unless the alkaline peroxide oxidation is followed by the usual nitric acid and bromine combustion.

Summary

- 1. The dry fusion method used in these studies tends to give low results when properly corrected for blanks.
- 2. These low and irregular results are due to the loss of reduced sulfur by volatilization during the heating period of the dry mixture. This loss is greater the more rapidly the temperature is increased.
- 3. The new Perhydrol method gives calculated values for cystine. The results are uniform and in general higher than by the fusion method on different forms of organically combined sulfur found in biological material.
- 4. Blank estimations for sulfates are made easily and accurately by adding a known amount of sulfate (10 cc. of 0.1 N solution) to the solution in order to hasten the complete precipitation of traces of sulfate.

EFFECT OF AMINO ACIDS IN RETARDING THE HYDROLYTIC DECOMPOSITION OF AN ENZYME (PANCREATIC AMYLASE)

By H. C. Sherman and Florence Walker Received May 14, 1923

In recent work dealing with the effect of amino acids upon the action of amylases we have found that glycine, alanine, tyrosine, phenylalanine, aspartic acid and asparagine exert a favorable influence upon the enzymic hydrolysis of starch.

As more fully described in previous papers, 1,2 the activity of the amylase was measured by the amount of reducing sugar formed when the quantity of enzyme necessary to saccharify about $^{1}/_{5}$ of the substrate acted for $^{1}/_{2}$ hour at 40° on 100 cc. of a 1% dispersion of Lintner "soluble" starch containing optimum amounts of sodium chloride and disodium phosphate. The reducing sugar thus formed, chiefly maltose, was estimated by finding the weight of cuprous oxide precipitated as the result of the action of the digestion mixture on 50 cc. of mixed Fehling solution for 15 minutes in a boiling water-bath.

The carefully neutralized amino acids added to the starch pastes did not alter the hydrogen-ion concentration of the digestion mixtures. The favorable effect upon the activity of the enzyme was most marked in the case of purified pancreatic amylase, the amount of reducing sugar produced by this enzyme being about 15% greater in the presence of any one of the above-mentioned amino acids in a concentration of 0.05%. This enzyme was, therefore, used in the present study, in which a further explanation of the favorable effect of the amino acids was sought.

Experiments have already been reported showing that: (1) the favorable influence of the amino acids cannot be attributed to their combination with some product or products of digestion which, if left free in solution might bring the starch-enzyme reaction to equilibrium, or else react with the enzyme itself, thereby rendering it inactive; (2) the effect is not due to a more favorable hydrogen-ion concentration induced by the presence of the amino acids, since in our experiments an optimum hydrogen-ion concentration was maintained throughout; (3) glycine is markedly effective in counteracting the deleterious influence of cupric sulfate on pancreatic amylase, thus suggesting that the amino acid may act by protecting the enzyme from some unknown injurious substance which may be present accidentally or as a constituent of the substrate or enzyme material; (4) positive evidence has been found that the favorable influence of amino

¹ Sherman and Walker, This Journal, 41, 1867 (1919).

² Sherman and Walker, ibid., 43, 2461 (1921).

acids is due at least in part to the fact that they prevent or retard the deterioration of the amylase in its aqueous solution.

In studying this last point, three methods of investigation have been used: (1) the resulting losses in activity of equal portions of the same enzyme solution were compared after these portions had stood in absence of substrate for a definite length of time at known temperatures, alanine having been added to some portions while others contained no amino acid; (2) the effect of temperature upon "activation" due to amino acids was determined; (3) a similar series of experiments was carried out in which the enzyme was allowed to act at these different temperatures for a longer time.

Protection of Pancreatic Amylase from Hydrolytic Destruction in Absence of Substrate

The enzyme was dissolved in (1) water alone, (2) water and alanine, 0.1%, (3) water with optimum concentrations of sodium chloride and disodium phosphate, (4) water with the same salts plus alanine. Such solutions were allowed to stand for 1 hour, in one series at 22° and in another at 40° , and their enzymic activities then determined, the results being expressed in terms of the weight of cuprous oxide obtained. In the determinations of enzymic activity, alanine was added to those solutions which had not previously contained it so as to have the same concentration of alanine present in all cases during the action of the enzyme upon the starch and the treatment of the resulting solution with the Fehling reagent.

The results are shown in Table I.

Table I $\begin{tabular}{ll} \textbf{Effect of Alanine in Retarding Deterioration of Pancreatic Amylase in Solution at 22° and 40° \\ \end{tabular}$

			Cuprous oxide			
Alanine 0.1%	NaCl Optimum conc.	Na ₂ HPO ₄ Optimum cone,	At 22° Mg.	At 40° Mg.		
absent	present	present	274	144		
present	present	present	275	198		
present	absent	absent	133			
absent	absent	absent	98			

These experiments give direct evidence that the amino acid does retard the hydrolytic destruction of the amylase. Solutions of pancreatic amylase (containing optimum concentrations of sodium chloride and phosphate) which have stood 1 hour at 40° show about 1/3 greater amylolytic activity when alanine has been added to the solution in advance. Under similar conditions except that the solution is kept at 22° instead of 40° there is no measurable difference, probably because the deterioration at this temperature and for this short time in the presence of optimum concentrations of salts is so small in either case that the effect of the amino acid is not demonstrable. Even at this lower temperature, however,

the deterioration of the enzyme in the absence of the salts was very marked and this deterioration was much retarded by the presence of the amino acid.

Effect of Variation of Temperature of Digestion

If protection against hydrolytic destruction explains the increased activity of enzymes in the presence of amino acids, it is logical to expect that conditions favoring the hydrolysis of the enzyme molecule, such as a higher temperature or subjection to a given temperature for a longer period, would increase the difference resulting from the presence of the amino acid. To test this point, a series of experiments was planned in which 30-minute and 60-minute digestions by pancreatic amylase with and without amino acid were carried out at temperatures ranging from 30° to 75°.

Table II shows the results obtained with glycine at different temperatures when 0.6 cc. of 0.01% enzyme solution acted upon 100 cc. of substrate

for 30 minutes and when $^{1}/_{2}$ the amount acted upon the same amount of substrate for 60 minutes. The experiments were repeated with phenylalanine replacing glycine, the results of which are given in Table III. The purified pancreatic amylase preparation employed in the phenylalanine experiments was about a year older than that used with glycine and only $^{2}/_{3}$ as active; consequently, $^{1}/_{3}$ more of the solution was added to each digestion mixture.

The results of the above experiments afford striking evidence that deterioration of the enzyme with increase in temperature is retarded by amino acids. For the 30-minute digestions, beginning with an increase at 30° of 19 mg. of cuprous oxide or 14%, the favorable influence of glycine reaches a maximum of 197 mg. of cuprous oxide or over 100% at 60° . Above this temperature the effect as represented by increase in milligrams of cuprous oxide declines sharply, although the percentage of apparent activation continues to increase up to 66.5° . The rapid falling off in activity above 60° is doubtless due to coagulation of the amylase which is not prevented by the amino acid.

The experiments with phenylalanine show the same general effect, though not in quite so marked degree as in the case of glycine, perhaps because of the lower molar concentration in which it was used. It will be observed from the tables that the 2 amylase preparations in absence of either amino acid behave somewhat differently, the less active one, employed in connection with phenylalanine, being destroyed more rapidly with increasing temperature. Glycine added to a substrate hydrolyzed by this enzyme at 60° gave practically the same result as obtained with phenylalanine. Hence the lack of perfect agreement in the temperature at which the optimum effect was found is probably due not to dissimilarity in the action of the two amino acids but rather to some difference in the amylase solutions connected with the deterioration which had already occurred in the less active preparation.

The most evident explanation of the marked temperature effect above shown is that the amino acids preserve the enzyme in solution from the destructive influence of hot water. Thus increase in temperature exerts two opposite influences upon amylolytic action. It accelerates the velocity of hydrolysis of starch into sugar by the amylase and at the same time increases the rate of deterioration (presumably hydrolytic destruction) of the enzyme. The second reaction being retarded by the presence of one of its products (amino acids), the first effect, that is increase in the rate of hydrolysis of the starch, becomes more noticeable.

When hydrolysis was continued for 60 minutes the amino acids produced a greater apparent activation at all temperatures (up to that at which coagulation of the enzyme occurred) than was observed in similar experiments of 30 minutes' duration. Digestions carried out at 40° for periods

of time from 20 minutes to 3 hours with and without glycine and tyrosine show the same increase in apparent activation with length of time of action of the amylase. This is what would be expected if the amino acid exerts its favorable influence by protecting against deterioration, since the longer the enzyme is subjected to an injurious temperature, the greater the deterioration and consequently the more apparent becomes the favorable effect of the conserving influence of the amino acid.

Summary and Conclusions

- 1. Highly purified preparations of pancreatic amylase, which deteriorate more rapidly in aqueous solution than the other amylases studied in this Laboratory, are also more affected by the presence of amino acids than are the other enzymes.
- 2. Solutions of pancreatic amylase (containing optimum concentrations of chloride and phosphate) which have stood 1 hour at 40° show considerably greater activity when alanine has been added to the solution in advance. Amylase solutions to which the chloride and phosphate have not been added deteriorate more rapidly; and with these the protective effect of the amino acid can be demonstrated at lower temperatures.
- 3. There is a striking increase in apparent activation by glycine and phenylalanine with increased temperature of digestion until coagulation of the enzyme occurs.
- 4. At the same temperatures there is greater apparent activation when hydrolysis is allowed to proceed for 1 hour than when the action is stopped at the end of 30 minutes.
- 5. All these facts point to the conclusion that the favorable influence of amino acids on the enzymic hydrolysis of starch is due, in large part at least and in all probability mainly, to a protection of the enzyme from deterioration in the aqueous dispersion in which it acts. This deterioration is probably due to gradual hydrolytic destruction.
- 6. That the presence of amino acids retards the hydrolytic destruction of the enzyme constitutes, as we have previously pointed out, an interesting addition to the evidence supporting the view that the enzyme itself is a substance of protein nature or one which contains protein as an essential constituent.

We are greatly indebted to the Carnegie Institution of Washington for grants in aid of the investigation.

THE SPONTANEOUS DISSOCIATION OF TRIPHENYLMETHYL DISULFIDE WITH THE FORMATION OF TRIPHENYL-METHYL. THE POTASSIUM DERIVATIVE OF TRIPHENYL CARBINOL AND ITS USE AS A SYNTHETIC AGENT

By F. F. BLICKE

Received May 25, 1923

n-Pentamethylene-S-triarylmethyl-dithio-urethans dissociate spontaneously, in solution, with the formation of triarylmethyls; the latter were isolated in the form of their characteristic peroxides.¹

It has now been found that triphenylmethyl disulfide also dissociates spontaneously, in solution, at ordinary temperature with the formation of triphenylmethyl; thus, when the colorless disulfide is dissolved in benzene the solution, colorless at first, soon assumes the deep yellow color which is characteristic for solutions of this radical. When air is passed into the solution, triphenylmethyl peroxide is precipitated. The rational explanation for the above phenomena is expressed as follows:²

$$\begin{array}{c} 2 \; (C_6H_5)_3C - S - S - C(C_6H_5)_3 \Longrightarrow 2 \; (C_6H_5)_3C - + \; 2 \; - S - S - C(C_6H_5)_3 \\ \downarrow \quad \text{oxygen} \\ (C_6H_5)_3C - O - O - C(C_6H_6)_3 \end{array}$$

A comparison of triphenylmethyl disulfide with triphenylmethyl peroxide, as regards dissociation, is interesting. Wieland³ has shown that triphenylmethyl peroxide dissociates very readily when a xylene solution of the material is heated to the boiling point. The dissociation, in this instance, occurs not between the triphenylmethyl group and oxygen but through the severance of the bond between oxygen and oxygen.

It now seemed desirable to prepare the hitherto unknown thioperoxide, $(C_6H_5)_3C$ —S—O— $C(C_6H_5)_3$, and study its behavior with regard to dissociation. It was thought that this substance might readily be prepared by reaction between triphenylmethyl sulfurchloride⁴ and a metallic derivative of triphenyl carbinol. $(C_6H_5)_3C$ —S—Cl + M—O— $C(C_6H_5)_3$ = $(C_6H_5)_3$ -C—S—O— $C(C_6H_5)_3$ + MCl.

Schlenk and Mair⁵ have reported that the sodium derivative of triphenyl-carbinol may be obtained by the action of metallic sodium upon a large excess of the molten carbinol at 185°. This method, however, is unsatisfactory since it is very difficult to free the hygroscopic sodium compound from the large amount of unchanged carbinol.

- ¹ Blicke, This Journal, 45, 544 (1923).
- ² Judging from the yield of peroxide it seems that only one of the triphenylmethyl groups of the disulfide is obtained in the form of triphenylmethyl.
 - ³ Wieland, Ber., 44, 2550 (1911).
 - 4 Vorländer and Mittag, ibid., 52, 415 (1919).
 - ⁵ Schlenk and Mair, ibid., 44, 1076 (1910).

It was found that metallic potassium reacts readily with triphenyl carbinol when the latter is dissolved in boiling xylene. The potassium derivative which is formed is soluble in hot xylene but quite insoluble in the cold solvent and therefore crystallizes out of the latter quite pure. $2(C_6H_5)_3C - OH + 2K = 2(C_6H_5)_3C - OK + H_2.$

Before undertaking a study of the reaction of the metallic compound with triphenylmethyl sulfurchloride it seemed desirable to study the reactions between the former substance and somewhat simpler compounds. Accordingly, the preparation of various triarylmethyl ethers and esters was attempted by treatment of the potassium compound with alkyl halides and acid chlorides, respectively. The potassium compound reacts readily with methyl iodide, and triphenylmethyl-methyl ether is formed in good yield: $(C_6H_5)_3C-OK+CH_3I=(C_6H_5)_3C-O-CH_3+KI$. By the use of ethyl instead of methyl iodide little or none of the corresponding ethyl ether is formed, providing the reaction is carried out under the same conditions. In this instance, ethylene and triphenyl carbinol represent the reaction products: $(C_6H_5)_3C-OK+C_2H_5I=(C_6H_5)_3C-OH+C_2H_4+KI$.

Benzoyl chloride reacts immediately with the metallic carbinol derivative with the formation of triphenylmethyl benzoate.

When an equivalent amount of triphenylmethyl sulfurchloride, dissolved in benzene, was added to the potassium compound, heat was developed and a red-brown solution resulted. The only crystalline, organic products that could be isolated from the reaction mixture were triphenyl carbinol and triphenylmethyl peroxide. Since a considerable amount of potassium chloride was formed, it seems that triphenylmethyl thioperoxide must have been produced initially; the peroxide may have resulted from the interaction of the thioperoxide and unchanged potassium compound: $2(C_6H_5)_3C-S-O-C(C_6H_5)_3+4(C_6H_5)_3C-OK=3(C_6H_5)_3C-O-O-C (C_6H_5)_3 + (C_6H_5)_3C - C(C_6H_5)_3 + 2K_2S$. This explanation of the formation of the peroxide receives support through the fact that triphenylmethyl sulfurchloride reacts with sodium methylate with the formation of triphenylmethyl-methyl thioperoxide;6 when an excess of the alcoholate was used there resulted only a sulfur-free compound which the above-mentioned investigators suspected was triphenylmethyl peroxide. We have repeated this work and found that the sulfur-free substance was unquestionably peroxide. When the potassium compound of triphenyl carbinol was added to the triphenylmethyl sulfurchloride, in the attempt to avoid an excess of the former substance at any time during the reaction, peroxide was again obtained.

The potassium compound reacts with triphenylchloromethane and it was thought that the resulting product might be triphenylmethyl ether, formed in accordance with the equation, $(C_6H_5)_3C-OK+Cl-C(C_6H_5)_3=$

⁵ Ref. 4, p. 416.

 $(C_6H_5)_3C$ —O— $C(C_6H_5)_3$ + KCl. However, in the examination of the reaction product no ether was found. From the mixture of products formed p-hydroxytriphenyl carbinol was isolated; the latter was probably present in the reaction mixture in the form of its anhydride, diphenyl-quinomethane. It is interesting to compare this result with that obtained by Gomberg⁷ when he attempted to prepare triphenylmethyl ether by the action of silver oxide upon triphenylchloromethane in benzene solution. In this case, also, the desired ether was not obtained and diphenyl-quinomethane was isolated as a product of the reaction. If it is assumed that Gomberg obtained $(C_6H_5)_3C$ —O—Ag as the initial product in his experiment, the two reactions then become comparable.

In addition, it was found that the potassium compound of triphenyl carbinol reacts at once with iodine, phosphorus trichloride and other substances which contain reactive halogen.

Experimental Part

Triphenylmethyl Disulfide.—This compound was readily prepared from triphenyl thiocarbinol according to the method of Vorländer and Mittag;8 the formation of the thiocarbinol, however, does not proceed smoothly. The investigators mentioned were the first to prepare triphenyl thiocarbinol; their method consists in treating triphenylchloromethane with sodium hydrogen sulfide, using ethyl alcohol as a solvent. Unfortunately, the method is not an entirely reliable one and occasionally fails to yield the desired product;9 this is due to the fact that triphenylchloromethane reacts with the ethyl alcohol, used as a solvent, with the greatest ease to form triphenylmethyl ethyl ether. We have been able to prepare the thiocarbinol by the action of potassium hydrogen sulfide on triphenylchloromethane, using benzene as a solvent. The potassium hydrogen sulfide, 10 prepared from 6 g. of potassium, was added to 14 g. of triphenylchloromethane, dissolved in 80 cc. of dry benzene. After the mixture had been shaken for 1 week the reaction mixture was filtered and the solvent allowed to evaporate. The slightly gummy product thus obtained was converted directly into triphenylmethyl sulfurchloride and then into the disulfide. The yield of the sulfurchloride compound, based on triphenylchloromethane, never exceeded 50% of that calculated.

Dissociation of the Disulfide.—A solution of 2.7 g. of the disulfide in 15 cc. of dry benzene immediately became deep yellow, the color of dissolved triphenylmethyl. A fairly rapid stream of dry air was passed through this solution and the escaping air was led into aqueous potassium hydroxide. The benzene solution soon became cloudy and after 1 hour quite a heavy precipitate had formed. After 8 hours the precipitated material was separated, washed with hot carbon disulfide and quickly recrystallized from toluene. The compound thus obtained melted at 185°; mixed with triphenylmethyl peroxide, prepared from triphenylchloromethane and molecular silver, the melting point of the mixture was found to be 185–186°. The yield of peroxide was 0.82 g. The alkaline solution was found to contain potassium sulfite, thus showing that sulfur dioxide had also been formed during the reaction.

In another experiment, 2.25 g. of the disulfide, dissolved in 10 cc. of benzene, was used. After air had been passed through the solution for 1 hour no peroxide appeared

¹⁰ Bloxam, J. Chem. Soc., 77, 758 (1900).

but the latter soon settled out of the solution when the sides of the containing flask were rubbed with a stirring rod; yield of peroxide, after 12 hours, 0.70 g.

Potassium Derivative of Triphenyl Carbinol.—A mixture of 11.5 g. of pure, dry triphenyl carbinol and 100 cc. of xylene, which had previously been refluxed over metallic sodium and then distilled, was put into a 500cc. round-bottom, 3-neck flask. The latter was fitted with a reflux condenser, which was closed with a soda-lime tube, and an inlet tube. After the air in the flask had been displaced by dry nitrogen 1.5 g. of potassium was added; the mixture was then refluxed, enough heat being applied to keep the xylene boiling fairly vigorously. A continuous stream of nitrogen was passed through the flask. After 3 to 4 hours the potassium had practically all disappeared. As the clear, hot solution cooled, the potassium compound precipitated at once in the form of colorless, transparent crystals. After 12 hours the supernatant liquid was decanted and the crystalline material removed from the flask. During the latter operation the material was protected from atmospheric moisture by a stream of nitrogen; yield of crystals, about 10 g.

When the transparent crystals were heated to 220°, under 20 mm. pressure, an amount of xylene was evolved that corresponded to about 21% of the weight of the original material; calcd. loss for 1 molecular equivalent of xylene, 25%. The material, which did not melt during this process, was converted into an opaque, granular substance. For the purposes of synthesis it is not necessary to free the potassium compound from xylene.

When exposed to the air the crystalline product is quickly converted into a powder. Contact with moisture changes the material to triphenyl carbinol and potassium hydroxide; a weighed portion of the xylene-free compound was thrown into water, the resulting potassium hydroxide estimated and was found to be 93.4% of the calculated amount. The low result is due to the fact that a small amount of carbinol, which was used in slight excess in the preparation of the compound, always settles out of the xylene.

Reaction with Methyl Iodide.—A mixture of 10 g. of the potassium compound (the material containing xylene of crystallization was used in this and in all subsequent experiments), 12 g. of pure methyl iodide and 30 cc. of dry benzene was gently refluxed for 2 hours, then poured into an evaporating dish and, after the solvent had evaporated, the crystalline residue was washed with water until free from potassium iodide. The dried material was boiled with 50 cc. of petroleum ether (80–100°) and then filtered. The first crop of crystals which appeared upon cooling proved to be carbinol, later the methyl-triphenylmethyl ether crystallized in pure condition. The substance melts at 83–4° as given in the literature. Yield 6 g., or 82% of the calculated amount.

Reaction with Ethyl Iodide.—Ten g. of the potassium compound, 12 g. of ethyl iodide and 30 cc. benzene were refluxed for 2 hours in a 100cc. flask. The gas evolved during the reaction amounting to 480 cc. (N. T. P.) was collected over water, backward diffusion of moisture into the reaction flask being prevented by a calcium chloride tube, and proved to be ethylene by converting it into ethylene bromide and identification of the latter by its melting and boiling points. The amount of ethylene found corresponds to 78% of that calculated. 7.0 g. of triphenyl carbinol was obtained; calc., 6.9.

Reaction with Benzoyl Chloride.—A mixture of 8 g. of the potassium compound, 3.8 g. of carefully purified benzoyl chloride and 30 cc. of benzene reacted immediately with considerable evolution of heat, moisture having been carefully excluded. After

A trace of unchanged potassium often remains mixed with the potassium compound. It is advisable, therefore, to treat the reaction mixture as described above; during the evaporation of the solvent the atmospheric moisture reacts with the potassium and the solid residue may then safely be treated with water.

¹² Hemilian, Ber., 7, 1208 (1874). Straus and Hüssy, ibid., 42, 2176 (1909).

24 hours the reaction mixture was poured into an evaporating dish, the solvent was removed and the organic matter was extracted with hot benzene. The benzene solution was concentrated under reduced pressure; triphenylmethyl benzoate separated from the cold, coned. solution in good yield. The compound was further purified by recrystallization from a mixture of chloroform and petroleum ether. The ester melts at 165–166°.

For the purpose of comparison the ester was prepared by another method: $4 \, \mathrm{g}$, of triphenylchloromethane, $6.5 \, \mathrm{g}$. of silver benzoate and $50 \, \mathrm{cc}$. of benzene were heated to $60 \, \mathrm{°}$, for 4 hours, in a bath. After the benzene had been removed from the reaction mixture by evaporation, the organic material was recrystallized twice from benzene. The ester, prepared by this method, melted at $165-166 \, \mathrm{°}$.

One g. of the ester was hydrolyzed quantitatively by boiling for 1 hour with 30 cc. of water containing a few drops of sulfuric acid.

Reaction with Triphenylmethyl Sulfurchloride.—A mixture of 8 g. of the potassium compound, suspended in 30 cc. of benzene, with an equivalent amount of triphenylmethyl sulfurchloride dissolved in the same solvent, became warm, and after standing for 24 hours protected from moisture the clear, red-brown solution was poured into an evaporating dish. The presence of a gelatinous, transparent precipitate, presumably colloidal potassium chloride, which was obtained in all of the reactions, made filtration of the reaction mixture impossible. After spontaneous evaporation of the benzene the residue was treated with dry ether; from the latter triphenyl carbinol was obtained. The etherinsoluble residue was washed with water to remove potassium chloride, dried, and then dissolved in a small amount of boiling toluene. As the solution cooled, triphenylmethyl peroxide was obtained.

Reaction with Triphenylchloromethane.—Equivalent amounts of triphenylchloromethane and the potassium derivative of the carbinol, suspended in benzene, were shaken in a sealed tube. After 4 hours the mixture was deep red and after 4 days the contents of the tube consisted of a heavy gelatinous precipitate and an orange-colored liquid. Absolute ether was added and the mixture was filtered; the filtrate was then heated under diminished pressure until the solvent was removed. The residue, which consisted of crystals and an orange-colored oil, was dissolved in acetone and, after the addition of 5% sodium hydroxide solution, was heated on a steam-bath until all of the acetone had evaporated. After filtration from alkali-insoluble material the filtrate was concentrated to a small volume; flaky crystals, possessing a pearly luster, were formed as the solution stood. This material was the sodium salt of p-hydroxytriphenyl carbinol. It was converted into both the colorless benzenoid and the yellow quinonoid forms of the hydroxycarbinol. When the yellow form of the carbinol was heated at 110° for several hours the brown-yellow fuchsone resulted; after several recrystallizations from benzene and petroleum ether this melted at $166-167^{\circ}$.

Summary

- 1. Triphenylmethyl disulfide dissociates spontaneously, in solution, at ordinary temperature with the formation of triphenylmethyl; the latter was isolated in the form of its peroxide.
- 2. The potassium derivative of triphenyl carbinol was prepared. It reacts with alkyl halides to form ethers and with acid chlorides to form esters. In some instances, however, the potassium compound reacts abnormally.

HYDROXYNAPHTHOQUINONE STUDIES. VI. THE CHLORINATION OF JUGLONE

By Alvin S. Wheeler, P. R. Dawson and Joseph L. McFwen Received June 7, 1923

The first work on the chlorination of juglone was done by Wheeler and Scott¹. They reported that the chlorination of juglone in cold glacial acetic acid solution gave juglone dichloride, an addition product, which lost hydrochloric acid by the action of hot alcohol, giving a monochloro substitution product. On the other hand the chlorination of juglone in

Chlorination of Juglone

hot acetic acid solution gave a dichlorojuglone which is a substitution product. The latter reaction was further studied by Wheeler and Dawson and several derivatives were made but the results were not published on account of incompleteness. They are now incorporated in this paper.

¹ Wheeler and Scott, This Journal, 41, 833 (1919).

They consisted briefly in the benzoylation of dichlorojuglone; the preparation of the sodium salt which was found to dye silk and wool fabrics certain buff shades readily; the alkylation of dichlorojuglone in which 1 chlorine atom was replaced by the aniline radical and finally the replacement of 1 chlorine atom by the hydroxyl group under the influence of hot alcoholic sodium hydroxide and the acetylation of this product. The work just carried out includes the alkylation of dichlorojuglone with p-chloro-aniline and p-toluidine; the reduction of dichlorojuglone with zinc and sulfuric acid and acetylation of this product; the reaction of sodium ethylate and attempts to prepare an oxime.

The chlorination of juglone was studied under various conditions. No chlorination was found to take place in carbon tetrachloride solution but it proceeded smoothly in glacial acetic acid. Scott passed chlorine in for 3 hours; Dawson reduced the time somewhat but McEwen finds 2 hours to be best.

In one preparation a very unexpected result was obtained, the whole product being a green amorphous substance. A compound of similar appearance and properties was obtained by Mylius² by boiling juglone with water. To determine whether the chlorine was concerned in the reaction we dissolved the juglone in hot acetic acid and set the solution aside overnight. The same amorphous green product was obtained. It was insoluble in the usual organic solvents, did not melt at 310° and dissolved in alkalies giving a deep violet solution. The formula of Mylius, $C_{20}H_{10}O_{7}$, suggests that oxidation of juglone has occurred with the condensation of two molecules to produce a peroxide:

The chlorine atoms in dichlorojuglone according to our belief are located at Positions 2 and 3. Whether we accept the Thiele Partial Valence theory, the Bamberger theory³ or the Willstätter formula⁴ for the constitution of naphthalene, the Positions 2 and 3 in juglone are reactive ones and substitution should readily take place there. For a time we thought that 1 chlorine atom might enter Position 8, since this is a phenol ring and the hydrogen at Position 8, para to the hydroxyl, would be reactive. However, our experiments show that 1 chlorine atom is more reactive than the other, being driven out of the molecule not only by strong bases such as sodium hydroxide but also by weak bases such as aniline and p-chloroaniline. In this connection it is interesting to note that as soon as 2 chlorine atoms are present in the aniline molecule, its basicity is so far

² Mylius, Ber., 18, 463 (1885).

³ Bamberger, Ann., 257, 49 (1890) and following papers.

⁴ Willstätter, Ber., 44, 3430 (1911).

reduced that it has no effect upon the dichlorojuglone molecule. If the 2 chlorine atoms are at Positions 2 and 3 we observe that the quinone ring is surcharged with negativity, having all 4 Positions occupied by oxygen or chlorine. It is very easy to believe that in such an environment 1 chlorine atom may be easily displaced.

In view of the fact that juglone readily takes up 3 bromine atoms, it is very peculiar that under the same conditions only 2 chlorine atoms enter the molecule, and a special attempt failed to introduce a third.

Attention is called to the color phenomena shown by the hydroxychlorojuglone. This compound dissolves in water, giving a deep red solution but if even a slight amount of acid is added, the solution becomes yellow. On neutralization of the acid, the red color reappears.

Experimental Part

The Chlorination of Juglone.—In order to arrive at the best conditions for the chlorination of juglone, carbon tetrachloride and glacial acetic acid were compared as media. There seemed to be little or no action in carbon tetrachloride solution but chlorination in acetic acid proceeded very smoothly. The time of passing in the chlorine and the subsequent heating were varied and the following procedure was finally adopted as best.

Two g. of juglone was dissolved in 20 cc. of glacial acetic acid and placed in a test-tube immersed in hot water. Chlorine, prepared by the action of hydrochloric acid on potassium permanganate and purified by passing through water, sulfuric acid and phosphorus pentoxide, was passed into the solution slowly for $1^3/_4$ hours and then rapidly for 20 minutes. As the solution cooled a mass of orange-red needles separated, the first crop weighed 1.82 g., a pure product; m. p., 149° . The second crop, obtained by concentrating the mother liquor, weighed 0.56 g.; m. p., 138° .

Owing to the easy formation of tribromojuglone, some attempts were made to introduce a third chlorine atom. Chlorine was passed into the hot solution more rapidly and for a longer time. The product consisted of less well defined crystals that were more compact, redder in color and more soluble in acetic acid and other solvents. The melting point was considerably lower, 110–116°, and was very slowly raised by repeated recrystallizations. The determination for chlorine gave a surprising result, the percentage being only slightly above that for dichlorojuglone. This reaction will be re-examined.

Sodium Salt of Dichlorojuglone. 5 —A solution of 1.4 g. of dichlorojuglone in 300 cc. of ether was shaken with 30 cc. of a 10% solution of sodium carbonate for 30 minutes. After the mixture had stood for some time the ether layer was removed and the dark colored precipitate in the water layer was filtered off. The sodium carbonate was washed out with small portions of cold water. The dry salt has an indigo-blue color and is somewhat soluble in alcohol. The aqueous solution has a deep violet color. Acidification liberates dichlorojuglone.

⁵ Work of P. R. Dawson.

Analysis. Subs., 0.3394: Na₂SO₄, 0.0841. Calc. for C₁₀H₅O₅Cl₂Na: Na, 8.68. Found: 8.01.

The preparation of the salt by adding sodium hydroxide to an alcoholic solution and precipitating with sodium chloride was less satisfactory owing to the difficulty of getting rid of the sodium chloride.

The sodium salt may be used for dying silk and wool shades of buff and brown. When, for example, silk is heated in such a solution the deep violet color soon turns to yellowish brown and the silk is dyed an attractive buff shade, fairly fast to light.

2,3-Dichloro-5-benzoxy-1,4-naphthoquinone,⁵ C₁₀H₅O₂.Cl₂.OCOC₆H₅.—A solution of 0.5 g. of dichlorojuglone in 5 cc. of benzoyl chloride was heated to boiling for 3 hours. The color changed from red to brown. Evaporation of the liquid gave a product weighing 0.64 g. which after several recrystallizations from benzene melted at 225°. It forms light yellow needles, slightly soluble in alcohol, acetone and moderately soluble in benzene.

Analysis. Subs., 0.1588: AgCl, 0.1320. Calc. for C_1 : $H_5O_4Cl_2$ (347): Cl, 20.46. Found: 20.53.

2,5-Dihydroxy-3-chloro-1,4-naphthoquinone, ⁵C₁₀H₃O₂(OH)₂Cl.—A mixture of 2.0 g. of dichlorojuglone, dissolved in 160 cc. of warm alcohol, and 80 cc. of 10% sodium hydroxide was boiled for 1 hour. The deep violet solution soon changed to dark red and a small amount of precipitate appeared. The mixture was poured into 200 cc. of cold water, and the precipitate dissolved. Upon acidification with hydrochloric acid an abundant separation of very fine yellow needles took place. This product weighed 1.45 g.; m. p., 188–189°. A second crop weighed 0.22 g.; m. p., 181–183°. The substance is extremely soluble in alcohol, slightly so in ligroin and fairly soluble in water, giving a deep red solution. The pure substance, m. p., 191°, is obtained by recrystallizing several times from dil. alcohol. The crystals are needles which are red when wet and golden-brown when dry.

Analysis. Subs., 0.1661: AgCl, 0.1062. Calc. for $C_{10}H_{6}O_{4}Cl$ (224.5): Cl, 15.81. Found: 15.83.

As stated above, the neutral solution in water is deep red. Addition of a slight amount of acid changes it instantly to yellow and neutralization restores the red color. Crystals obtained from the 2 solutions are identical in form and melting point.

2,5-Diacetoxy-3-chloro-1,4-naphthoquinone, 5 C₁₀H₃O₂Cl(OCOCH₃)₂.—A solution of 0.5 g. of the hydroxy derivative in 8 cc. of acetic anhydride was gently boiled for 8 hours. The color gradually changed from dark red to yellow-brown. The product, precipitated by the addition of cold water, weighed 0.62 g. and melted at 142–143°. On recrystallization twice from alcohol the pure substance is obtained in beautiful, fine yellow needles, melting sharply at 147°.

Analyses. Subs., 0.2509, 0.1908: AgCl, 0.1187, 0.0895. Calc. for $C_{14}H_9O_6Cl$ (308.5): Cl, 11.51. Found: 11.72, 11.64.

2-Anilino-3-chloro-5-hydroxy-1,4-naphthoquinone,⁶ C₁₀H₃O₂.NHC₆H₅.Cl.OH.— A solution of 1 g. of dichlorojuglone in 75 cc. of alcohol was added 0.4 g. of aniline (slightly in excess of 1 molecular equivalent). The reaction began at once, and the solution became deep violet-red. The mixture was boiled for 15 minutes and then cooled. Very small, short, flat needles separated in abundance. Viewed in the mass they have a violet-carmine color with a metallic luster. Under the microscope they appear to resemble chips of pine bark because of their color and the jagged ends. The first crop weighed 0.9 g., m. p., 218–221°. A second crop weighed 0.22 g. Recrystallization from

Work of Dawson and McEwen.

acetone raised the melting point to 222°. The substance is fairly soluble in alcohol, very soluble in benzene and best purified from acetone.

Analysis. Subs., 0.1524: AgCl, 0.0726. Cale. for $C_{16}H_{10}O_3NCI$ (296.6): Cl, 11.83. Found: 11.88.

An attempt was made to carry out the reaction with 2,4-dichloro-aniline but even after it had been heated all day the dichlorojuglone was recovered unchanged. *p*-Monochloro-aniline reacted easily, as described below.

2-p-Chloro-anilino-3-chloro-5-hydroxy-1,4-naphthoquinone, 7 $C_{10}H_3O_2$.NHC $_6H_4$ Cl.-Cl.OH.—To a solution of 1 g. of dichlorojuglone in 75 cc. of hot alcohol, 0.53 g. of p-chloro-aniline was added, and the mixture was boiled for 30 minutes, the color turning to a dark brownish-red. As the solution cooled 0.8 g. of the product crystallized out. It consisted of dark reddish-purple, flat needles with jagged ends, that melted at 237°. The pure substance, obtained by recrystallization from acetone, melted at 243°. The substance is easily soluble in benzene, and moderately soluble in alcohol or ether.

Analysis. Subs., 0.1765: AgCl, 0.1530. Cale. for $C_{16}H_9O_3NCl_2$ (334): Cl, 21.33. Found: 21.45.

2-p-Toluino-3-chloro-5-hydroxy-1,4-naphthoquinone, 7 C₁₀H₃O₂.NHC₆H₄CH₃.Cl.OH. —An alcoholic solution of 1 g. of dichlorojuglone and 0.44 g. of p-toluidine was boiled for several minutes. Crystals began to appear before boiling commenced. The first crop of crystals weighed 0.8 g. These were dark, reddish-purple, flat needles with jagged ends and a brilliant luster. Recrystallization from acetone gave a pure product melting at 234° .

Analysis. Subs., 0.1560: AgCl, 0.0723. Calc. for $C_{17}H_{12}O_2NCl$ (313.6): Cl, 11.31. Found: 11.46.

1,4,5-Trihydroxy-2,3-dichloronaphthalene, $^7C_{10}H_3(OH)_3Cl_2$.—To a suspension of 2 g. of dichlorojuglone in 50 cc. of ether were added some sulfuric acid (1:5) and zinc dust in small portions at short intervals, while the mixture was well shaken. As the dichlorojuglone was reduced it was taken up by the ether which became faintly yellow. The ether was separated, washed well with water and allowed to evaporate at room temperature. The residue was a mass of gray crystals with a metallic luster, resembling aluminum powder. The product weighed 2.0 g. and melted at 154–156° with decomposition. It was purified by dissolving it in alcohol and adding water until crystallization began. The pure product consisted of very small short prisms, gray in the mass with a brilliant metallic luster, and melting at 157° with decomposition. There is danger of decomposing the compound in the purifying process. We lost two small lots which became nearly black. It is readily soluble in acetone and in ether, difficultly soluble in hot benzene and insoluble in ligroin.

Analysis. Subs., 0.1771: AgCl, 0.2085. Calc. for $C_{10}H_6O_3Cl_2$ (245): Cl, 28.98. Found: 29.12.

1,4,5-Triacetoxy-2,3-dichloronaphthalene, 7 $C_{10}H_3(OCOCH_3)_3Cl_2$.—A solution of 1 g. of the reduction product in 15 cc. of acetic anhydride was boiled for 12 hours, soon turning yellow. Evaporation of the liquid gave a product melting at 165–170°. After recrystallization from alcohol it melted at 182° and consisted of well developed, transparent needles that were light yellow when viewed in the mass. The substance is easily soluble in acetone, fairly soluble in benzene and alcohol and nearly insoluble in ether.

Analysis. Subs., 0.1535: AgCl, 0.1196. Calc. for C₁₆H₁₂O₆Cl₂(372): Cl, 19.06. Found: 19.27.

Reaction with Sodium Ethylate. From an equivalent molecular mixture of di-

⁷ Work of McEwen.

chlorojuglone and freshly made sodium ethylate a dark purple precipitate formed immediately (in benzene solution). When this was dissolved in water and acidified with hydrochloric acid, the solution turned yellow and a yellow precipitate formed. This proved to be the hydroxychlorojuglone, m. p., 191°, described above. It showed the same color phenomena. We had hoped to find also an ethoxy derivative of dichlorojuglone.

Attempt to Prepare an Oxime.—One g. of dichlorojuglone was dissolved in 20 cc. of alcohol containing 0.3 g. of hydroxylamine hydrochloride (1 molecular equivalent), and 2 drops of strong hydrochloric acid. After the solution had boiled for 2 hours and then cooled, a product was obtained, but it contained no nitrogen and proved to be unchanged dichlorojuglone. The experiment was tried with 2 molecular equivalents of the hydroxylamine salt and boiling was continued for 8 hours, but with no better success.

Summary

- 1. The best method of chlorinating juglone is described.
- 2. A description of the sodium salt and the benzoate of dichlorojuglone is given.
- 3. One chlorine atom of dichlorojuglone is replaced by hydroxyl by the action of alcoholic sodium hydroxide. This hydroxyl derivative and its acetate are described.
- 4. Dichlorojuglone was arylated by weak bases such as aniline, p-chloro-aniline and p-toluidine but not by dichloro-aniline. In each case 1 chlorine atom is replaced.
- 5. Dichlorojuglone was reduced in acid solution with zinc, giving a trihydroxynaphthalene. The triacetoxy derivative was also prepared.
- 6. Sodium ethylate yields an hydroxy derivative of dichlorojuglone and not an ethoxy.
 - 7. Hydroxylamine hydrochloride does not give an oxime.
 - 8. Reasons are given for locating the chlorine atoms at Positions 2 and 3. Chapel Hill, North Carolina

THE MECHANISM UNDERLYING THE REACTION BETWEEN ALDEHYDES OR KETONES AND TAUTOMERIC SUBSTANCES OF THE KETO-ENOL TYPE

By E. P. Kohler and B. B. Corson Received June 9, 1923

The discovery that aldehydes and ketones can be condensed with aceto-acetic ester, cyano-acetic ester, diketones, and other substances containing active hydrogen, was a natural consequence of the use of reactions which are supposed to involve aldol condensation for the synthesis of unsaturated compounds. The reagents are not essentially different from those used in these earlier syntheses, the catalysts used to induce reaction are, for the most part, the same, and the two processes usually give the same type of unsaturated compound. Most chemists, doubtless, therefore

assume that the mechanism of the two reactions is also the same, namely, aldol condensation followed by loss of water.

Other views have, however, also been expressed. Knoevenagel, who substituted primary and secondary amines for the sodium alcoholate which had previously been used as the condensing agent, accounted for the catalytic action of the amines by the mechanism:

$$RCHO + 2R_2NH \Longrightarrow RCH = (NR_2)_2 + H_2O$$

$$RCH(NR_2)_2 + H_2C < \longrightarrow RCH = C < + 2R_2NH$$
(2)

In support of this mechanism he showed that hydrobenzamide can be used in place of benzaldehyde and ammonia, and Schiff bases in place of the corresponding aldehydes and amines. It is now known,² however, that tertiary amines can serve as catalysts in these condensations even though they are incapable of reacting with aldehydes and ketones in the manner predicated by Knoevenagel.

A mechanism of an entirely different type was first proposed by Rogerson and Thorpe³ when they found that sodium cyano-acetic ester can be condensed with aceto-acetic ester and with its monomethyl derivative, but not with dimethyl aceto-acetic ester. Since the possibility of condensation here appears to be related to the capacity for enolization, they assume that the metallic derivative is condensed with the enolic modification of the ketonic ester. $CH_3C(OH)=CHCOOC_2H_5+HC(Na)(CN)CO_2C_2H_5$ \longrightarrow H_2O + $CH_3C=CHCOOC_2H_5$

$$H_2O + CH_3C = CHCOOC_2H_5$$

$$C(Na)(CN)CO_2C_2H_5$$

Harding, Haworth and Perkin⁴ adopted this view to account for the fact that they obtained, mainly, a β,γ unsaturated ester when they condensed cyclohexanone and cyano-acetic ester in the presence of either sodium methylate or piperidine. Extending Thorpe's mechanism to ketones which at best enolize but little, and to reactions in which amines are used as condensing agents they interpret their results as follows:

Thorpe's mechanism implies that only aliphatic ketones can be condensed with cyano-acetic ester, and that β,γ unsaturated compounds are the primary products in these condensations. In its support, Haworth⁵ showed, shortly afterwards, that benzophenone failed to react at all under

- ¹ Knoevenagel, Ann., 281, 25 (1894).
- ² Hann and Lapworth, J. Chem. Soc., 85, 46 (1904).
- ³ Rogerson and Thorpe, ibid., 87, 1685 (1905).

conditions in which a variety of ketones that are capable of enolization are condensed with great ease.

The latest exposition of this mechanism is contained in a lengthy discussion by Ingold⁶ on the condensation of ketones and aldehydes with the sodium derivative of cyano-acetic ester. The point of view on which this discussion is based is given in the following passage:

"... there can be no doubt but that it is the enolic modification of the ketone which actually enters into the reaction because ketones, such as benzophenone of which no enolic modification can exist, fail to react, while others condense with a readiness apparently proportionate to their capacity for tautomeric change."

To the reasons for holding this view which had been given by others Ingold now adds the general statement that ease of condensation is apparently related to capacity for tautomeric change. He realizes that this is inconsistent with the extraordinary ease with which aldehydes—especially aromatic aldehydes which are incapable of enolization—enter into the reaction, but disposes of the difficulty by suggesting that these may react in a tautomeric form containing bivalent carbon, as, for example, C_6H_5 —C—OH.

The view that these condensations involve the enolization of aldehydes or ketones seemed to us improbable on a variety of grounds. We could find no reasons for assuming that the reactions with cyano-acetic ester are in any way different from those with other substances containing active hydrogen atoms. The formation of β, γ unsaturated compounds in certain special cases can be explained in other ways. The relative ease with which aldehydes and the various ketones enter into the reaction seems to be adequately accounted for by the known differences in the activity of these substances in addition reactions. Thus the well known measurements of Stewart⁸ and of Zelinskey⁹ show that all aldehydes combine with other substances more rapidly than does any ketone; that acetone, aceto-acetic ester and cyclic ketones, like cyclohexanone, combine more rapidly than other ketones; and that benzophenone combines more slowly than any except the most highly substituted aliphatic ketones. The relative activity of these substances in condensation and in addition reactions is, therefore, approximately the same.

Inasmuch as there are carbonyl compounds that are incapable of enolizing and yet combine fairly readily with other substances, it ought to be possible to determine definitely whether enolization is involved in these condensations or not. The two most promising substances for this purpose are the esters of mesoxalic and benzoylformic acids. The

⁶ Ingold, ibid., 119, 329 (1921).

⁷ Lapworth in a recent paper has adduced evidence that the ester obtained by Harding, Haworth and Perkin is probably an α, β -unsaturated compound.

⁸ Stewart, J. Chem. Soc., 87, 185 (1905).

⁹ Petrenko-Kritschenko, Ann., 341, 150 (1905).

condensation of mesoxalic ester and cyano-acetic ester was studied by Schmitt. In the presence of piperidine he obtained along with more complex products a substance whose structure he did not succeed in establishing, but which doubtless was the unsaturated condensation product, $(C_2H_5O_2C)_2C:C(CN)CO_2R$.

We have used methyl benzoylformate and have found that under the influence of sodium methylate, ammonia, methyl amine, aniline and piperidine, methyl cyano-acetate condenses with it in the same way and almost with the same ease that it condenses with aldehydes. The product is the unsaturated compound, II.

$$\begin{array}{cccc} C_6H_5C(OH)CO_2CH_3 & & C_6H_5CCO_2CH_3 \\ & & & & & & \\ CH(CN)CO_2CH_3 & & & C(CN)CO_2CH_3 \\ & & & & & & \\ I & & & & & \\ \end{array}$$

Using the same condensing agents but operating under different conditions it is possible to get as the principal product the saturated hydroxyl compound, I.

With these facts established there remains no reason for assuming that either the reaction between aldehydes or ketones and substances which have active hydrogen, or aldol condensation involves the enolization of aldehydes or ketones.

The addition product (I) is a stable substance. When it is perfectly pure it neither readily loses water nor reverts to its components. Thus, when it is dissolved in pure boiling methyl alcohol or acetone it causes an elevation corresponding to its molecular weight and the solutions can be boiled for hours without further change in the boiling point. When it is heated under very low pressures it partly distils, partly dissociates into its components. Efficient dehydrating agents, however, eliminate water. Thus when it is heated with phosphorus pentachloride in phosphorus oxychloride or digested with glacial acetic acid it passes smoothly into the unsaturated ester (II). Since none of this unsaturated ester is obtained when a mixture of equivalent quantities of the two components is treated in the same way, it must here be formed by loss of water from the hydroxy ester.

The addition product is exceedingly sensitive to bases, disappearing more or less rapidly in the presence of any of the condensing agents used in its synthesis. Thus, when it is added to boiling methyl alcohol or acetone containing relatively very small quantities of any of these bases the boiling point steadily rises and when it finally becomes constant, the elevation corresponds to a molecular weight that is much too small. The solution now contains dimethyl malonate, and methyl benzoylformate as well as addition product; no unsaturated compound could be isolated from it. When solutions of the addition product, containing a larger quantity of these

¹⁰ Schmitt, Ann. chim., [8] 12, 408 (1907).

bases are boiled or, better, when the solid addition product is suspended in a little of these solvents containing a small quantity of base, and the mixture is kept at the ordinary temperature it gradually passes into the unsaturated compound. These relations are most plausibly expressed by the following scheme:

$$\begin{array}{c} C_{6}H_{5}COC_{2}CH_{3} & \longleftarrow \\ CH_{2}(CN)CO_{2}CH_{3} & \longleftarrow \\ I & \downarrow \\ C_{6}H_{5}COC_{2}CH_{3} & \longleftarrow \\ I & \downarrow \\ C_{6}H_{5}COC_{2}CH_{3} & \longleftarrow \\ I & \downarrow \\ C_{6}H_{5}C-CO_{2}CH_{2} & + H_{2}O \\ & \downarrow \\ C_{6}H_{5}C-CO_{2}CH_{3} & \longleftarrow \\ I & \downarrow \\ C_{6}H_{5}C-CO_{2}CH_{3} & \longleftarrow \\ C_{6}H_{5}C-CO$$

If this scheme correctly represents the mechanism by which the unsaturated ester is formed, then the basic condensing agents that are constantly employed in the synthesis of α,β unsaturated compounds fulfil a 2-fold function; they bring about condensation, and they cause elimination of water. There is, however, at present, no proof that the hydroxy ester is an intermediate product in the formation of the unsaturated compound, just as there is no satisfactory evidence that the analogous reactions which are used in the synthesis of unsaturated aldehydes and ketones really involve aldol condensation. Inasmuch as the addition product in the presence of bases reverts to an equilibrium with its components, it is impossible, in the absence of all accurate knowledge of the kinetics of the reaction, to determine whether the unsaturated ester is formed by loss of water from the addition product or directly from the components by some other path. This phase of the matter is still under investigation and will be considered in a later paper.

There is nothing peculiar in the condensations with cyano-acetic esters. Dimethyl malonate behaves in precisely the same way. The addition product is less soluble, and therefore a little more easily got; the residual hydrogen in the malonic ester residue is less active than that in the cyano ester, hence the addition product loses water less readily, and as the resulting unsaturated compound is a liquid it is more difficult to get it as a direct product of condensation. These are only such minor differences as are to be expected. The course of the reaction is the same: probably addition-equivalent to aldol condensation-followed by loss of water. It is safe to assume, therefore, that all condensations between aldehydes or ketones and substances containing active hydrogen occur in this manner.

Experimental Part

Preparation of Materials

Benzovlformic Acid.—The acid was made by the oxidation of acetophenone as directed by Claus¹¹ as well as by the oxidation of mandelic acid by the method of Acree. 12 We prefer the latter; it is more convenient,

11 Claus and Neukranz. J. prakt. Chem., [2] 44, 77 (1891). Kailan, Monatsh., 28,

12 Acree, Am. Chem. J., 50, 389 (1913). Evans, ibid., 35, 115 (1906).

less expensive and more easily conducted on a large scale. Probably the best method for getting pure acid from residues which, owing to the presence of water or small quantities of benzoic acid, are reluctant to crystallize, is distillation under diminished pressure. In a good vacuum the pure acid distils practically without decomposition—the boiling point being about 148° at 4–6 mm. The oily residues distilled at 145–149° at 4–6 mm.; the distillate was colorless and solidified promptly. When the quantity distilled was not too great there was no evidence of decomposition until near the very end of the distillation.

Methyl Benzoylformate.—Claisen¹³ states that the esters of benzoylformic acid are readily made by saturating alcoholic solutions of the acid with hydrogen chloride, but he usually made them from benzoyl cyanide. He gives $246-248^{\circ}$ as the boiling point of the methyl ester. Our first preparation made from the acid and methyl alcohol, boiled at 257° —nearly 10° above the point given by Claisen. As it proved to be unexpectedly resistant to condensation, it was analyzed and found to be the acetal, $C_6H_5C(OCH_3)_2CO_2CH_3$.

Analyses. Calc. for C₁₁H₁₄O₄: C, 62.8; H, 6.7. Found: C, 63.1, 62.5; H, 6.7, 6.2.

Other preparations by the same method gave products composed largely of the ketonic ester, but in order to avoid all possible complications nearly all condensations were first carried out with ester that was made through the silver salt.

II. Condensation of Methyl Benzoylformate and Methyl Cyano-acetate

It was stated in the introduction that the equilibrium, $C_6H_5COCO_2CH_3$ + $CH_2(CN)CO_2CH_3$ \Longrightarrow $C_6H_5C(OH)CO_2CH_3$, is established with ex-

CH(CN)CO₂CH₃

traordinary rapidity. The evidence for this statement is as follows. When a few drops of a saturated solution of sodium methylate in methyl alcohol is added to a mixture of equivalent quantities of the two esters which is kept at 0°, the liquid rapidly thickens, a solid addition product begins to separate, and in 5 to 10 minutes the entire mixture solidifies. It now contains 75 to 80% addition product, and as this does not increase when the mixture is allowed to stand for several hours it evidently represents the amount in equilibrium under these conditions. A small quantity of ammonia, methyl amine, or piperidine may be substituted for the sodium methylate without altering the result. Diluting the mixture with a solvent both diminishes the rate and shifts the equilibrium towards the left, as would be expected, but the latter effect can be counteracted by operating at a lower temperature; in an equal volume of methyl alcohol at -20° the amount of addition product is still 72-75%.

¹⁸ Claisen, Ber., 12, 629 (1879).

At 0° in the presence of these small quantities of base, the reaction does not go beyond the formation of the addition product, or more probably it does not go further at a rate that is significant. In a mixture that was kept at this temperature for 4 hours no unsaturated compound could be detected by the delicate test with permanganate. The isolation of the pure addition product, therefore, involves only its separation from the unchanged esters and the base used as catalyst. This is, however, not at all easy to accomplish. The equilibrium is so mobile that the substance partially reverts to its components when it is dissolved in any solvent in the presence of even the small quantity of base that is occluded by the crystals. In the presence of acids, on the other hand, it slowly loses water and passes into the unsaturated compound. After comparing a number of methods for handling the material we adopted the following procedure.

Four or five drops of a saturated solution of sodium methylate in methyl alcohol is added to a mixture of 16.4 g. of methyl benzoylformate and 13 g. of methyl cyanoacetate. The mixture is shaken in ice water until it has completely solidified (10-15 minutes), then placed in a freezing mixture in which it is allowed to remain for an equal length of time. It is then thoroughly mixed with about 10 cc. of acetyl chloride, care being taken to break up any small lumps that may form in the process, filtered, washedfirst with cooled acetyl chloride diluted with ether, and finally very thoroughly with water—and dried. This leaves about 20 g. of a very finely divided solid that melts at 140-145°, and usually can be recrystallized without further trouble, but occasionally contains traces of occluded base. It is best, therefore, to digest it with 10 cc. of acetyl chloride for several hours, during which the fine powder is changed into small lustrous crystals. The substance is now analytically pure, but still melts poorly at 140-145°. It probably contains a small quantity of a stereoisomer because, while the melting point improves somewhat on repeated recrystallization from ether or chloroform, it becomes sharp at 155° after recrystallization from chloroform that contains a small quantity of phosphorus pentachloride.

Dimethyl α -Phenyl- α -cyano- β -hydroxysuccinate. I.—The addition product is sparingly soluble in ether and acetyl chloride, moderately soluble in chloroform and in carbon tetrachloride, readily soluble in acetone and in methyl alcohol. It crystallizes from chloroform in 6-sided plates, from ether in hard lustrous tables. It does not lose water when heated by itself but even the purest specimens partially dissociate into methyl benzoylformate and methyl cyano-acetate when heated to a high temperature in glass.

Analysis. Calc. for C₁₃H₁₃O₅N: C, 59.3; H, 4.9; N, 5.3. Found: C, 58.9; H, 5.1; N, 5.2.

Dimethyl α -Phenyl- β -cyano-ethylene Dicarboxylate. II.—The unsaturated condensation product is much easier to get and to handle than the addition product. When the mixtures that give the saturated compound at low temperatures are allowed to stand at the ordinary temperature or when the amount of catalyst is increased the principal product is the unsaturated compound. The reaction is reversible but the process is slow and the equilibrium favorable. The most effective condensing agent is sodium methylate, but when this is used as the catalyst there are complications due to the water which is one of the products of the reaction. This not only destroys the methylate but also leads to by-products, because both benzoylformic and cyano-acetic esters are hydrolyzed with uncommon ease. The following experiments illustrate the formation of the substance by direct condensation.

I. A small quantity of a solution of sodium methylate was added to a solution of 5 g. (1 molecular equivalent) of methyl benzoylformate and 4 g. (1.3 molecular equivalents) of methyl cyano-acetate in 10 cc. of dry methyl alcohol. The mixture was boiled for an hour during which alkalinity was maintained by successive additions of small quantities of the alcoholate—in all about 0.2 molecular equivalent. The clear, pale yellow solution was then kept at the ordinary temperature for several days during which it gradually deposited a mass of colorless crystals. These were washed with cold methyl alcohol and recrystallized either from ether or methyl alcohol. The average yield in 5 condensations by this method was 72%.

II. A mixture of 5 g, of the ketonic ester and 4 g, of the cyano ester was diluted with 1 cc. of methyl alcohol and then treated with 0.2 g, of methylamine hydrochloride and 0.2 g, of dry sodium carbonate. After standing at room temperature for 3 days this mixture began to deposit crystals of the unsaturated compound. After 3 weeks the yield of pure unsaturated ester was about 70%.

The ester is also easily obtained by the action of bases or of acids on the hydroxy ester. Thus, when a drop of concd. sodium methylate solution was added to 5 g. of the finely powdered ester suspended in 5 cc. of dry methyl alcohol, the liquid became pale yellow, the hydroxy ester gradually disappeared, and large crystals of the unsaturated compound took their place. After 5 days, during which alkalinity was maintained by occasional additions of methylate, the yield was 75%.

The most satisfactory method for transforming the hydroxy into the unsaturated ester consists in heating its solution in glacial acetic acid. For this purpose a suspension of the ester in 4 times its weight of glacial acetic acid is digested on a steam-bath for 3 hours. It is then free from hydroxy ester. The unsaturated ester may be isolated either by diluting the solution with just enough water to produce a faint milkiness or by pouring it into sodium carbonate solution and extracting with ether. The only by-product in either case is a trace of acid.

Analysis. Calc. for C13H11O4N: C, 63.7; H, 4.5. Found: C, 63.8; H, 4.5.

The ester melts at 79–80°. It is moderately soluble in ether and in cold methyl alcohol, sparingly soluble in benzene, and insoluble in petroleum ether. When allowed to crystallize slowly from methyl alcohol it separates in large, transparent prisms. Its solution in acetone reduces permanganate with great ease.

III. Proof of the Structure of the Condensation Products

Our formula for the addition product is based on the method by which it is obtained and on its relation to the unsaturated ester which is formed from it by the elimination of water. But few substances are known which are constituted like this unsaturated compound. These are

The characteristic property of all of these substances is their extreme resistance to hydrolysis. Our unsaturated compound shows the same peculiarity, but we succeeded in transforming it into two stereoisomeric acids that still contained the cyanogen group. We undertook, therefore, to relate it to phenylfumaric acid but were balked by the behavior of these dibasic acids, when they were heated. One of them readily lost water and formed an anhydride; the other sublimed without decomposition.

$$\begin{array}{c} C_6H_5CCO \\ \parallel \\ CNCCO \\ IV \end{array} \begin{array}{c} C_6H_5CCO_2H \\ \parallel \\ CNCCO_2H \end{array} \begin{array}{c} C_6H_5CCO_2CH_3 \\ \parallel \\ C(CN)CO_2CH_4 \end{array} \begin{array}{c} C_6H_5CCO_2H \\ \parallel \\ C(CN)CO_2CH_5 \end{array} \begin{array}{c} C_6H_5CCO_2H \\ \parallel \\ C(CN)CO_2CH_5 \end{array}$$

The problem was finally solved by the addition of hydrogen to the unsaturated ester as well as to one of the dibasic acids and by transforming the hydrogenated compounds into phenyl succinic acid.

$$\begin{array}{c} C_6H_5CCO_2H \\ \parallel \\ CNCCO_2H \end{array} \longrightarrow \begin{array}{c} C_6H_6CHCO_2H \\ \parallel \\ CNCCO_2H \end{array} \longrightarrow \begin{array}{c} C_6H_5CHCO_2H \\ \parallel \\ CNCHCO_2H \end{array} \longrightarrow \begin{array}{c} C_6H_5CHCO_2H \\ \parallel \\ CH(CO_2H)_2 \end{array} \longrightarrow \begin{array}{c} C_6H_5CHCO_2H \\ \parallel \\ CH_2CO_2H \end{array}$$

Hydrolysis of the Unsaturated Ester with Bases.—Fourteen and four-tenths g. of the ester was added to 100 cc. of a cold saturated solution of potassium hydroxide in methyl alcohol. The ester dissolved at once and a crystalline solid soon began to separate from the solution. After the mixture had been kept at the ordinary temperature for 36 hours, the solid was removed, and thoroughly washed, first with dry methyl alcohol, finally with dry ether. It was completely soluble in water. From its water solution concd. acids precipitated an unsaturated dibasic acid, while dil. acids precipitated the corresponding acid potassium salt.

 α -Cyano- β -phenylmaleic Acid, III.—The acid is precipitated from solutions of its salts in fine very pale yellow needles. It is moderately soluble in warm water; readily soluble in acetone, in alcohol, and in ether; almost insoluble in chloroform, in carbon disulfide, and in petroleum ether. As it does not crystallize well from any of these solvents, it was dried in a vacuum and analyzed without further purification.

Analysis. Calc. for C₁₁H₇O₄N: C, 60.8; H, 3.2. Found: C, 60.7; H, 3.3.

The acid potassium salt, precipitated by adding dil. acid to aqueous solutions of the dipotassium salt, is moderately soluble in water or methyl alcohol. It was recrystallized from the latter, and thus obtained in colorless needles that melted at 193-195°.

Analyses. Calc. for C₁₁H₆O₄NK: K, 15.3. Found: 15.5, 15.3.

α-Cyano-β-phenylmaleic Anhydride, IV.—When the unsaturated dibasic acid is heated rapidly it melts with effervescence at about 142°. The effervescence is due to loss of water, which begins at a much lower temperature, and the melting point is that of the anhydride. The ease with which the acid loses water accounts for the difficulties met in recrystallizing it; solutions in boiling water deposit the anhydride in place of the acid. The substance was recrystallized from ether, from which it separated in fine yellow needles that melted at 145-146°.

Analysis. Calc. for C₁₁H₅O₃N: C, 66.3; H, 2.5. Found: C, 66.3; H, 2.6.

All attempts to hydrolyze either the condensation product or the unsaturated dibasic acid to the corresponding tribasic acid were unsuccessful. Cold alcoholic potassium hydroxide produced no further effect. Concd. aqueous alkalies attacked the cyano ester only on heating; ammonia was given off freely but the alkali evidently reversed the condensation reaction, because the principal product was benzoyl-formic acid.

Hydrolysis of the Unsaturated Ester with Acids.—The cyanogen group in the condensation product is just as resistant to the action of acids as it is to that of bases. The ester was recovered almost completely from a solution in dry methyl alcohol which had been saturated with hydrogen chloride and kept at the ordinary temperature for 3 days; and the result was the same when a similar solution was heated for 27 hours in a steamjacketed autoclave. A partial hydrolysis of the ester was obtained as follows.

A mixture composed of 10 g. of ester, 10 g. of glacial acetic acid, and 20 cc. of coned. sulfuric acid was heated first on a steam-bath for 3 hours, and finally at the boiling point for 5 minutes. It was then cooled and diluted with water whereupon it very slowly deposited 3 g. of pale yellow crystals.

 α -Cyano- β -phenylfumaric Acid, V.—The acid crystallizes from boiling water in colorless plates containing 2 molecules of water of crystallization which is given off below 100°. The anhydrous acid melts without decomposition at 158–160°, and in a vacuum sublimes without change. It is readily soluble in acetone, moderately soluble in methyl alcohol and in boiling water, sparingly soluble in chloroform and in ether.

Analyses. Calc. for $C_{11}H_7O_4.2H_2O$: H_2O , 14.2; C, 52.2; H, 4.4. Found: H_2O , 14.5; C, 52.3; H, 4.4.

This method of hydrolysis was very unsatisfactory; it never gave more than 30% of the possible amount of dibasic acid, in many cases it gave much less or none, and it was always difficult to get a pure product.

Reduction.—The unsaturated dibasic acid was reduced with sodium amalgam, and the ester catalytically in the presence of platinum. In each case a part of the material was reduced further than to the corresponding saturated compound, the reduction involving also the cyanogen group. The product obtained by catalytic reduction was ultimately transformed into phenylsuccinic acid, but as the reduction with sodium amalgam proved to be more satisfactory only this will be described.

Thirty per cent. more than the calculated amount of 2% sodium amalgam was added in the course of 3 hours to an aqueous solution of the dipotassium salt, the alkalinity being reduced from time to time by the addition of acid. The solution was then made feebly acid and shaken with ether. This extracted an acid which after crystallization melted at 168–169°. This substance was also isolated from the mixture by boiling the product from catalytic reduction with alkali.

Analysis. Calc. for C₁₁H₁₃O₄N: C, 59.2; H, 5.8. Found: C, 59.2; H, 6.1.

The substance contains nitrogen, and the composition corresponds to that of the amino acid which would be obtained by complete reduction: C₆H₈CH₂(CO₂H)CH-(CH₂NH₂)CO₂H.

The filtrate from the amino acid was evaporated to complete dryness, the residue first extracted with acetone to remove the last of the amino acid, then dissolved in water and acidified with concd. hydrochloric acid. This precipitated an acid which melted at 162–164°, and gave a methyl ester that melted at 56–57°. It was completely identified by comparison with a specimen of phenylsuccinic acid prepared according to Bredt and Kallen. 14

Trimethyl-phenylethane Tricarboxylate, C6H5CHCO2CH3

-Some of the dipotas-CH(CO₂CH₂)₂

sium salt of the unsaturated ester was reduced with sodium amalgam, which was added rapidly at a low temperature. After half an hour the alkaline solution was decanted from the mercury, acidified with excess of strong hydrochloric acid, and extracted with ether. The ether, on evaporation, left an oil. This was esterified with methyl alcohol and hydrogen chloride. The resulting ester was purified by recrystallization from a mixture of ether and ligroin. It crystallizes in needles and melts at $107-108^{\circ}$.

Analysis. Calc. for C14H16O6: C, 60.0; H, 5.7. Found: C, 59.7; H, 5.6.

IV. Addition of Dimethyl Malonate to Methyl Benzoylformate

The addition was brought about in exactly the same way as that of methyl cyano-acetate. It apparently took place with the same rapidity and resulted in an equilibrium not very different from that formed in the case of the cyano ester, the yield of solid addition product being about 80%. The solid was digested with acetyl chloride and then recrystallized from ether.

Analysis. Calc. for $C_{14}H_{16}O_7$: C, 56.8; H, 5.4. Found: (I) C, 56.5; H, 5.5. (II) C, 56.8; H, 5.4.

Molecular Weight: Calc. for $C_{14}H_{16}O_7$: mol. wt., 296. Found, in freezing glacial acetic acid: 304.

Trimethyl β -Phenyl- β -hydroxy-ethane- α , α , β -tricarboxylate, $C_6H_5C(OH)CO_2CH_3$

CH(CO₂CH₂)₂

The addition product is sparingly soluble in ether, moderately soluble in benzene, chloroform and carbon tetrachloride, readily soluble in acetone and glacial acetic acid. It crystallizes from ether in lustrous prisms and melts at 109–111°. The pure substance is stable, but like the analogous product obtained with cyano-acetic ester it is extremely sensitive to alkalies. This is illustrated by our first attempt to determine its molecular weight by the boiling-point method. The solvent was methyl alcohol which had been distilled from lime and then slowly redistilled twice with the aid of an efficient still head. The substance (2.7547 g.) was added to the boiling solvent (23.43 g.) in pellets. It dissolved at once but the boiling point continued to rise steadily for half an hour. When it finally became constant the elevation (0.48°) corresponded to a molecular weight of 215 instead of 296 calculated. Similar results were obtained in carefully purified acetone. In these cases methyl benzoylformate could be detected by the odor and its presence was definitely established by pouring the solutions into water, extracting with ether and shaking the ethereal solution with bisulfite.

That this reversal of the addition reaction is due to the presence of a trace of base was established as follows. The substance was recrystallized from ether which had been washed with 1:1 sulfuric acid and distilled. The acetone was refluxed with tartaric acid, distilled and fractioned with the aid of a Glinsky still head. Using these materials the

¹⁴ Bredt and Kallen, Ann., 293, 342 (1896).

boiling point became constant in 4 minutes and did not change materially in 3 hours; 2.0713 g. of substance in 23.1 g. of acetone produced an elevation of 0.556° corresponding to a molecular weight of 274 instead of 296 calculated.

Dimethyl β-Phenyl-ethylene-α,α,β-tricarboxylate, C₆H₅CCO₂CH₃

As the un

saturated ester was obtained only as a liquid it was not easy to determine the effect of dehydrating agents on the hydroxy ester. We used, therefore, the means that had been found most effective in the case of the corresponding cyano compound. A solution of the ester in phosphorus oxychloride containing a little more than one equivalent of phosphorus pentachloride was sealed up in a tube and heated in a steam-jacketed autoclave for several hours. The chlorides of phosphorus were then removed with ice water, the oil dissolved in ether, the ethereal solution washed with sodium carbonate, dried and distilled. Under a pressure of 10 mm. most of the product distilled at 180–190°. Thus far the oil has shown no tendency to crystallize.

Analysis. Calc. for C₁₄H₁₆O₆: C, 60.4; H, 5.0. Found: C, 59.8; H, 5.1.

Hydrolysis and Reduction.—A small quantity of the oil was added to cold coned. alcoholic potassium hydroxide. It dissolved at once and a solid potassium salt soon began to separate. This was washed with methyl alcohol and ether, then redissolved in water and acidified. As the resulting acid was a liquid it was neutralized and reduced at 40° with excess of sodium amalgam. The result was a solid acid that melted at 190°. Spiegel¹⁵ gives 191°, Alexander¹⁶ 170–171° as the melting point of phenylethane tricarboxylic acid. On esterification with methyl alcohol it gave a methyl ester that melted at 108° and when it was heated it lost carbon dioxide, forming phenylsuccinic acid which was identified by its melting point and that of a mixture with a sample of this acid.

Summary

- 1. At low temperatures, in concentrated solutions, and in the presence of sodium methylate, ammonia, methyl amine and piperidine, methyl benzoylformate and methyl cyano-acetate react and very quickly form the equilibrium, $C_6H_5COCO_2CH_3$ + $CH_2(CN)CO_2CH_3$ \longrightarrow $C_6H_5-C(OH)CO_2CH_3$
- CH(CN)CO2CH3.
- 2. At higher temperatures, the product of the reaction is an unsaturated ester which can also be formed by eliminating water from the addition product.
- 3. The reaction between methyl benzoylformate and dimethyl malonate is in every respect like that with the cyano-acetate.
- 4. The question whether the unsaturated compounds which are obtained in reactions like these are formed by addition and loss of water from the resulting aldol or ketol, or by some other path, remains to be answered; but it is certain that neither aldol condensation nor the reaction between aldehydes or ketones and substances containing active hydrogen involves the enolization of aldehydes or ketones.

THE REACTION BETWEEN CYANO-ACETIC ESTERS AND BENZALACETONE

By E. P. Kohler and Paul Allen, Jr.
Received June 9, 1923

In a paper dealing with the mechanism of the reaction between ethyl cyano-acetate and ketones Haworth¹ used as one of his illustrations the condensation of this ester with benzalacetone. In this reaction he obtained an unsaturated acid for which he gives the melting point 188° and which he represents by Formula I. He hydrolyzed this first to an acid amide, II, and finally to an another monobasic acid melting at 190° to which he ascribes Formula III.

$$\begin{array}{cccc} C_0H_6CH:CHC(CH_3):C(CN)CO_2H, & C_0H_6CH:CHC(CH_3):C(CONH_2)CO_2H \\ & & & I \\ & & & & II \\ & & & & C_0H_6CH:CHC(CH_3):CHCO_2H \end{array}$$

Vorländer,² 12 years earlier, had made a careful study of this same reaction. By almost exactly the same procedure that was used by Haworth, he obtained an unsaturated monobasic acid melting at 180°, which on complete hydrolysis gave another monobasic acid which melted at 187–188°. Vorländer showed pretty conclusively that these substances are the hydroresorcinol derivatives represented by Formulas IV and V.

We have repeated this condensation following Haworth's procedure exactly, and obtained a product melting at 180°. Although there was no reasonable doubt that this is a hydro-resorcinol derivative, we, nevertheless, oxidized it with permanganate. The product was phenylsuccinic acid, which could not possibly be formed from the unsaturated compound represented by I, but would be the normal oxidation product of a substance represented by IV. Vorländer's conclusions are, therefore, confirmed in every respect, and Haworth's products are represented by IV, V and VI. The process by which the hydro-resorcinol derivative is formed may be represented as follows:

¹ Haworth, J. Chem. Soc., 95, 480 (1909).

² Vorländer, Ann., 294, 253 (1897).

The first step constitutes Michael's reaction which, as was shown by Vorländer in the paper cited, is reversible. In the presence of the large amounts of sodium alcoholate used by Vorländer and by Haworth the concentration of the primary addition is always small but when the amount of condensing agent is reduced to a trace there is no difficulty in isolating the intermediate compound. The process is, therefore, exactly like that considered in the preceding paper, the conjugated system behaving, as usual, like an elongated carbonyl group.

Experimental Part

I. Condensation According to Vörlander and to Haworth

A suspension of sodium ethyl cyano-acetate in alcohol was made by adding 28 g. of ethyl cyano-acetate to a concentrated solution of sodium ethylate containing 5 g. of sodium. To this was added a solution of 36 g. of benzalacetone in just enough alcohol to liquefy it. When this mixture was heated it turned dark and gradually deposited a solid sodium compound. After this had been heated for an hour it was removed, washed thoroughly with absolute alcohol and ether until it became nearly white, dissolved in water, and acidified. The resulting solid, after repeated recrystallization from methyl alcohol, melted constantly at 180°; yield, 26.5%. Three more condensations carried out with variations in the conditions gave the same product.

Methyl Ether.—Dry hydrogen chloride was passed slowly into a methyl alcoholic solution of the condensation product for 15 minutes. The solution on evaporation deposited a solid which had the composition of a methyl ether, melted at 171–172°, and in every way answered Vorländer's description of the methyl ether of cyanophenyl-dihydro-resorcinol. There can, therefore, be no doubt that Haworth's product is identical with that previously obtained by Vorländer.

Oxidation.—A solution of 9.4 g. of the condensation product melting at 180–181° in sodium carbonate was treated with aqueous permanganate until the color no longer disappeared at the ordinary temperature; this required 33.5 g. All the organic products were collected in ether by suitable operations, and the acids were then extracted from the ether with sodium carbonate. From the carbonate solution hydrochloric acid precipitated a solid which melted at 165° and which gave a methyl ester that crystallized in tables and melted at 58°. The melting points of phenylsuccinic acid and of its methyl ester are given as 168° and 57°, respectively. As the observed melting points are slightly different from these, the ester was analyzed.

Analysis. Calc. for C12H14O4: C, 64.8; H, 6.2. Found: C, 64.5; H, 6.4.

These results prove that the oxidation product is phenylsuccinic acid and that Vorländer's formula for the condensation product is right.

II. Condensation with a Small Quantity of Sodium Methylate Methyl α -Cyano- β -phenyl- γ -acetyl Butyrate, $C_0H_5CHCH_2COCH_3$

HC(CN)CO₂CH₃.—

A 5% solution of sodium methylate was added drop by drop to a solution of 27.5 g. each of benzalacetone and methyl cyano-acetate until the mixture was alkaline to litmus. The solution was then boiled for about 12 hours, alkalinity being maintained meanwhile by addition of small quantities of the methylate solution as required. The resulting yellow liquid was freed from alcohol by distillation and from acids by solution in ether and extraction with sodium carbonate. The ether on evaporation left an oil. As this showed no tendency to crystallize, it was rectified under diminished pressure. The fractions collected below 190° contained unchanged ketone which was identified by its melting point and probably also unchanged cyano ester. The very pale yellow liquid distilling at about 196° at 7 mm. was analyzed; yield, 32.5 g., or 70.2%.

Analyses. Calc. for $C_{14}H_{16}O_3N$: C, 68.6; H, 6.2. Found: C, 68.7, 68.6; H, 6.2, 6.2. The Ethyl Ester.—In the hope that the ethyl ester might solidify, ethyl cyano-acetate was substituted for the methyl ester in the condensation with benzalacetone; but it likewise was obtained only as a very viscous oil. It boils at 203° at 12 mm. The yield was 50%.

Analysis. Calc. for C₁₅H₁₇O₂N: C, 69.5; H, 6.5. Found: C, 69.2; H, 6.6.

Semicarbazone.—As all efforts to induce the esters to solidify were fruitless, the methyl ester was converted into a semicarbazone in order to get a solid compound for identification. To this end a strong solution containing semicarbazine and a large excess of potassium acetate was made by adding a saturated methyl alcoholic solution of potassium acetate to a concentrated solution of 4 g. of the hydrochloride in water, and removing the precipitated potassium chloride. The clear solution obtained in this way was mixed with a solution of 3 g. of the addition product in methyl alcohol and the mixture set aside. It soon began to deposit the semicarbazone in minute white needles that melted at 156–157°.

Analysis. Calc. for C15H18O3N4: C, 59.6; H, 6.0. Found: C, 59.3; H, 6.2.

Internal Condensation.—A concentrated methyl alcoholic solution of the methyl ester was boiled with the equivalent quantity of sodium methylate for an hour. The sodium salt which separated was washed with alcohol and ether, then dissolved in water. From the water solution acids precipitated cyano-phenyl-dihydro-resorcinol which melted at 181°.

Dimethyl β -Phenyl- γ -acetyl-ethylmalonate, $C_{\delta}H_{\delta}CHCH_{2}COCH_{3}$

CH(CO₂CH₃)₂.—

A solution of 3.5 g. of the cyano ester in methyl alcohol was saturated with hydrogen chloride and set aside. On slow evaporation it deposited a

colorless solid which after recrystallization from methyl alcohol melted at 64°. The filtrate, on suitable treatment, yielded more of the same substance, the total yield being about 60%. It is much more easily obtained by direct addition of dimethyl malonate to benzalacetone. Thus a methyl alcoholic solution containing 2.4 g. of ketone and 3 g. of ester was allowed to stand at room temperature for several days during which it was kept alkaline by successive additions of a few drops of a dilute solution of sodium methylate. On evaporation it deposited a pale yellow solid, which became colorless on recrystallization. When the substance was heated alone or mixed with the product from the cyano ester the melting point was 64°.

Analysis. Calc. for C₁₅H₁₈O₅: C, 64.7; H, 6.5. Found: C, 64.4; H, 6.3.

The substance has neither the composition nor the properties of a dihydro-resorcinol derivative. As it does not reduce permanganate it cannot be an unsaturated compound such as would be formed by addition to the carbonyl group of the ketone. It must, therefore, have the structure assigned to it.

Summary

- 1. In the presence of a small quantity of sodium alcoholate, benzalacetone combines with cyano-acetic esters and malonic esters. The products are saturated compounds formed by addition to the double linkage of the ketone.
- 2. In more concentrated solutions of the alcoholate the addition products undergo further condensation to hydro-resorcinol derivatives. The reaction, therefore, takes place in the manner stated by Vorländer, and Haworth's interpretation is incorrect.

ASYMMETRIC DYES

By C. W. PORTER AND HARRY K. IHRIG Received June 11, 1923

During the past 5 years, 35 asymmetric dyes have been synthesized in this Laboratory and studied with reference to the possibility of selective dyeing. We have held the opinion that selective absorption of an optically active form from a racemic mixture by silk, wool or living tissue would constitute evidence of chemical, rather than physical, union between the dye and the substance which it colors. Interest in this type of investigation has been stimulated by the observation that optically active forms of other types of asymmetric compounds show specific biochemical reactions.¹

¹ Neuberg and Wohlgemuth, Ber., 34, 1745 (1901). Piutti, Compt. rend., 103, 134 (1886). Mayor, Ber., 37, 1225 (1904).

Willstätter recognized the importance of finding out whether the asymmetric molecules of protein-like substances such as silk and wool would accomplish the resolution of a racemic dye by combining with one form only, but at that time there were no asymmetric dyes in existence.²

Porter and Hirst³ prepared several asymmetric dyes by treating p-aminobenzophenone with Grignard reagents, diazotizing the condensation products, and coupling with various amines and phenols. They reported the selective absorption by wool of the levo form of one of their dyes. They were unable to obtain reproducible results of a quantitative character.

Ingersoll and Adams have prepared optically active derivatives of d- and l-phenylamino-acetic acid and obtained evidence of selective absorption of one of them by wool.⁴

The work reported in this paper represents a successful attempt to accomplish the resolution of a racemic dye by the selective action of wool.

Two new series of asymmetric dyes were produced. The members of the first group were made by producing asymmetric amines through the condensation of bromo acid bromides with acetanilide, then diazotizing these products and coupling with various aromatic amines and naphthols. The dyes of the second series were prepared from amino-mandelic acid by diazotizing the acid and coupling with aromatic amines and with naphthols.

Optically active compounds were obtained by resolving racemic aminomandelic acid into its d and l forms before diazotization. The resolution was accomplished by fractional crystallization of the cinchonine salts. Dyes derived from d- and l-m-mandelic acid and β -naphthol melt at 210° and have specific rotations of $+47^{\circ}$. \pm .5° and -47° . \pm .5°.

When wool is dyed in a racemic mixture of these dyes, the solution containing the unused portion of the compound is levorotatory. Both forms of the dye are taken up by the wool but they are absorbed at different rates. By using an excess of wool and extending the time of contact to 72 hours the residual dye in solution was almost a pure levorotatory compound.

Experimental Part

m-Nitromandelic Acid.—m-Nitrobenzaldehyde was made by the action of chromyl chloride and water on a solution of m-nitrotoluene in carbon disulfide.⁵ The aldehyde was treated with potassium cyanide and acetic acid. The resulting cyanohydrin was hydrolyzed by Heller's method.⁶ The reduction of the nitro compound to aminomandelic acid was accomplished by means of ferrous sulfate and barium hydroxide. A solution of 20 g. of m-nitromandelic acid in 200 cc. of warm water was treated with a suspension of 255 g. of crystallized barium hydroxide in 1200 cc. of water, and a solution of 184 g. of crystallized ferrous sulfate in 800 cc. of water. The suspension of barium hydroxide was obtained by heating the water until all of the base had dissolved, then cooling the solution and constantly shaking it. The reduction proceeded rapidly at 30°,

² Willstätter, Ber., 37, 3758 (1904).

Porter and Hirst, This Journal, 41, 1264 (1919).

⁴ Ingersoll and Adams, ibid., 44, 2930 (1922).

⁵ Widmann, Ber., 13, 678 (1880).

⁶ Heller, ibid., 46, 280 (1913).

the whole mass changing in color from green to brown within a few minutes. After the mixture had been vigorously stirred for an hour, it was filtered. The clear filtrate was treated with sulfuric acid until all of the barium had been precipitated and the solution was distinctly acid. The barium sulfate was removed by filtration and the filtrate evaporated on a water-bath. The product was recrystallized from hot water. The crystals melt with decomposition at 130° . The yield was about 60° .

Resolution of m-Amino-mandelic Acid.—A suspension of 20 g. of crystalline cinchonine and 11 g, of m-aminomandelic acid in 500 cc. of water was heated on the waterbath for an hour, and shaken frequently. After cooling, the solution was filtered and allowed to stand in an open vessel at room temperature. The first crystals appeared after 4 days. Later, however, seeding decreased the time to a few hours. The crystals were roset-shaped and on drying fell to a powder. They were recrystallized from hot water (25 cc. of water for each g. of the dry salt); m. p., 156.5°. The pure crystals were dissolved again in hot water and the solution was cooled to room temperature, treated with ammonium hydroxide until all the cinchonine was precipitated and the solution gave the odor of ammonia. The cinchonine was filtered off and the filtrate was freed from ammonia by evaporation at room temperature over sulfuric acid in a vacuum desiccator. It was then acidified with hydrochloric acid and the evaporation was continued at room temperature. The dextrorotatory amino acid crystallized in a few days. It was recrystallized twice from water; m. p. 130° (decomp.); $[\alpha]_p = +33.80^\circ$. After several crops of mixed crystals had been removed from the mother liquor the levo product was obtained nearly pure by fractional recrystallization at ordinary temperatures. The yield was poor; m. p., 130° (decomp.); $[\alpha]_{\rm p} = -33.65^{\circ}$.

Dextro-m-Azo-β-naphthol-mandelic Acid.—d-m-Aminomandelic acid prepared as described above was diazotized at 0° and poured into a cold alkaline solution of β-naphthol. The solution became blood red. The dye was precipitated by making the solution faintly acid, and was recrystallized from glacial acetic acid. It is soluble in bases, slightly soluble in alcohol and in acetic acid, insoluble in water; m. p., 210° ; $[\alpha]_D = +49^{\circ} \pm 5^{\circ}$

Levo-m-Azo- β -naphthol-mandelic Acid.—This dye was prepared by the methods applied in the synthesis of the dextro compound. Its color, melting point, solubility and other properties are identical with the corresponding properties of the dextrorotatory dye; $[\alpha]_D = -49^{\circ} \pm 5^{\circ}$.

Dyeing Experiments

Many experiments were made with fresh, clean wool and with silk. The fibers were dyed by pure d and pure l derivatives of m-mandelic acid and β -naphthol, and by racemic mixtures of the dyes. The rates of absorption have not been measured, but a typical example, indicating selective absorption, may be given. A solution containing 1 g. of the racemic dye in 75 cc. of acetic acid was treated with 2.5 g. of wool at 20° for 24 hours. The solution was then filtered and its rotation measured. A 250watt nitrogen-filled Mazda lamp was used as a source of light. (This dye gives an optically clear solution, and satisfactory readings of the colored solution can be made.) At the end of 24 hours the reading was -0.66°. Fresh wool was then added. At 48 hours the reading was -0.91°. Control samples of wool in acetic acid without the dye did not develop optical activity. There was no extraction of optically active compounds from the wool.

Other Compounds.—Incidentally, in the course of this investigation, the following compounds, not mentioned above, were prepared and analyzed.

p-Azo-β-naphthol-mandelic Acid, HO·C₁₀H₆·N:N·C₆H₄·CHOH·COOH.—From diazotized p-aminomandelic acid and β-naphthol; it is a bright red dye, insoluble in acids but soluble in bases and in hot alcohol; m. p., 118°. Calc.: N₂, 8.7. Found: 8.45, 8.23.

p-Azo-resorcinol-mandelic Acid, $(HO)_2C_6H_4\cdot N: N\cdot C_6H_4\cdot CHOH\cdot COOH.$ —A red dye, soluble in bases, slightly soluble in alcohol and in acetic acid; m. p., 154° (decomp.). Calc.: N_2 , 9.72. Found: 10.95, 11.14.

p-Azo-dimethylaniline-mandelic Acid, $(CH_3)_2N\cdot C_6H_4\cdot N:N\cdot C_6H_4\cdot CHOH\cdot COOH.$ —A brown dye, insoluble in bases but soluble in acids and slightly soluble in water. It becomes bright red in acid solution; m. p., $125-129^\circ$ (decomp.). Calc.: N_2 , 14.05. Found: 14.21, 13.95.

m-Azo-resorcinol-mandelic Acid, (HO)₂C₆H₃·N:N·C₆H₄.CHOH·COOH.—A red dye, soluble in alcohol, water and in bases; m. p., over 280° .

m-Azo-dimethylaniline-mandelic Acid, $(CH_3)_2N \cdot C_6H_4 \cdot N : N \cdot C_6H_4 \cdot CHOH \cdot COOH.$ —A reddish-purple dye, soluble in acids and in alcohol but insol. in bases; m. p., 158°.

m-Azo-phenol-mandelic Acid, $HO \cdot C_6H_4 \cdot N : N \cdot C_6H_4 \cdot CHOH \cdot COOH$.—A bright yellow compound, soluble in bases and in hot alcohol, but insoluble in acids; m. p., 119°. Calc.: N_2 , 10.33. Found: 10.56.

β-Naphthol-azo-α-hydroxy-propionophenone, CH_3 ·CHOH·CO· C_0H_4 ·N: N· $C_{10}H_7H$.— A red dye made by condensing α-bromopropionyl bromide with acetanilide, hydrolyzing the condensation product, diazotizing the resulting p-aminopropionophenone and coupling with β-naphthol. It is soluble in alcohol, ether and bases, and insoluble in water and in acids; m. p., 132°. Calc.: N_2 , 9.00. Found: 9.39, 9.34, 9.37.

β-Naphthol-azo-α-hydroxybutyrophenone, CH₃·CH₂·CHOH·CO·C₆H₄·N:N·C₁₀-H₇OH.—A red dye from p-aminobutyrophenone and β-naphthol. It is soluble in bases, alcohol, or acetone and insoluble in acids; m. p., 72°.

 β -Naphthol-azo- α -hydroxy-isovalerophenone, (CH₂)₂CH·CHOH·CO·C₆H₄·N:N-C₁₀H₇OH.—A red dye from the condensation product of α -bromo-isovaleryl bromide and acetanilide by hydrolysis, diazotization of the amine and coupling with β -naphthol. It is soluble in benzene, ether or bases and is insoluble in acids; m. p., above 265°.

Summary

Representatives of 2 series of asymmetric dyes have been prepared, analyzed and described.

A dye derived from m-aminomandelic acid and β -naphthol has been obtained in pure optically active forms.

The dextro form of this dye combines with wool faster than does the corresponding levo form.

DIRECT CONVERSION OF DERIVATIVES OF DICHLORO-ACETIC ACID INTO DERIVATIVES OF TRICHLORO-ACETIC ACID

By Alvin S. Wheeler and Samuel C. Smith¹ Received June 14, 1923

In a paper just published by us² it was shown that nitrodichloro-acetanilides are formed when the isomeric nitro-anilines are treated with dichloro-acetic acid in the presence of phosphorus pentoxide. During the progress of this study it was observed that the reaction between o-toluidine and dichloro-acetic acid took a different course when no dehydrating agent was present. When the substances are brought together at 0° or below in the molecular ratio of 1:1, a simple salt of o-toluidine and dichloro-acetic acid is formed, analogous to aniline acetate. On the other hand, when an excess of acid is used and the heat of the reaction is allowed to take its course, a complex reaction takes place, the product being a trichloro-acetic acid derivative which appears to be a salt of o-toluidine and trichloro-acetic acid. We then turned our attention to other amines and found the same to be true of aniline, p-toluidine, q-naphthylamine and q-nitro-aniline.

Very little study has been made of the reaction between dichloro-acetic acid and aromatic amines. Beamer and Clarke³ state that they prepared aniline dichloro-acetate, melting at 122° , and aniline trichloro-acetate melting at 140° , but do not substantiate their claims by any analyses; hence their work is of little significance. Our aniline trichloro-acetate melts at 163° , and not at 140° . Baralis⁴ describes a p-toluidine dichloro-acetate, m. p. 140– 141° and a p-toluidine trichloro-acetate, m. p. 137° . We prepared the latter compound and find that it melts at 135° . The journal containing this article is not in the Chemical Abstract list and we have so far been unable to locate it in any library.

A number of articles have been published which describe reactions of dichloro-acetic acid and aromatic amines yielding products containing no chlorine, such as those of Meyer,⁵ Duisburg⁶ and Heller.⁷

The production of trichloro-acetic acid derivatives from dichloro-acetic acid proceeded so smoothly that we felt it necessary to examine the purity

- ¹ This paper constitutes a portion of Part II of a thesis by Samuel C. Smith submitted in candidacy for the degree of Doctor of Philosophy in June, 1923, at the University of North Carolina.

of our dichloro-acetic acid. It was redistilled and the portion boiling at 191° was used in our work

Calc. for C₂H₂O₂Cl₂ (mol. wt., 129): Cl, 55.03. Found: 55.09.

The further precaution was taken of treating the same amines with trichloro-acetic acid. The compounds were identical in every case with those made from dichloro-acetic acid. Again, the composition of the trichloro compounds was proved by regenerating the constituents. For example, aniline trichloro-acetate obtained from dichloro-acetic acid was decomposed by sodium hydroxide, aniline being set free, whereas treatment of an alcoholic solution with sulfuric acid gave the ethyl ester of trichloroacetic acid. The identity of the latter was proved by its conversion into trichloro-acetamide; m. p., 141°.

A complete analysis was made in one case only, that of o-toluidine trichloro-acetate made from dichloro-acetic acid.

The constitution of the compounds may be represented by one of the following formulas.

rmulas. O
$$H_3$$
 OH H I $CCl_3-C-O-N-C_6H_5$ or II $CCl_3-C-N-C_8H_5$

In I we have a pentad nitrogen and therefore an ammonium salt. In II we have a triad nitrogen and a compound of the chloral hydrate type, in which 2 hydroxyl groups are attached to one carbon atom, the stability of such a compound being due to the strong negative environment of the 3 chlorine atoms. The decomposition products which we have obtained throw no light on whether one is better than the other, but we lean to Formula II.

In order to explain why we get a trichloro and not a dichloro compound, we must conceive that 2 molecules of dichloro-acetic acid are rearranged into 1 of trichloro-acetic acid and one of monochloro-acetic acid under the influence of the amine which is basic in character: 2 CClClHCOOH → CCl₃.COOH + CH₂ClCOOH.

It may seem inconsistent to employ an outside agent (phosphorus pentoxide) in any of these reactions in view of the basis on which this study is built, but it was found important to do so in order to facilitate the identification of monochloro-acetic acid in the same reaction with trichloro-acetic acid. The last compounds described in the experimental part are the nitroacetanilides of these acids.

Experimental Part

Dichloroacetates

o-Toluidine Dichloro-acetate, CH₃C₆H₄NH₂.CHCl₂COOH.—A solution of 5 g. of o-toluidine in 20 cc. of carbon tetrachloride was slowly mixed with a solution of 6.1 g. of dichloro-acetic acid in a like amount of the solvent while kept cold with ice. A dense

precipitate formed which weighed 8.5 g. It crystallized out of alcohol in prismatic crystals; m. p., 140°. The salt is pure white but turns brown on exposure to the air and light. Continued boiling with water converts it into o-toluidine trichloro-acetate.

Analysis. Subs., 0.2496: AgCl, 0.3078. Calc. for $C_9H_{11}O_2NCl_2$ (mol. wt., 236): Cl, 30.08. Found: 30.51.

p-Toluidine Dichloro-acetate, CH₂C₆H₄NH₂.CHCl₂COOH.—This compound was prepared in the same way as the o-toluidine salt. If care is not taken to hold the temperature down, the reaction takes a different course and a mixture of products is obtained, as shown by its low melting point. This may explain the low melting point, 140°, found by Baralis; our product melts at 160°. Recrystallized from alcohol, the crystals are prismatic and pure white, but turn brown on exposure to the air.

Analysis. Subs., 0.5401: AgCl, 0.6665. Calc. for $C_9H_{11}O_2NCl_2$ (mol. wt. 236): Cl. 30.08. Found: 30.55.

Trichloro-acetates

Aniline Trichloro-acetate, (from Dichloro-acetic Acid), $C_6H_6NH_2.CCl_3.COOH.$ —To 5.0 g. of aniline was added 7 cc. of dichloro-acetic acid. A great deal of heat was evolved as the product crystallized. Water was added and heat applied until the product dissolved. As the solution cooled, a mass of colorless crystals formed which melted at 160°. Several recrystallizations from water raised the melting point to 163°; yield of crude product, 7.5 g.

Analysis. Subs., 0.2440: AgCl, 0.4088. Calc. for C₈H₈O₂NCl₃ (mol, wt. 256.5): Cl, 41.52. Found: 41.44.

The substance crystallizes from hot water in colorless plates that turn reddish on exposure to the air. It is very soluble in hot water, slightly so in cold water, soluble in alcohol, slightly soluble in ether or benzene. It is decomposed by potassium hydroxide solution, and aniline is set free, as proved by the melting point (198°) of its hydrochloride. It is also decomposed by sulfuric acid. In this case trichloro-acetic acid was proved to be a product by its conversion into ethyl trichloro-acetate, boiling at 170° (756 mm.) and the formation of the trichloro-acetamide from this ester; m. p., 141°.

Aniline Trichloro-acetate (from Trichloro-acetic Acid).—To 5.0 g. of aniline was added 9.0 g. of trichloro-acetic acid. When the mixture was heated gently a vigorous reaction took place. The product crystallized from hot water in plates that melted at 163°. The constituents were also brought together in carbon tetrachloride solution at —3°. The same product, melting at 163°, was obtained. Beamer and Clarke⁸ give 145° as the melting point, but they made no analysis.

Analysis. Subs., 0.4878: AgCl, 0.8149. Calc. for $C_8H_8O_2NCl_3$ (mol. wt., 256.5): Cl, 41.52. Found: 41.10.

This product is therefore identical with the one obtained from dichloro-acetic acid. o-Toluidine Trichloro-acetate (from Dichloro-acetic Acid), CH₃C₆H₂NH₂CCl₃CO-OH.—Five g. of o-toludine and 7 cc. of dichloro-acetic acid were mixed. The reaction proceeded as described above. The product crystallized from hot water in colorless plates; m. p., 167-168° (decomp.).

Analyses. Calc. for $C_0H_{10}O_2NCl_3$ (mol. wt., 270.5): C, 39.92; H, 3.69; N, 5.17; Cl, 39.37. Found: C, 40.04; H, 3.70; N, 5.11; Cl, 38.93.

o-Toluidine trichloro-acetate decomposes at its melting point, two products being identified as chloroform and carbon dioxide. It is slightly soluble in cold water, very soluble in hot water, soluble in acetone, alcohol, insoluble in benzene or ligroin. Potassium hydroxide liberates o-toluidine, shown by the melting point of its hydrochloride,

⁸ Ref. 3, p. 1067.

214-216°. Sulfuric acid liberates trichloro-acetic acid, shown by converting it into its ethyl ester and its amide.

o-Toluidine Trichloro-acetate (from Trichloro-acetic Acid).—Five g. of o-toluidine and 8.0 g. of trichloro-acetic acid were heated together. The product was recrystallized from hot water and proved to be identical with the compound described above in melting point (167–168°), crystal form and solubility.

Analysis. Subs., 0.5122: AgCl, 0.8147. Calc. for $C_9H_{10}O_2NCl_3$ (mol. wt. 270.5): Cl, 39.37. Found: 39.34.

p-Toluidine Trichloro-acetate (from Dichloro-acetic Acid), CH₃C₆H₄NH₂.CCl₃COOH.—Five g. of p-toluidine was added to 7 cc. of dichloro-acetic acid. Much heat developed and to the mixture while still hot was added 20 cc. of water. A light yellow precipitate formed. This was recrystallized from hot water except for a small insoluble portion. The pure substance consists of colorless prismatic needles; m. p., 135° (decomp.). The solubilities correspond to those of the ortho compound.

Analysis. Subs., 0.3385: AgCl, 0.5353. Cale. for $C_9H_{10}O_2NCl_3$ (mol. wt., 270.5): Cl, 39.37. Found: 39.11.

p-Toluidine Trichloro-acetate (from Trichloro-acetic Acid).—Five g. of p-toluidine was mixed with 8.0 g. of trichloro-acetic acid. The product crystallized from hot water in prismatic needles; m. p., 135° (decomp.).

Analysis. Subs., 0.5021: AgCl, 0.7978. Calc. for $C_9H_{10}O_2NCl_3$ (mol. wt., 270.5): Cl, 39.37. Found: 39.31.

 α -Naphthylamine Trichloro-acetate (from Dichloro-acetic Acid), $C_{10}H_7NH_2.CCl_3CO-OH$.—Five g. of α -naphthylamine was mixed with 9.1 g. of dichloro-acetic acid and the mixture warmed a little, since the reaction in this case was somewhat slow. No solution was apparent. The mush of crystals was washed with 50 cc. of water. The crude product, melting at 170°, weighed 10.4 g., the calculated amount being 10.7. After the substance was washed with boiling water or recrystallized from dilute alcohol the melting point was raised to 173°, with decomposition. The compound crystallizes from alcohol in pale violet plates which are only slightly soluble in hot water, are soluble in alcohol or acetone, and insoluble in ether or benzene.

Analysis. Subs., 0.3587: AgCl, 0.4950. Calc. for $C_{12}H_5O_2NCl_3$ (mol. wt., 306): Cl, 34.74. Found: 34.37.

 α -Naphthylamine trichloro-acetate was also made from trichloro-acetic acid by gently heating a mixture of the constituents. Recrystallization from dil. alcohol gave pale violet plates; m. p., 173°.

m-Nitro-aniline Trichloro-acetate (from Dichloro-acetic Acid), $C_0H_4NO_2NH_2.C-Cl_3COOH.$ —To 5.0 g. of m-nitro-aniline was added 15 cc. of dichloro-acetic acid which was sufficient to dissolve it. After the solution had been heated on the water-bath for 10 minutes it was poured into 100 cc. of cold water. The crystalline precipitate formed melted at 143°. Recrystallization from hot water raised the melting point to 147° but continued boiling with water caused hydrolysis. The crystals are pale yellow plates, soluble in alcohol, slightly soluble in ether and insoluble in benzene.

Analysis. Subs., 0.4049: AgCl, 0.5722. Calc. for $C_8H_7O_4N_2Cl_3$ (mol. wt., 301): Cl, 35.32. Found: 34.89.

p-Nitrochloro-acetanilide (from Dichloro-acetic Acid), C₆H₄NO₂NHCOCH₂Cl.— Five g. of p-nitro-aniline was warmed with 12 cc. of dichloro-acetic acid. After reaction had taken place (analogous to the reactions described above), 5.0 g. of phosphorus pentoxide was added and the mixture heated on the steam-bath for 10 minutes, then poured into 100 cc. of cold water and allowed to stand overnight for complete crystallization to take place. The precipitate was then extracted with carbon tetrachloride. The insoluble portion proved to be p-nitrochloro-acetanilide and the solution contained p-nitro-trichloro-acetanilide.

The portion insoluble in carbon tetrachloride was recrystallized from alcohol. It consisted of yellow prisms, m. p. 177° , insoluble in water, soluble in acetone or ether.

Analysis. Subs., 0.3311: AgCl, 0.2191. Calc. for $C_8H_7O_3N_2Cl$ (mol. wt., 214.5): Cl, 16.55. Found: 16.37.

That this compound was p-nitrochloro-acetanilide was proved by comparison with the product made directly from monochloro-acetic acid. To $5.0\,\mathrm{g}$. of p-nitro-aniline was added $5.0\,\mathrm{g}$. of phosphorus pentoxide and $5.0\,\mathrm{g}$. of monochloro-acetic acid. After the mixture had been heated until fusion took place, $100\,\mathrm{cc}$. of water was added. The precipitate formed was recrystallized from alcohol, as yellow prisms; m. p., 177° .

Analysis. Subs., 0.1974: AgCl, 0.1344. Calc. for $C_8H_7O_9N_2Cl$: Cl, 16.55. Found: 16.37.

p-Nitrotrichloro-acetanilide (from Dichloro-acetic Acid), $C_6H_4NO_2NHCOCl_3$.— The portion soluble in carbon tetrachloride was purified by evaporation of the solvent and extraction of the residue with 50% alcohol. The portion insoluble in the alcohol melted at 135-140°. It was recrystallized from carbon tetrachloride. The pure substance consists of light yellow prismatic needles that melt at 140° with previous softening. It is soluble in acetone, alcohol, benzene or chloroform.

Analysis. Subs., 0.0341: AgCl, 0.0521. Calc. for $C_8H_6O_3N_2Cl_3$ (mol. wt., 283.5): Cl, 37.56. Found: 37.79.

To prove that this was p-nitrotrichloro-acetanilide the substance was synthesized from trichloro-acetic acid. To 5.0 g. of p-nitro-aniline was added 5.0 g. of phosphorus pentoxide and 7.0 g. of trichloro-acetic acid. The mixture was heated until it melted. To remove any unchanged p-nitro-aniline dil. hydrochloric acid was used for precipitation. The substance was purified by recrystallizing from carbon tetrachloride and obtained as light yellow needles; m. p., 140°, with previous softening.

Analysis. Subs., 0.2365: AgCl, 0.3598. Calc. for $C_8H_5O_3N_2Cl_3$: Cl, 37.56. Found: 37.61.

Summary

- 1. The dichloro-acetates of o- and p-toluidine were prepared from dichloro-acetic acid.
- 2. The trichloro-acetates of aniline, o- and p-toluidine, α -naphthylamine and m-nitro-aniline were prepared from dichloro-acetic acid. The same trichloro-acetates were prepared from trichloro-acetic acid.
- 3. To prove the presence of monochloro-acetic and trichloro-acetic acids in the reaction of dichloro-acetic acid on aromatic amines, the *p*-nitrochloro-acetanilides were prepared, separated and identified.
- 4. Two molecules of dichloro-acetic acid exchange a hydrogen and a chlorine atom under the influence of these weak bases, thus yielding trichloro-acetic acid derivatives from dichloro-acetic acid.

CHAPEL HILL, NORTH CAROLINA

THE BROMINATION OF 2-AMINO-PARA-XYLENE AND CERTAIN NEW AZO DYES

By Alvin S. Wheeler and E. W. Constable¹ Received June 16, 1923

E. Fischer and Windhaus² prepared a bromine derivative of 2-amino-pxylene by brominating its formyl derivative. The product contained 1 bromine atom and as for the constitution of the compound they merely say, "The location of the bromine, for which three possibilities exist, is still not known, but we hold it as probable that the halogen is in the position para to the amino (2) group." We have established the location of the bromine definitely at Position 5 by a short series of reactions. Instead of using the formyl derivative of Fischer and Windhaus, we prepared the acetyl derivative and treated this with bromine in glacial acetic acid solution. The monobromo compound thus obtained was hydrolyzed with strong hydrobromic acid, giving the hydrobromide of 2-aminobromo-bxylene, melting at 255°. The free amino acid was identical with the one prepared by Fischer and Windhaus. Its diazotization by the Sandmever method gave 2,5-dibromo-p-xylene, m. p. 75.5°, a compound of known constitution. While this was sufficient to locate the bromine at Position 5. we extended the proof by oxidizing this compound with fuming nitric acid to 2,5-dibromoterephthalic acid, m. p. 316°, and finally converting this into its diethyl ester which melts at 125°.

Having established the constitution of the compound as 2-amino-5-bromo-p-xylene, we prepared a few azo dyes. It was found that the bis compound was produced when the bromo derivative was coupled with phenol, resorcinol and α -naphthol, but not in the case of β -naphthol. The β -naphthol derivative is very brilliant in color, a scarlet-red and the crystals are splendid, long needles. The other dyes are quite ordinary in appearance. Owing to difficulty in making sodium salts, the tinctorial properties on silk and wool were tried by employing the development method of application.

Experimental Part

2-Aceto-amido-5-bromo-p-xylene, (CH₃)₂C₆H₂NHCOCHBr₃.—Five g. of 2-aceto-amido-p-xylene (m. p., 137°) was dissolved in 20 cc. of glacial acetic acid by gentle heating and then cooled. The solution was kept cold while 1 molecular equivalent (4.9 g.) of bromine was slowly added. Five volumes of water were added to the thick mush of crystals that formed and the mixture was well stirred. The yield was equal to the weight

¹ This paper constitutes a portion of a thesis submitted by E. W. Constable in candidacy for the degree of Master of Science in June, 1923, at the University of North Carolina

² Fischer and Windhaus, Ber., 33, 1974 (1900).

of the raw material taken. The crude product melted at 185°, recrystallization from alcohol raising the melting point to 187°. It crystallizes in colorless needles grouped in fluffy masses of rosets, and is very difficultly soluble in water, but soluble in alcohol and in ether. One g. dissolves in 8 cc. of hot alcohol.

Analysis. Subs., 0.2180; AgBr, 0.1639. Calc. for C₁₀H₁₂ONBr (242); Br, 33.05. Found: 33.08.

This compound was prepared by C. K. Brooks in this Laboratory.

2-Amino-5-bromo-p-xylene Hydrobromide, $(CH_3)_2C_6H_2BrNH_2.HBr$.—Five g. of the aceto-amido compound was heated with 75 ec. of hydrobromic acid, d., 1.3. Hydrolysis was completed in a short time, the hydrobromide crystallizing out as the solution cooled. The product weighed 20% more than the raw material. It was recrystallized from absolute alcohol or, better, hydrobromic acid. It consists of flat needles; m. p., 255°, (decomp.).

Analyses. Subs., 0.2059, 0.4346. Calc. for C₈H₁₀NBr.HBr: NaOH, 0.0293, 0.0618. Found: 0.0294, 0.0615.

- **2,5-Dibromo-**p-**xylene**, $(CH_3)_2C_6H_2Br_2$.—The hydrobromide described above was dissolved in water containing some hydrobromic acid and diazotized at a low temperature. After the addition of copper powder and potassium bromide, the mixture was distilled with steam. The crystals that appeared in the distillate were recrystallized from dil. alcohol, water being added to the alcoholic solution until crystallization began. The product consisted of plates; m. p., 75.5° . It was, therefore, identical with the 2,5-dibromo-p-xylene described by Jannasch.
- 2,5-Dibromoterephthalic Acid, $(COOH)_2C_6H_2Br_2$.—The dibromoxylene was heated above 300° with 20 parts of nitric acid, d., 1.15, in a sealed tube for 8 hours. The product consisted of leaf-like crystals that melted at 313° (uncorr.). Fileti and Crosa⁴ give 316–317° as the melting point of 2,5-dibromoterephthalic acid.
- 2,5-Dibromo-diethylterephthalate, (COOC₂H₅)₂C₆H₂Br₂.—The acid was readily esterified by boiling it with absolute alcohol containing a little dry hydrogen chloride. The glistening leaf-like crystals that appeared as the solution cooled melted at 125°. Fileti and Crosa⁵ state that this ester melts at 125°.

Azo Dyes

2,4–(Bis-5-bromo-2-p-xylylazo)phenol, $[(CH_3)_2C_6H_2BrN_2]_2C_6H_3OH$.—One molecular equivalent of aminobromoxylene hydrobromide was diazotized and then treated with $^1/_2$ molecular equivalent of phenol dissolved in a minimum quantity of dil. alkali. After 10 minutes the solution was acidified with acetic acid. The dull brown precipitate that formed was recrystallized from glacial acetic acid. The pure compound consists of small, dark brown scales with a metallic luster when viewed in the mass, while under the microscope they are pale green; m. p., 233–234°. By employing the development method of application this dye may be made to color silk an écru and wool an orange-brown.

Analysis. Subs., 0.1029: AgBr, 0.0759. Calc. for $C_{22}H_{20}ON_4Br_2$ (516): Br, 30.98. Found: 31.39.

2,4-(Bis-5-bromo-2-p-xylylazo)resorcinol, $[(CH_3)_2C_5H_2BrN_2]_2C_5H_2(OH)_2$.—One molecular equivalent of the hydrobromide was diazotized and then treated with $^1/_2$ molecular equivalent of an alkaline solution of resorcinol. After 10 minutes acetic acid was added in excess, producing a dark brown precipitate. This was boiled with ben-

³ Jannasch, Ber., 10, 1357 (1877).

⁴ Fileti and Crosa, Gazz. chim. ital., 18, 309 (1888).

⁵ Ref. 4, p. 310.

zene and the solution filtered hot. From the filtrate the product crystallized in fine, microscopic crystals of claret-brown color in the mass. It was further purified by recrystallizing from a 1:1 mixture of benzene and acetone. The pure substance melts at 263°. By employing the development method of application the dye may be made to color silk an écru and wool a Brazil-red.

Analysis. Subs., 0.0205: AgBr, 0.0146. Calc. for C₂₂H₂₀O₂N₄Br₂ (532): Br, 30.08. Found: 30.01.

2,4-(Bis-5-bromo-2-p-xylylazo) α -naphthol, $[(CH_3)_2C_6H_2BrN_2]_2C_{10}H_5OH$.—This dye was prepared in the same way as were those described above. The product was purified by boiling it in a large quantity of alcohol, filtering the solution while hot and allowing the filtrate to cool. The crystals separating from the cold solution are of indefinite shape, very dark brown to black when viewed in the mass and melt at 222–223°. When applied by the development method, this dye colors silk a Mars-orange and wool a claret-brown.

Analysis. Subs., 0.0325: AgBr, 0.0216. Calc. for $C_{28}H_{22}ON_4Br_2$ (566): Br, 28.23. Found: 28.28.

1-(5-Bromo-2-p-xylylazo) β -naphthol, (CH₃)₂C₅H₂BrN₂C₁₀H₅OH.—One molecular equivalent of the hydrobromide was diazotized, made alkaline and treated with 1 molecular equivalent of β -naphthol in alkaline solution. Acidification produced a brilliant red precipitate, weighing 40% more than the hydrobromide taken. On recrystallizing from acetone it was obtained in very beautiful, long scarlet-red needles in felted masses. Applied as the other dyes above, this dye colors silk a light red and wool a Nopal-red.

Analysis. Subs., 0.0673: AgBr, 0.0360. Calc. for $C_{18}H_{15}ON_2Br$ (355): Br, 22.51. Found: 22.76.

Summary

- 1. Bromination of 2-aceto-amido-p-xylene yields a monobromo derivative in which the bromine is located at Position 5 as proved by the following series of reactions: 2-aceto-amido-bromo-p-xylene (new) \longrightarrow 2-amino-bromo-p-xylene \longrightarrow 2,5-dibromo-terephthalic acid \longrightarrow 2,5-dibromo-diethylterephthalate.
- 2. The following new azo dyes were prepared: 2,4-(bis-5-bromo-2-p-xylylazo)phenol; 2,4-(bis-5-bromo-2-p-xylylazo) α -naphthol; 1-(5-bromo-2-p-xylylazo) β -naphthol.

CHAPEL HILL, NORTH CAROLINA

NEW BOOKS

Beiträge zur Geschichte der Naturwissenschaften und der Technik. (Contributions to the History of Science and Technology.) By Prof. Dr. Edmund O. von Lippmann, Dr. Ing. E. H. at the Technischen Hochschule at Dresden, Director of the "Zuckerraffinerie Halle" at Halle A.S. 314 pp. 2 figs. Verlag von Julius Springer, 1923, Berlin. 16.5 cm. × 24.5 cm. \$1.60 paper, \$1.90 bound.

This last work by Professor Lippmann comprises a selection of miscellaneous papers upon the history of alchemy, chemistry and chemical technology which have been published during the past 10 years in the Chemiker Zeitung, Zeitschrift für Angewandte Chemie and other periodicals.

It was at the request of the numerous friends of his two previous volumes of "Essays and Addresses" (Abhandlungen und Vorträge) upon historical chemistry that the author has compiled this third collection of scattered articles.

The 36 contributions of the new volume show the same variety of interest and scholarly attention to detail that have always characterized the historical researches of Professor Lippmann. "Chemical Papyri of the Third Century" (2 papers), "Origin of the name Caput Mortuum," "First Occurrence of the Word Chemistry," "On the History of Alcohol and Distillation" (6 papers), "Use of Petroleum in the Middle Ages," "Chemical and Technological Contents of the Medieval Receipt Books of Heraklius, Theophilus Presbyter, and Vitalis de Furno" (3 papers), "Chemical and Technological References in Dante," "Petrarch upon Alchemy," "The Alchemists J. I. and I. Hollandus" (2 papers), "The Philosopher's Stone and Homunculus, Two Alchemistic Problems in Goethe's Faust," "A biographical Note upon Liebig," and "The Centenary of Robert Mayer" are selected from the various titles to show the diversity of subjects which are discussed.

As belonging to the author's special field of technology, the papers upon "The Medieval Sugar Industry" and "Sugar Monopolies of the Middle Ages" form important addenda to his well-known "History of Sugar" published in 1890. There are also comments upon several recently discovered letters of Achard (the first manufacturer of beet sugar), a paper upon "Goethe and Sugar Manufacture," an article upon "The History of the Vacuum Pan," and an address upon "The Development of the Sugar Industry in Germany between 1888 and 1913."

For the casual reader of historical chemistry we know of no recent work which provides more pleasant entertainment than this new volume of Professor Lippmann's collected papers; while for those more critically inclined the numerous explanatory footnotes and bibliographic references offer abundant opportunities for additional study.

The book is printed in clear Roman type and is provided with a good index of both names and subjects. It should find a place in the library of every chemist, whether teacher or technologist, who is interested in the cultural aspects of his science.

C. A. BROWNE

Catalytic Action. By K. George Falk, Harriman Research Laboratory, The Roosevelt Hospital, New York. The Chemical Catalog Company, Inc., 1 Madison Avenue, New York, U. S. A., 1922. 172 pp. 23.5 × 15.5 cm. Price \$2.50.

The enormous growth of so-called catalytic industrial operations during the present century has stimulated research in the field of the mechanism of catalysis and indeed of chemical action in general. Owing to the wide range of literature which investigators have to cover it is both important and necessary that from time to time a serious attempt should be made by someone actively interested in the subject to summarize the work in at least its more important aspects. In this respect the monograph of Dr. K. G. Falk is doubly welcome in that it not only fills one of these gaps but it also presents the case in a very readable form with ample references.

The volume contains 8 chapters, the first 3 dealing with the phenomena, criteria and theories of catalytic action. Two chapters are devoted to a discussion of the energy relations and recent theories in chemical action, 2 to enzyme action and life processes, while the last chapter includes a discussion on contact catalysis.

Dr. Falk believes that the only tenable theory of catalytic action is the associative theory which was originally definitely advanced by H. E. Armstrong, and the argument in the whole volume is thrown onto this hypothesis. It is now generally admitted even by the protagonists of the radiation theory that when a catalyst G operates in the union of two substances A and B, a complex of the general type AC or BC is first formed, which then reacts to form the complex ABC, with subsequent decomposition. The stability of these intermediate compounds is also a criterion of the catalytic efficiency of C. The objection to the theory is that it is too vague, since it is in reality merely a restatement of the fact that chemical action is action by contact. We require to know the nature of the complex and why it is more reactive than the original substances in order to obtain some insight into the modus operandi of chemical action and to assist us in the choice of a catalyst that will permit a chemical action to proceed at a determined speed. The author gives an excellent resumé of Stieglitz's work on the hydrolytic decomposition of the imido esters in which definite proof is advanced that the positive ion formed by the complex imido ester H+ is much more reactive than the imido ester atom. It is possible that the transformation of a substance into a charged ion by reaction with either hydrogen or hydroxyl ion may generally increase its reactivity with ions of the opposite sign. An extension of this hypothesis would indicate that an ester would form a complex with either hydrogen or hydroxyl ions and thus serve as the nucleus of an amphoteric electrolyte, a point which might possibly be confirmed by migration experiments. There are, however, many other ways in which molecular reactivity may be produced.

That on association of the catalyst and reactant a molecular rearrangement may take place to give a decrease of free energy of the system is evidenced by citation of the work of Stieglitz and Derick but to include coupled and induced reactions, such as Traube's slow oxidations, in the same category would necessitate a somewhat wide extension of our present ideas on the subject. A study of the oxidation potentials of systems which can be transformed from a coupled to a catalytic reaction by alteration of

the hydrogen-ion concentration of the medium indicates an alternative method of investigation.

The author gives a brief but descriptive review of the various proposed atom structures before dealing with the varied problem of radiation and chemical change, in which the views of the various rivals are expressed impartially; the somewhat important criticisms and suggestions of Lindemann might have been included.

The chapters on enzyme action and life processes are extremely illuminating and present the interesting properties of such colloidal catalysts in a very readable form.

In the chapter on contact analysis the transition of the views of Bodenstein and Fink into the monomolecular film theory of Langmuir is given and a few examples of the varied types of decomposition that may be obtained with different catalysts. It might have been well to have extended the section on promoter action in catalysis, as this may in all probability provide an important method for investigation into two factors influencing surface action, namely, the effect of adsorption of reactants and products and the possible variation in the orientation and polarity of the adsorbed substance with the catalytic material.

Dr. Falk is to be congratulated on the production of an excellent monograph, which is both pleasantly and clearly printed.

ERIC K. RIDEAL

The Formation of Colloids. By The Svedberg, Professor of Physical Chemistry in the University of Upsala. Monographs on the Physics and Chemistry of Colloids. D. Van Nostrand Company, 25 Park Place, New York, 1921. viii + 119 pp. 22 figs. 12.5 × 19 cm. Price \$2.00 net.

This is the first of a series of monographs that The Svedberg proposes to issue. It is his plan to keep the series up to date by new editions of such parts of the subject as develop with special rapidity.

As the author announces in the first monograph, he aims "to give a survey of the processes which cause the formation of colloids—or of heterogeneous systems with a relatively large boundary surface—especially with regard to the conditions that determine the degree of subdivision of the systems formed."

The formation of disperse systems in a vacuum, in gases, in liquids and in solids is presented in a scholarly manner. The discussion of formation in a vacuum is short but extremely interesting. As might be expected, the Bredig process of electric pulverization of metals with the oscillatory arc is discussed ably and at some length. The author favors the view that the sol is formed by condensation of metal gas and the sediment by dispersion of melted metal.

His distinction between volume condensation and surface condensation (p. 57) is interesting. In this connection he cites the striking fact that ul-

traviolet light converts an alcoholic solution of sulfur into a colloidal suspension by transforming the sulfur into another allotropic modification.

Among the best features of the monograph are the pages devoted to colloidal gold with their detailed equations and the excellent historical discussion of this particular colloid. Good, also, is the treatment of sulfur.

Peptization deserves fuller treatment. We find on p. 108 that "the so-called peptization processes are in general to be considered as reversible coagulations. They are not real dispersion processes, the degree of dispersion not being altered by the peptization, but only the mutual distances of the particles." The difference between peptization by solvent and by solute is not stressed. Under "Dispersion" the preparation of emulsions was merely touched upon but doubtless this will later become the subject of a complete monograph. The Plauson mill and the Premier mill are either too recent in development or too uncertain to be mentioned.

Colloid chemistry will be debtor to Svedberg for this series of monographs. He writes with authority.

HARRY N. HOLMES

Organic Syntheses. Annual Publication of Satisfactory Methods for the Preparation of Organic Chemicals. Vol. II. James Bryant Conant, Harvard University, Editor-in-Chief; Roger Adams; Hans Thacher Clarke; Oliver Kamm. John Wiley and Sons, Inc., New York; Chapman and Hall, Limited, London, 1922. vii + 100 pp. 3 figs. 23.5 × 15 cm. Price \$1.50.

The first volume of the "Organic Syntheses" was favorably reviewed in detail by E. P. Kohler.¹ The second volume now at hand reaffirms in the preface the purpose of this series: "The preparation of materials for research, always time-consuming and annoying, is made increasingly so by the inexactness of the published information which so often omits essential details. Because of this, much needless experimentation is necessary in order to obtain the results given in the published reports. As the additional information thus acquired is seldom published, duplication of such experiments occurs again and again,—a waste of time and material. It is hoped these difficulties may be remedied by the publication of this series of pamphlets. In other words, the authors hope to make this a clearing house for the exchange of information as to methods of preparation of some of the most needed organic chemical reagents."

As is well known, we owe to the Department of Chemistry of the University of Illinois the inception of the laudable purpose expressed in the above quotation. Four pamphlets under the title "Organic Chemical Reagents," edited by Roger Adams and co-workers, have been published by that University. The present new series of Organic Syntheses "aims to make available in a permanent form complete detailed directions for the preparation of various organic chemical reagents." In fact, nine out

¹ This Journal, 43, 2702 (1921).

of the twenty-five preparations in Vol. II, of the "Organic Syntheses" are reproduced from the "Organic Chemical Reagents, II" with only slight changes.

The reliable nature of the laboratory directions for the various substances is vouched for by several investigators, and the names of the chemists who have studied the experiments is attached to each preparation, "so that further information concerning any obscure point can be obtained if any question arises in using these directions." The order of treatment is: (1) Procedure,—giving explicit directions for the preparation of the substance in 250g. to 2kg. lots; (2) Notes,—which explain why it is essential to observe the conditions laid down in the directions; (3) other methods of preparation, including a complete bibliography on the particular substance.

The preparation of the following organic chemicals is included in this volume: benzalacetophenone; benzyl benzoate; benzyl cyanide; α, γ -dichloro-acetone; p-dimethylamino-benzaldehyde; ethyl oxalate; ethyl phenylacetate; glycerol α, γ -dichlorohydrin; glycerol α -monochlorohydrin; hydrazine sulfate; mesitylene; methyl red; p-nitrobenzoic acid; p-nitrobenzyl cyanide; p-nitrophenylacetic acid; nitroso-p-naphthol; phenylacetic acid; phenylacetylene; phenylhydrazine; phthalimide; quinoline; quinone; sodium p-toluenesulfinate; 1,3,5-trinitrobenzene; 2,4,6-trinitrobenzoic acid.

The editors deserve the hearty support, as well as the thanks of the chemical profession. Let us hope that the issue of Vol. III will not be long delayed.

M. GOMBERG

Qualitative Organic Analysis. By OLIVER KAMM. 260 pp. John Wiley and Sons, Inc., New York, 1923. 15 × 23 cm. Price \$1.75.

This laboratory textbook is essentially the course in Qualitative Organic Analysis that has been given to his classes at the University of Illinois by Professor Kamm. A careful examination of its contents has convinced the reviewer that when used under a competent instructor it should prove an admirable and practical one. As the author remarks in his preface: "Qualitative Organic Analysis has not been taught generally because of the assumption on the part of the chemists that the multiplicity of organic compounds excludes the possibility of a systematic procedure. This is the opinion only of those who have not taught the subject; those who have had experience in presenting the work both in the classroom and laboratory realize that qualitative organic analysis is capable of logical and systematic treatment and that it is of fundamental importance in the training of the chemist in the organic field."

The work is specially arranged for a one semester course of 32 laboratory periods of 3 hours each, the first week being given to solubility tests

of known compounds, 5 weeks to the classification of known compounds, 6 weeks to the identification of 6 or 8 individual compounds, and 4 weeks to the examination of mixtures. The section of classified tables of compounds at the end of the book enables the student to apply the knowledge gained to a great diversity of substances, and the training in fundamental principles and methods given is so varied and well planned that the work as a whole deserves the highest commendation.

Special emphasis is rightly given to the importance of the solubility of different classes of organic compounds for purposes of classification, separation and identification. Due attention is, however, also given to special methods for the determination of the chemical class to which a compound belongs by application of chemical tests to the small scale preparation of characteristic derivatives, to the determination of physical constants, and to the special technique of small scale preparations.

The book deserves a hearty welcome wherever organic chemistry is taught.

S. P. MULLIKEN

The Chemistry of Urea. The Theory of its Constitution, and of the Origin and Mode of its Formation in Living Organisms. By EMIL A. WERNER, Sc.D., Professor of Applied Chemistry in the University of Dublin. Longmans, Green and Company, 55 Fifth Avenue, New York; 39 Paternoster Row, London, E. C. 4; Toronto; Bombay, Calcutta and Madras; 1923. xii + 212 pp. 24.5 × 15.5 cm. Price \$4.75 net.

This volume is one of a series of monographs on biochemistry edited by R. H. A. Plimmer and F. G. Hopkins. The chemistry of urea is a subject of quite general interest and, hence, contributions to our knowledge of it will, indeed, be welcomed by many investigators.

The subjects listed in the table of contents of this monograph include the following: history of urea, mechanism of Wöhler's synthesis, constitution of cyanic acid, thermal decomposition of urea, decomposition of urea when heated in presence of acids and alkalies, interaction of urea and nitrous acid, mechanism of syntheses of urea from derivatives of carbonic acid, miscellaneous syntheses of urea, synthesis of urea from cyanamide, conditions necessary for the existence of true carbamides, properties of urea on the basis of the cyclic formula, occurrence of urea in nature, constitution of salts of ammonia and their relation to urea, and decomposition of urea in alkaline solution by hypochlorites and hypobromites.

The body of the material is presented in 15 chapters, the logical sequence of which is to be commended. A summary of methods for the detection and estimation of urea is presented in Appendix I. Appendix II gives the physicochemical constants of urea and also contains a short discussion of urea formation in its relation to nitrogen fixation. An extensive bibliography is appended which, though by no means complete, should be of assistance to those interested in this subject.

The material is presented from a much more restricted point of view than the title of the book and the chapter headings indicate, being limited essentially to a polemical discussion of the constitution of urea. As stated by the author in the preface, one of the main objects of the book is to refute the long-standing conception of the carbamide formula for urea, and to show that the cyclic formula proposed by himself disposes of disagreements between facts and theory in the chemistry of urea. The choice of material presented has been rather closely governed by this object and it is somewhat unfortunate that the fact is not more accurately reflected in the title of the work. The limited treatment of the subject is further indicated in the preface by the statement "the chemistry of substituted derivatives of urea is outside the scope of this work which is restricted to the consideration of the constitution of urea itself."

Since it is not the function of a single reviewer to pass upon the merits of the arguments which the author leaves to the judgment of all who are interested, it would be somewhat out of place to enter here into any detailed discussion. The book appears to be an excellent presentation of the views of the author but the reviewer believes that critical readers will fail to be convinced by the arguments offered in many instances. For example, those investigators who have had experience with the behavior of cyanamide in aqueous acid or alkaline solutions will certainly fail to agree with the author's impressions as set forth in Chapter IX, concerning the constitution of cyanamide, the mechanism of its polymerization and its relation to urea. The deductions as to the constitution of urea drawn from its relation to cyanamide are based on entirely erroneous information.

In the discussion of the subject "Urea and Nitrogen Fixation" the statement, "The fact that cyanamide is not directly hydrolyzed to urea, but requires a concentration of acid necessary to produce a salt of urea appears to be a serious drawback to the economic production of urea from this source," is likewise in error.

The book has a cardboard binding and the quality of the paper is rather poor, but the presswork is very good.

THE ATOMIC WEIGHT OF ANTIMONY FROM DIFFERENT SOURCES. I. PRELIMINARY

By Sheikh D. Muzaffar Received January 11, 1923

Ever since the discovery of isotopes, investigation of samples of an element from different sources has become important. Values for the density, the melting point and the atomic weight may show slight variations among different samples. The differences are accounted for on the isotopic theory, and whenever observed indicate the presence of isotopes in an element.

A review of the earlier work on the atomic weight of antimony suggested that its equivalent weight might be different in samples prepared from ores from different parts of the earth. With this idea in mind the present work was undertaken with stibnites from Hungary, Bolivia, Borneo and Peru. The results indicate a striking variation in the value of the atomic weight, but since this seems to be the second case of its kind (that of lead being the first), the figures need a confirmation by the study of the element from other sources and by more work on the methods of the purification of the element. This is, therefore, a preliminary notice of the phenomenon.

Preparation of Materials

Ammonium Bromide was prepared according to the method suggested by A. Scott.¹ Silver.—Through the kindness of Mr. C. T. Heycock, a sample of silver was used that had been purified and employed by him in his work on the atomic weight of rubidium, and also by A. Scott¹ in his work on the ratio of ammonium bromide to silver.

Arsenious Oxide, a chemically pure grade, was sublimed 6 times at 90° in a long, evacuated hard-glass tube which was sealed under reduced pressure and warmed before sealing to fill it with the vapor of the substance. The oxide was weighed into the titration bottles immediately after its preparation.

¹ Scott, J. Chem. Soc., 103, 849 (1913).

Potassium Bromate, a chemically pure grade purchased from a commercial source, was found to contain 0.02% of hygroscopic moisture when it was dried in a vacuum desicator over fused calcium chloride. Accessory Reagents used in the analytical work, or incidental to the purification of materials, were purified and always tested to assure their freedom from interfering impurities. Distilled water was specially prepared and was free from ammonia.

Preparation of Pure Antimony

Stibnites from Peru, Bolivia, Borneo and Hungary were obtained. Each ore was separately digested in concd. hydrochloric acid and from the extract antimony trichloride was obtained by fractional distillation at 220° followed by 5 redistillations. The chloride was next transformed into chloro-antimonic acid (SbCl₅.HCl.4¹/₂H₂O) by the method of W. Schmid.² SbCl₃ + Cl₂ + $4^{1}/_{2}$ H₂O \longrightarrow SbCl₅.HCl. $4^{1}/_{2}$ H₂O. The fourth crop of the crystals of this salt was broken up in a large amount of distilled water and the solution boiled to complete the hydrolysis. Antimonic acid thus precipitated was washed and evaporated to dryness with nitric acid to expel the last traces of the chloride. The antimony oxide thus formed was reduced with potassium cyanide in silica crucibles and the metal cast in plaster moulds free from iron. The buttons of antimony obtained were scrubbed with clean sand and from them a 1mm, layer was filed off all around. They were then washed thoroughly and etched in dil. sulfuric acid, washed again in distilled water and melted in silica crucibles under borax. The metal was kept at its melting point for a long time and slowly cooled. It was again superficially cleaned as described above, and powdered in an agate mortar.

The powdered metal was melted in a current of pure dry hydrogen over a lime support as employed by T. W. Richards in his purification of silver. Bright buttons of antimony thus obtained were etched, dried and powdered in an agate mortar. The powdered metal was heated in a current of pure dry hydrogen to dry it and to reduce the traces of oxide that may have been formed during powdering. This treatment was given just before the metal was weighed for the determination of the density or the atomic weight.

All of the 4 samples of antimony were prepared and purified under identical conditions to assure their superficial uniformity. The method as outlined above was suggested by E. Groschuff⁴ after a rigorous investigation and comparison of all the methods so far known for obtaining pure antimony, and was adopted by H. H. Willard and McAlpine⁵ in the preparation of antimony for determination of its atomic weight.

Balance and Weighings.—Weighings were made on a balance sensitive to 0.05 mg., using standardized weights and the method of substitution.

- ² Schmid, Z. anorg. Chem., 44, 37 (1905).
- ³ Richards, This Journal, 27, 459 (1905).
- 4 Groschuff, Z. anorg. Chem., 193, 164 (1918).
- 5 Willard and McAlpine, This Journal, 43, 797 (1921).

Ratio of Potassium Bromate to Arsenious Oxide

Method.—Arsenious acid was transferred directly from the balance pan into stoppered bottles. After a few cubic centimeters of sodium hydroxide solution had been added, the bottles were warmed on a waterbath to effect solution, and when they had cooled 100 cc. of moderately strong hydrochloric acid was poured into each. Titration with potassium bromate solution was carried out in exactly the same manner as described later for antimony.

On standardization, 1.000 g. of potassium bromate in solution was found to be equivalent to 0.0034487 g. of arsenious oxide. The ratio $3As_4O_6$: $4KBrO_3$ was found to be: (1) 1.78154, (2) 1.77983, (3) 1.77870, (4) 1.77455, (5) 1.77805, (6) 1.77901, (7) 1.77875; av., 1.778633. The calculated molecular weight of potassium bromate is 167.02; that determined from the above ratio is 166.92, with 0.02% moisture and 0.04% experimental error.

Ratio of Ammonium Bromide to Silver

This was determined in a Stas box by the method of A. Scott.¹ Ammonium bromide solution was standardized against silver. 1.000 g. was found to be equivalent to 0.00108015 g. of silver or 0.00098082 g. of silver bromide. One g. of silver nitrate solution was equivalent to 0.99335 g. of ammonium bromide solution. Solid ammonium bromide was compared to pure silver and the ratio NH₄Br: Ag was found to be (1) 0.90770, (2) 0.90734, (3) 0.90788; av., 0.90776. From this the atomic weight of silver is determined to be 107.91. This is affected by 0.03% experimental error.

Ratio of Silver to Potassium Bromate

A weighed quantity of potassium bromate was transferred to a stoppered bottle, dissolved in distilled water and reduced to potassium bromide with a slight excess of sulfur dioxide solution. The bottle was then warmed and a few drops of fuming nitric acid were added to oxidize sulfite to sulfate. In a separate bottle the requisite quantity of silver was dissolved in nitric acid according to the method of Stas. Both the bottles were taken into a dark room, and the silver solution after dilution was transferred completely into the bromide solution bottle. The titration was completed in the Stas box in the same manner as described for the ratio of ammonium bromide to silver. The ratio KBrO₃: Ag was found to be (1) 1.54923, (2) 1.54875, (3) 1.54900, (4) 1.54900, (5) 1.54892; av., 1.54924 (reduced to a vacuum). The molecular weight of potassium bromate, from the ratio, is found to be 167.13, from which 0.02% moisture and 0.045% experimental error are to be deducted.

Ratio of Antimony to Potassium Bromate

Antimony was dried in a current of hydrogen immediately before use. It was weighed by transfer from a weighing bottle into a clean, conical flask. The metal was dissolved in concd. sulfuric acid and the cooled

solution was transferred completely to a stoppered bottle containing 100 cc. of distilled water and 20 cc. of hydrochloric acid. A quantity of potassium bromate, approximately but slightly less than equivalent, was weighed, dissolved in hot distilled water and the solution poured into the bottle that contained antimony solution, in small quantities at a time. The reaction is represented by the equation 3SbCl₃ + KBrO₃ + 6HCl → 3SbCl₅ + KBr + 3H₂O. Since the quantity of potassium bromate added is less than the equivalent amount, an excess of antimony trichloride is left in the above process. This was titrated with 0.01 N potassium bromate solution, using methyl orange as the indicator. The bromate solution was standardized against the sample of antimony under consideration. As the ratio of the metal to bromate is different with different samples of antimony, the standardization of the solution was repeated before each new sample of the metal was analyzed. The solution was drawn from a weight pipet and the strength expressed as grams of antimony equivalent to 1.000 g. of solution. The amount of antimony that reacted with the solution was deducted from the total antimony taken, and thus only that quantity of the metal was considered that had reacted with the solid bromate. All of the samples of antimony were titrated under precisely the same conditions; therefore, there could be no error of experiment that could modify the relative differences of the element from different sources. The ratio of the different samples of antimony to potassium bromate. 3Sb: KBrO₃, was found to be as follows.

Table I

121.144	121.563	121 720	122 374

In conclusion the author wishes to express his thanks to Mr. C. T. Heycock for his keen interest in the problem.

Summary

Antimony metal has been prepared from stibnites from Hungary, Borneo, Peru and Bolivia, and compared with potassium bromate by

solution in sulfuric acid, addition of solid potassium bromate and completion of the titration with $0.01\ N$ potassium bromate solution. The purity of potassium bromate was established by comparison with silver and arsenious acid. The atomic weights of antimony thus obtained are as follows: stibnite from Hungary, 121.14; from Borneo, 121.56; from Peru, 121.72; from Bolivia, 122.37.

ELECTROMETRIC TITRATION OF IODATE, BROMATE, CHLORATE, FERRICYANIDE WITH TITANOUS SULFATE

By W. S. HENDRIXSON Received May 22, 1923

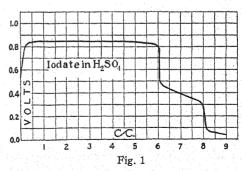

In a recent paper from this Laboratory¹ it was stated that work was in progress on the titration of oxidizing substances with titanous ion.

In the work described in the present paper the same general methods and the same apparatus as mentioned in the former paper were used. The stirrer was provided with a mercury seal and all titrations were carried out in an atmosphere of carbon dioxide. All solutions affected by light were kept in bottles coated with a black enamel paint, provided with siphons and never unstoppered. Titanium solutions were standardized with permanganate and dichromate. The latter and the solutions of pure potassium iodate, bromate and chlorate were made up by weight and the contents of calibrated flasks at 20° .

Titration of Iodate with Titanous Ion

A 0.05 N solution of iodate was made up by weight and also standardized with pure iodide and thiosulfate. The volume of the solution at the end

of the titrations was about 300 cc. and its acidity was between N and 2 N with sulfuric acid. Hydrochloric acid was unsatisfactory. A sharp drop of about 0.3 volt occurred when the iodate was all decomposed, as shown in Fig. 1. The iodine set free reacted slowly on further addition of titanium and an excess was required to drive the

reaction to completion. Possibly the sharp rise in voltage at first shows the effect of hypo-iodous acid, the first fall the decomposition of all the iodate, and the final fall the completed reduction of the iodine. The

¹ Hendrixson and Verbeck, This Journal, 44, 2382 (1922).

second fall is fairly sharp but irregularly delayed by about 1 cc., the average for the determinations of Table I being 29.92 cc., while that calculated is 28.95. The correct end-point is found by multiplying the volume of titanium at the first fall by 1.2, which is in accord with the following equations representing the stages in the reduction:

$$5\text{Ti}_2(SO_4)_3 + 2\text{HIO}_3 + 5\text{H}_2SO_4 = 10\text{Ti}(SO_4)_2 + 6\text{H}_2O + \text{I}_2$$
 (1)
 $\text{Ti}_2(SO_4)_3 + \text{I}_2 + \text{H}_2SO_4 = 2\text{Ti}(SO_4)_2 + 2\text{HI}$ (2)

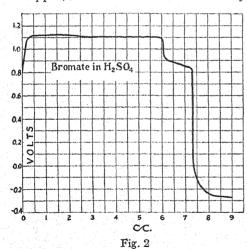

Table I gives the results thus obtained. The concentration of the titanous solution was $0.05~N~\times~1.727$; 50 cc. of iodate solution was used in each experiment.

TABLE I
TITRATION WITH TITANOUS ION

Titration of Bromate with Titanous Ion

After the first draft of this paper had been written there came to the notice of the author the work of Zintl and Wattenberg, in which they used bromate as one of the substances for back-titration in the determination of copper,² and of arsenic and antimony with titanium.^{2b} In their first

paper the work was carried out at 80° and no adequate description is given of the details of the titration of bromate against titanium. Their work does not seem to interfere with the main purposes of this study, which have been to ascertain whether these halogen acids could be accurately and quickly determined directly and at room temperature with titanous salts, and by the electrometric method.

Pure potassium bromate free from bromide, iron and other impurities likely to occur, was

used in making a $0.05\ N$ solution. In the first series, the titration vessel containing 50 cc. of bromate solution, 200 cc. of boiled water and 10 cc. of $10\ N$ sulfuric acid, was filled with carbon dioxide after which the vessel³ was closed air-tight except for the exit through the mercury seal. The

² Zintl and Wattenberg, (a) Ber., 55, 3366 (1922); (b) 56, 472 (1923).

³ Knecht and Hibbert, "New Reduction Methods in Volumetric Analysis," 1918, p. 65.

curve obtained on adding titanium in excess strikingly resembles that for iodate and is shown in Fig. 2. The sudden rise at first and the two falls in potential have the same meaning. Apparently either fall may be used for determining the end-point, by calculation, of course, if the earlier fall is used. In this work the long, abrupt fall marking the disappearance of the bromine was preferred. In some experiments free way was provided for the escape of bromine from the titration vessel and its passage over potassium iodide solution, but only a trace of free iodine was obtained. When the vessel was tightly stoppered, therefore, the escape of bromine must have been negligible.

Five experiments carried out as described gave the concentration of the bromate solution $0.05~N~\times~1.002$, with the average deviations from this factor +0.0007 and -0.004.

Hydrochloric acid can be used to advantage instead of sulfuric, if not in concentration sufficient to set bromine free before the titration vessel can be filled with carbon dioxide. Apparently, it should not greatly exceed 0.5 N at the end of the titration. In the presence of this acid a smaller amount of bromine seems to be set free, the two reactions running more or less simultaneously, and the end-point is more quickly reached. The first fall in potential, found when sulfuric acid is used, is nearly obliterated in the presence of hydrochloric. In Table II the acid varied from 0.5 N to N, and the concentration of the titanium solution was 0.05 $N \times 1.4663$; 50 cc. of bromate solution was used in each experiment.

TABLE II

Titration of Bromate with Titanous Ion in Hydrochloric Acid 50 cc. of Bromate Solution Used

The literature shows increasing use of bromate as an analytical reagent, making greater the need of methods for its rapid and accurate determination under various conditions. It is hoped to give this matter further and more detailed study.

Titration of Chlorate with Titanous Ion

Knecht and Hibbert³ and Kikuchi⁴ have titrated chlorate with excess of titanous salt, titrating back with ferric iron and thiocyanate as indicator. Kikuchi titrated iodate and bromate also, working in all cases at 60°. The results here obtained show that chlorate may be accurately determined at room temperature by the addition of titanous salt at the end-point.

Apparently, chlorate may be titrated with titanium in either sulfuric or hydrochloric acid solution from less than N to more than 4 N. Expts.

⁴ Kikuchi, J. Chem. Soc. Japan, 43, 173 (1922); C. A., 16, 1716 (1922).

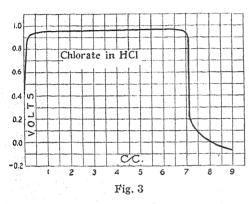

3 and 4, Table III, were carried out in sulfuric, and others in hydrochloric acid. Fig. 3 shows a very great rise in potential, due to hypochlorous acid,

Table III

TITRATION OF CHLORATE WITH TITANOUS ION

 $T_{12}(SO_4)_3$, cc..... 35.52 35.60 35.45 35.60 35.75 35.57 Chlorate factor.. 0.9990 1.0025 0.9920 1.0025 1.0060 1.0010 Av., 0.05 $N \times$ 1.0013

when a little titanium solution is added, then nearly constant voltage, then a very sharp curve to the nearly vertical drop of about 0.8 volt.

The titanous solution was $0.05 N \times 1.407$; 50 cc. of chlorate solution was used in all experiments.

Experiments similar to those with bromate showed, by titration of the iodine set free with thiosulfate, that with the free exit thus provided, not more than 1 part in 600 of the chlorine escaped oxidation in the titration vessel and, hence, when the vessel was closed the chlor-

ine that escaped must have been negligible.

Titration of Ferricyanide with Titanous Ion

The determination of ferricyanide by the potential method seems as simple and accurate as the determination of ferric iron in other compounds. When the solution is concentrated and sulfuric acid is used, a brown precipitate forms near the end of the titration with titanium, but this does not interfere with the end-point.

A solution of pure potassium ferricyanide, determined by the iodine method showed a concentration of $0.05~N~\times~0.7200$. Six titrations with titanium gave a mean for the factor of 0.7201, and the average departures from the mean were +0.0005 and -0.0004.

The author wishes to express his hearty appreciation to Mr. Paul W. Hush and Mr. Neil L. Crone for assistance in this work.

Summary

- 1. Iodate, bromate and chlorate have been determined electrometrically at room temperature by the addition of titanous salt to the solution to the end-point; that is, without adding an excess and titrating back with an oxidizing agent.
- 2. Iodate is best determined in sulfuric acid by the addition of titanium to the solution until the first drop in potential is reached, which marks the

disappearance of the iodate; bromate and chlorate may be determined in either sulfuric or hydrochloric acid by adding titanium to the solution until the final drop which marks complete reduction, is reached.

3. Ferricyanide also may thus be determined electrometrically with titanium as accurately as any other form of ferric iron.

THE CONDUCTANCE OF DILUTE AQUEOUS SOLUTIONS OF HYDROGEN CHLORIDE

By Henry C. Parker¹ Received June 4, 1923

Introduction

In a recent investigation,² Kraus and Parker determined the conductance of iodic acid, using water of various degrees of specific conductance and both glass and quartz cells. If it is assumed that the measurements made in quartz cells with water having a specific conductance of $0.09-0.12\times10^{-6}$ are correct, the presence of an error was demonstrated in the measurements made with water of higher specific conductance and with glass cells. The use of glass cells was shown to influence the results to a somewhat greater extent than the impurities that are present in ordinary "conductivity water." The limiting value for the equivalent conductance of iodic acid, found from the measurements in the quartz cells, was about 0.9% higher than the value found from the measurements in glass cells.

It appeared of interest to confirm the results of Kraus and Parker by carrying out a series of measurements with a typical strong acid in a quartz cell. Hydrochloric acid was chosen, since the equivalent conductance of the chloride ion is known with considerable certainty, and since solutions of this acid may be made by weighing the constituents involved.

Preparation of Materials

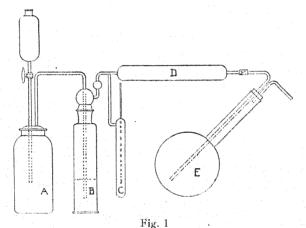

The hydrochloric acid was prepared by means of the apparatus shown in Fig. 1.

In this figure, A is the generating flask; B is a wash bottle, containing "special" sulfuric acid, and C is a trap, introduced to prevent the water in the absorption flask from being drawn back into the generating flask. This trap is likewise filled with "special" sulfuric acid. The absorption flask E is constructed of clear quartz and has a capacity of approximately 1500 cc. D is the drying tube containing phosphorus pentoxide. With the exception of a short piece of rubber tubing, connecting the absorption flask to the drying tube, all connections are of glass. In order to avoid contamination,

¹ National Research Fellow in Chemistry.

² Kraus and Parker, This Journal, 44, 2429 (1922).

no stopcock grease was used on any of the ground-glass joints. The entire apparatus was cleaned and dried, the absorption flask being cleaned with cleaning mixture, live steam, distilled water, and finally with purified air. After drying, the absorption flask was weighed; and after several rinsings about 1000 g. of special conductivity was collected. About 80 g. of a highly purified commercial sodium chloride, which had been purified from insoluble matter by filtration and evaporation of the solution to dryness, was then introduced into the generating flask and the sulfuric acid was allowed to flow upon it. Toward the end of the reaction a small amount of heat was applied to the generating flask, but care was exercised to keep the reaction running smoothly. When the reaction in the flask was completed, the difference in the weight of the absorption flask amounted to about 45 g. and this weight, together with the weight of the water originally introduced into the flask, gave the data necessary for the purpose of calculating the strength of the acid, with the accuracy of a few thousandths of 1%. Both of these

weights were reduced to a vacuum. In this reduction, allowance was made for the change in density of the solution, and thus the difference between these weights gave the weight of the hydrogen chloride reduced to a vacuum.

The acid prepared in this manner had a concentration of approximately 1.4 N. About 150 g. of this concentrated solution was transferred by means of air pressure into a second quartz flask, which contained a weighed quantity (about 1000 g.) of the special conductivity water. The strength of this dilute solution (approximately 0.1 N) was still known to a few thousandths of 1%. This was the solution that was employed in making up the dilute solutions whose conductance was finally measured. The water employed in making up these solutions was prepared in the still described by Kraus and Dexter.⁴ The method of purifying the air as well as other details of manipulation were the same as those previously employed with icdic acid and need not be further described here.

Measuring Apparatus

The apparatus employed in carrying out the electrical measurements was the same as that previously employed by Kraus and Parker. A fre-

³ This purification was ca ried out by Mr. G. F. Des Autels, to whom thanks are also due for checking several resistances and supervising the generation of the hydrogen chloride.

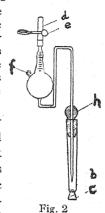

⁴ Kraus and Dexter, This Journal, 44, 2468 (1922).

quency of 1217 was used throughout this investigation at a potential of approximately 7 volts.

The dilute solution, mentioned above, was introduced into the large quartz cell from the weight pipet which is shown in Fig. 2.

All parts of this pipet that come in contact with the acid are constructed of quartz. The capacity is approximately 50 cc. The glass tube b serves the double purpose of centering the pipet over the hole in the stopper of the cell through which the solution was introduced, and of preventing evaporation when the weight of the pipet is being determined. The stopper h into which this glass tube is ground is made of de Khotinsky cement. The flow of the acid solution from this pipet is governed by the pinch clamp e.

The cell used in these measurements is the 3-liter Vitreosil flask called Cell II in the article by Kraus and Parker, a drawing of which is shown in Fig. 3 of that article. In the present investigation, however, the glass tubes, which were used to support the electrodes were replaced by quartz, the seals being made after the manner described by Kraus.⁵ With these new electrodes it

will be called Cell II_d . Owing to the difference in expansion between platinum and quartz, it was impossible to connect the brace across the lower ends of the electrodes to the upper part of the electrode stems, as was done with Cell II. The electrodes were held rigidly, however, by means of 2 heavy platinum wires, crossed nearly at right angles and welded to the small platinum tube leading from the quartz seal. This method gives sufficient rigidity for all purposes.

Intercomparison of Cell Constants

In a recent article, Kraus and Parker showed the presence of an error in the data given by Kohlrausch and Holburn which have been commonly used for the purpose of determining the cell constants in conductance investigations. They suggested the use of the data given by Kohlrausch and Maltby for the specific conductance of potassium chloride, as a basis for this determination, and gave the necessary data for making up these solutions by weight methods. This was the procedure adopted in the present investigation. It was necessary, however, to use auxiliary cells of pipet form in order to calibrate Cell II_d. The constants for these auxiliary cells were determined at 18°, the data for which are found in Table I, while the intercomparison between these and Cell II_d was carried out at 25°.

Av.	11.657_{4}	5.94768	3,15074

The apparatus used in these intercomparison measurements is shown in Fig. 3 of a recent article by Parker. In these measurements, unlike the measurements given in that article, the tube at o, the stopcock at q, and the pinch clamp at p were used in order to break the column of liquid through the tube e, just before resistance measurements were taken. This was accomplished by introducing a slight air pressure into the system at a, when the stopcock q was open.

In the present investigation, 4 pipet cells were intercompared with the Cell II_d . These 4 cells, called Cells A, B, C and D, were connected by means of T-tubes in the neighborhood of d (Fig. 3 mentioned above) and also at the upper part of the stem, where connections were made with the air line. In this manner the 4 cells acted simultaneously when the solution was being mixed. Resistance measurements were taken upon the 5 cells at each of a series of concentrations. Measurements were also made when the pipet cells were connected in series and parallel combina-

⁹ Parker, This Journal, 45, 1371 (1923).

tions. The results obtained with Cells II_{d} , A and D, and with the parellel-series combination (obtained when B and C are connected in parallel and in series with D) are given in Table II. Cells A, B and C have electrodes of 1 sq. cm. cross section, while Cell D has electrodes of twice this area. Cell A is about 15 cm. in length, while the others are half this length.

In the first column are given the resistances of Cell II_d obtained at each of a series of concentrations of potassium chloride. The data given in the second column have been obtained by dividing the resistance of Cell II_d by the resistance of Cell A, for the same concentration, and multiplying this by the constant of Cell A as found in Table I. The data found in the third and fourth columns have been obtained in a similar manner by making use of the resistances of the parallel-series combination and of Cell D, respectively. The values found in these columns, therefore, represent the apparent "cell constant" of Cell II_d for that particular concentration, when this is determined by intercomparison with the cell in question. These values are plotted against the resistance of Cell II_d in Fig. 3.

Theory for the Variation

A theory to account for the variation in the apparent "cell constant" exhibited in the curves shown in Fig. 3 is outlined in a recent article by Parker. This theory accounts for this variation by the presence of an adsorbed layer in proximity to the electrodes, which has a greater or less resistance than the body of the solution according as the electrolyte is adsorbed negatively or positively, in this layer. This theory appears to be supported by the present investigation. It appears probable that potassium chloride is negatively adsorbed at a platinum surface, while hydrochloric acid is positively adsorbed. 11

Such an absorbed layer would be affected to a considerable extent by the conditions under which measurements were made. First, the resistance of this layer would have a relatively less effect upon the total resistance of the cell if the distance between the electrodes was great. Second, the resistance of such a layer would be inversely proportional to the cross section of the electrodes. Third, the adsorption occurring would be sensitive to factors such as traces of grease, dissolved gases, etc., which would lower the surface tension. Fourth, if we assume that the effect of the alternating current is to "spread out" this layer, it is evident that the "spreading" would be influenced by the voltage and frequency of the alternating current. The first of these phenomena has, in a previous communication, 12 been shown to occur. The occurrence of the second

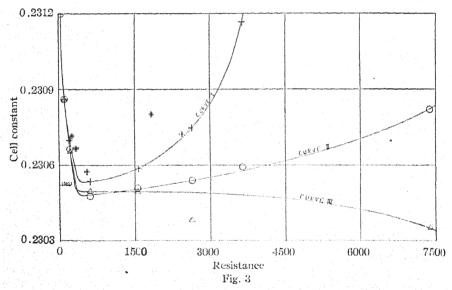

¹⁰ Ref. 9, p. 1378.

¹¹ Pickles, J. Chem. Soc., 119, 1278 (1921). Schilow, Z. physik. Chem., 100, 425 (1922).

¹² Ref. 9, p. 1376.

will be demonstrated in a subsequent article. The third effect has been noted by the writer and was mentioned by Taylor and Acree.¹³ The occurrence of the fourth was mentioned by Kraus and Parker,¹⁴ in their measurements upon iodic acid, where it was found that an increase of voltage caused an apparent increase in the resistance of potassium chloride and a decrease with iodic acid solutions. (A decrease is likewise obtained with hydrochloric acid.) This difference in sign may be accounted for by the difference in sign of the adsorption.

If we have negative adsorption in the case of potassium chloride solution, then the resistance of the adsorbed layers in contact with the electrodes will be greater than that of the body of the solution. Hence the observed resistances in the more dilute solutions may be expected to be greater than the true resistances. Since the "cell constant" is proportional to the resistance of a given solution, such a cell as Cell II_d would exhibit an increasing "cell constant" in the more dilute solutions when intercompared with a cell showing a relatively smaller correction, due to these adsorbed layers. In case the intercompared cell exhibited a relatively greater

correction, then the apparent "constant" of Cell II_d would decrease in the more dilute solutions. Both of these cases may be seen in Fig. 3, where the "constant" of Cell II_d is shown as a function of the observed resistance. Its "constant" has been determined by intercomparison with 3 cells, 2 of which show a relatively smaller correction and the third a greater. Curves I and II, representing the former case, were plotted

¹³ Taylor and Acree, This Journal, 38, 2416 (1916).

¹⁴ Ref. 2, p. 2438.

from the intercomparison data obtained with Cells A and D, respectively, while Curve III, representing the latter case, represents measurements with the parallel-series combination. The large effect obtained when cells are measured in series seems to be characteristic of these phenomena.

The independent and characteristic variation exhibited by the curves in Fig. 3 constitutes one of the strongest proofs that the effect is caused in the cell. It is evident that the measurements at the higher resistances are not at fault, or at least not to the same extent for each cell, since no single correction curve for the higher resistances could possibly be drawn which would reconcile these variations.

Selection of Cell Constant

The effect of such an adsorbed layer would probably become negligible in the more concentrated solutions. In order to determine the constant of a cell, therefore, this would make it advantageous to use as concentrated a solution as possible, providing the resistance is sufficiently high to avoid polarization effects. This condition has been fulfilled in all cases where the standard cells were calibrated directly against the standard potassium chloride solutions, so it is believed that the values given in Table I are accurate. With Cell II_d, however, it is impossible to utilize one of these standard solutions, on account of the presence of polarization at the low resistances which would be obtained. The electrodes of Cell II_d are about 2.3 cm. apart, so it is probable that there will be a considerable correction for the adsorbed layers, at the higher resistances, when potassium chloride solutions are used. It is evident that, if a cell could be found which would give nearly the same relative correction as Cell II_d at a given concentration but which could be calibrated with one of the standards in the more concentrated solutions, the corrections would cancel in the more dilute solutions, where the two cells could then be intercompared. Such a secondary cell is illustrated in the case of the parallel-series combination. It is evident from the curves of Fig. 3 that the Cell D has a somewhat greater correction than Cell IId, while the parallel-series combination has only a slightly smaller correction. Curve III, therefore, is most suitable for the determination of the correct "constant" for Cell IId.

Cell II_d was thrice intercompared with Cells A, B, C and D. The results that were obtained after Run I with hydrochloric acid and at the conclusion of Run II indicated a constant about 0.02% greater than that found in the first series of measurements. This is shown by the points above Curve I, Fig. 3, where the results obtained after Run I are indicated as double crosses and those after Run II as triple crosses. The difference was so small, however, that the same "constant" for Cell II_d was assumed for the two runs, the results of the two intercomparisons being averaged. If we select Curve III to determine the "constant" of Cell II_d,

it is evident from the preceding discussion that the position upon this curve the most likely to give the correct value would be in concentrated solutions, just before the commencement of polarization. When this value was determined from Curve III, a correction of 0.01% was added, on account of the higher value found in the two later intercomparisons. The final value thus selected was 0.23052, which is indicated in Fig. 3. If Curves I or II had been chosen, instead of Curve III, this value would be changed to the extent of about $\pm 0.015\%$.

It is probable that hydrochloric acid is positively adsorbed from the solution in contact with the electrodes. Whether the actual resistance should be greater or less than the observed will depend on two factors. First, the resistance of the adsorbed layer would be less than that of the body of the solution, and if the alternating current is assumed to cause considerable "spreading" of this adsorbed material, the resistance observed might be less than the true resistance. Second, if this adsorption takes place to such an extent that the concentration in the body of the solution is reduced, the observed might be greater than the true resistance. The large volume of the solution (3 liters) surrounding the electrodes of Cell II_d would reduce an error of the latter nature, but in any case it is probable that these factors both are small and partly compensate each other, so it is evident that no correction should be applied to this "constant" when measuring acid solutions. The assumption will be made then that this value remains fixed at 0.23052, for these solutions.

Density of Hydrochloric Acid

The densities of the solutions of hydrochloric acid which were used in these calculations were taken from the data of Cameron and Robinson. These data are plotted in Fig. 4. It is seen that the points at 0.005 and $0.01\ N$ do not coincide with the curve, which is drawn straight down to the density of water at $25\,^\circ$, in the more dilute solutions. These points appear to be somewhat in error, although the other points agree with the results of Reyher¹⁶ for more concentrated solutions, so it is thought that the remaining points are sufficiently reliable. In any case, the corrections for the change of density upon the dilute solutions used in this investigation are almost negligible. The densities were read from the smooth curve shown in Fig. 4.

Experimental Procedure and Results

The experimental procedure was very similar to that employed in the investigation with iodic acid, the principle changes being due to the use of a solution of hydrogen chloride, instead of a solid in order to make up the solutions whose conductance was examined. The water in which the

¹⁵ Cameron and Robinson, J. Phys. Chem., 14, 1 (1910).

¹⁸ Reyher, Z. physik. Chem., 2, 548 (1888).

hydrogen chloride was absorbed and that used for diluting the concentrated solution was drawn from the cell as it was being filled with the conductivity water, and consequently was the best obtainable. The diluted standard hydrochloric acid solution, added to the cell, was allowed to stand in the quartz pipet for an hour before the latter was refilled and weighed. The pipet was handled with great care in order that the weighings should be accurate. The smallest amount of acid solution weighed was 0.6 g., while the weighings were reproducible to better than 0.1 mg. In all, 50 cc. of the dilute acid solution was added to the cell. The neck of the quartz flask serving as a cell was large enough so that this amount of

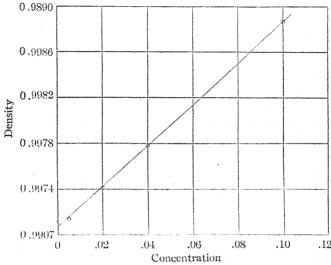

Fig. 4.—Density of HCl at 25°. Cameron and Robinson

liquid made a difference in the height of the solution of about 25 mm. It was experimentally determined that the addition of this amount of solution did not change the "cell constant" appreciably.

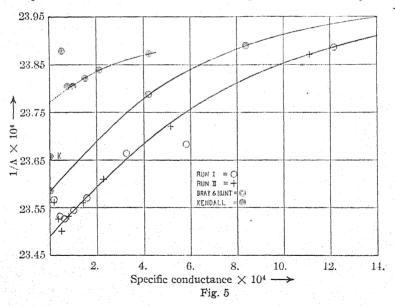

The data obtained in these measurements are given in Table III, where are shown the values of the equivalent conductance and the concentration, the latter of which is expressed in millimoles per liter. The molecular weight assumed for the hydrochloric acid is 36.468. At the bottom are given the weight of water in the cell, the specific conductance of the water, the cell constant, resistance of the leads and the strength of the acid solution that was added to the cell. The latter is expressed as grams of hydrogen chloride (reduced to a vacuum) per gram of solution (weighed in air). The other weights are reduced to a vacuum.

These data are shown in Fig. 5, where $1/\Lambda$ is plotted against $C\Lambda$. The consistency of this work with hydrochloric acid is seen to be nearly as great as that of the results with iodic acid. The impurities in the water are

shown to influence the results to a somewhat greater degree than in the case of iodic acid. A possible explanation is that the dilute acid solution becomes slightly contaminated when it is being introduced into the cell. The first two points in each run will have to be neglected, when extrapolating

to infinite dilution, for this reason. The seventh point of Run I is also in error for some unknown reason.

Conductance Data at Round Concentrations

The data given in Table III were plotted on a large scale in order to interpolate the values at round concentrations. $\Lambda_0 - \Lambda$ was plotted against

C. The first two points of each run were neglected, and Runs I and II were weighted as 1:2, which is about the relative precision of two runs carried out in succession in this manner. The values for the concentration expressed in millimoles per liter, the values for the specific conductance, for γ , for K, and for the equivalent conductance, Λ , which were obtained by means of this plot are given in Table V. In the last column are given the average deviations of the experimental points from the interpolated curve, when these points have been weighted as above.

In Table VI are found the values at round concentrations for iodic acid, from the work of Kraus and Parker. The for this interpolation the values of $\Lambda_0 - \Lambda$ were plotted against C, for the more dilute solutions, while Λ was plotted directly against C in the more concentrated. Run 1 was neglected, and Runs 2, 3, 4 and 5 were weighted in proportion to the numbers 1:2:3:4 which is, again, about the relative precision of a series of measurements carried out in this manner. Runs 6 and 7 were weighted as 1:2, over the part of the concentration range covered by these runs. The first two points in Runs 6 and 7 were neglected for reasons given in that article. The data given in Table VII (Kraus and Parker, Run 10) obtained in glass cells, are used for the interpolation below $0.01\ N$, where the concentration is high enough so that the impurities in the water and alkali from the glass do not measurably affect the results.

The average deviations of the experimental points from the interpolated curve are again given in the last column when weighted as above. If the different runs are not weighted, these deviations will, of course, be

¹⁷ Ref. 2, pp. 2439-40. In Table VI, p. 2439 the data given for the concentrations of Run 7 are expressed in moles per liter instead of millimoles, as indicated at the top of this table.

increased, but the values given in this column are very close to the values which would be found by using the more precise of the runs and neglecting

the others. For that reason these values represent the true precision of the interpolated results more nearly than the values obtained by giving equal weight to the different runs. It may be mentioned that these interpolated results agree, in the more concentrated solutions, with the work of Ostwald¹⁸ and Groschuff¹⁹ upon iodic acid, well within the limits of their experimental error. This fact gives a check upon the values of the cell constants used in these measurements.

Discussion

The experimental values of $1/\Lambda$ and $C\Lambda$ obtained in the two runs with hydrochloric acid are plotted in Fig. 5. In comparison with the similar curve for iodic acid, given by Kraus and Parker, ²⁰ it is seen that the form of the curve is very similar in the two cases. The slope of the curve for hydrochloric acid is less steep, showing the latter to be the more highly ionized, but the concentration range over which the measurements approximate a straight line, within the experimental error, is nearly identical. This type of curve may thus be considered the general form holding for solutions of strong acids. It is evident that such acids obey the mass-action law to a much closer approximation in the very dilute solutions than is the case with the inorganic binary salts.

The value for the equivalent conductance at infinite dilution obtained from this curve is 425.69. If the value for Λ_0 for the chloride ion at 25° is assumed to be 75.8, as found by Noyes and Falk, 21 this will give a value of 349.89 for the limiting value of the hydrogen ion at 25°. The corresponding value obtained with the iodic acid was 349.93. It is evident that this check is even better than could be reasonably expected, although these numbers are based, in reality, upon the relative values of Noves and Falk for the Λ_0 of the iodate ion at 18° and the chloride ion at 25°,22 and thus these measurements constitute a check upon these relative values. The greater chance for a discrepancy between the work with iodic acid and hydrochloric acid, however, consisted in the determination of the cell constants, in the two cases. When the cell constants were determined in the investigation with iodic acid, it was not recognized that these quantities varied with the concentration in the case of some electrolytes, and it was more by accident than intention that the determination of this quantity was made in the neighborhood of the minimum of the cell constant curve for Cell II, when intercompared with the standard cell. The accurate method of intercomparison used in the present investigation had not then been devised and, since the measurements in the more dilute

²² Thus, in the work with iodic acid the value for Λ_0 of the iodate ion, at 25°, was experimentally determined with considerable precision, in terms of the value given by Noyes and Falk, for 18°.

solutions were inconsistent, there was no other choice than to accept the measurements made in the neighborhood of this minimum point. The degree of precision obtained in these two investigations, which is indicated by the values for the average deviations from the interpolated curve, would indicate, of course, that a check of this order of magnitude might be expected.

The value of the mass-action constant, corresponding to the straight line drawn in the more dilute solutions of Fig. 5 is 0.105, while the corresponding value for iodic acid was found to be 0.0717. Whatever other significance these values may have, it is probable that at least they measure the relative "strength" of these acids.

Work of Other Investigators.-Hydrochloric acid has been the subject of several important investigations, although no two of the investigations show agreement at infinite dilution. Most of the investigations have been carried out at 18°, but these may be compared with the measurements at 25°, with the aid of a few assumptions. Thus, the difference in the Λ_0 values for the hydrogen ion at 18° and 25° was found experimentally by Kraus and Parker to be 34.31; while the difference between the corresponding values for the chloride ion given by Noyes and Falk, is 10.3, giving a total of 44.6 to be added to the value of Ao for the hydrochloric acid at 18° in order to transform this value to that for $25^{\circ}.^{23}$ When this quantity is added to the values of Λ_0 at 18° . the following values are obtained at 25°, for the two most accurate investigations: Goodwin and Haskell, 24 - 424.7; Noyes and Cooper, 25 - 423.6. The values obtained in the investigations made at a temperature of 25° are as follows: Bray and Hunt, 26 -424: Kendall. 422.7. The values obtained are seen to vary between 422.7 and 424.7. for the Λ_0 of hydrochloric acid at 25°. All of these investigations were made with glass cells and conductivity water of only a fair degree of purity. In none of these investigations were the solutions made up by weight methods, a procedure that has been accomplished in the present investigation.

Conclusion

The results of Kraus and Parker with iodic acid in glass and quartz cells and with water of various degrees of purity would indicate that, except for experimental error, the investigations mentioned in the pre-

 23 It is believed that this value of 44.6 is relatively accurate, since the relative values of Λ_0 at 18° and 25° are known to a greater degree of precision than the absolute values. Thus, if the value given by Bates [This Journal, 35, 534 (1913)] or by Washburn [This Journal, 40, 158 (1918)] had been chosen for the Λ_0 of the iodate ion at 18°, instead of that of Noyes and Falk, the Λ_0 values of the hydrogen ion, determined by Kraus and Parker at 18° and 25° would both have been increased to the extent of 0.1 or 0.2, respectively, while the difference between these values at 18° and 25° would have remained unchanged. Similarly, the difference in the values of Λ_0 for the chloride ion at 18° and 25°, as found by the extrapolation method used by Bates and Washburn, would agree closely with the value 10.3 obtained by Noyes and Falk.

- ²⁴ Goodwin and Haskell, Phys. Rev., 19, 369 (1904).
- 26 Noyes and Cooper, Carnegie Inst. Pub., 63, 137 (1907).
- ²⁶ Bray and Hunt, This Journal, 33, 787 (1911).
- ²⁷ Kendall, *ibid.*, **39**, 13 (1917).

ceding paragraph should give a value of Λ_0 approximately 0.9% low.28 This should vary, however, with the circumstances surrounding the investigations. Thus Goodwin and Haskell used a cell of which the greater part was of platinum, and employed two different methods of correcting for the impurities in the water, so it is evident that their determination should be but slightly lower than the value found in the present investigation. Bray and Hunt, whose calculated values are indicated in Fig. 5, used the results of Goodwin and Haskell for extrapolation, so these results should likewise, be, close. Both of these conditions are fulfilled. The results of Noves and Cooper and of Kendall, of which the latter are shown in Fig. 5, are 0.5% and 0.7% lower, respectively, than the results obtained in the present investigation. The value of Λ_0 given by Kendall, however, is not obtained by extrapolation but by adding the limiting value for the chloride ion to a value of the hydrogen ion previously obtained. The value 422.7, obtained in this manner, is indicated in Fig. 5 at a point considerably below his experimental results and marked "K." An extrapolation such as indicated by the dotted line would give a result of 420.7, showing difference of 1.2% from the results obtained in the present investigation. The value for the mass-action constant, determined from this extrapolation, would be about 0.08 higher than that obtained in the present investigation. Thus, it is indicated that the results of other investigators confirm the conclusions reached by Kraus and Parker regarding the effect of (1) the impurities in the water and (2) the use of glass cells upon the conductance of an acid solution.

It is interesting to note that the impurities of the water in the investigation by Kendall are apparently of a different nature from those obtained in the present investigation. This is seen by the sharper minimum in his experimental results. The next experimental point in the more dilute solutions would come far above the plot. The slope of the line given by Bray and Hunt's calculated values is nearly identical with that obtained in the present investigation. This fact would tend to support the expedients employed by Goodwin and Haskell for the elimination of the effect of the impurities in the water. The actual experimental values obtained by Bray and Hunt are far above the plot and cannot be indicated. It appears, however, that their curve would coincide with the curve obtained in the present investigation, if these were extended to the more concentrated solutions.

The value of Λ_0 for the hydrogen ion obtained in this investigation is based upon a somewhat firmer foundation than the value obtained with

Upon extrapolating to infinite dilution the results for iodic acid in a glass cell, 386.04 is found for Λ_0 , a value 0.9% lower than for the results in quartz cells. The corresponding value of the mass-action constant is 0.05 high.

iodic acid, due to the greater certainty in the determination of the cell constant. Heretofore, the values of Λ_0 for the other ions were known to a considerably greater degree of accuracy than was the case with the hydrogen ion. These two investigations upon iodic acid and hydrochloric acid seem to have reversed the situation. The extrapolation of the results with strong acids appears to be somewhat more safely accomplished, due to the fact of closer conformity to the mass-action law. Until the values for the chloride and iodate ions are known with a greater degree of accuracy, there is small purpose in giving the value for the hydrogen ion to more than one decimal place. However, if it is assumed that the value for the chloride ion at 25° is 75.8, the most probable value for the hydrogen ion appears to be 349.89 \pm 0.05. This number will, of course, represent a lower limit to this value, due to the method of extrapolation.

Summary

- 1. The conductance of aqueous solutions of hydrochloric acid has been determined at 25° between the concentrations of 0.04 and 3.0 millimoles per liter. The solutions were made up by weight methods to an accuracy of a few hundredths of 1%. Water was used having a specific conductance of the order of 0.1×10^{-6} .
- 2. The values for the equivalent conductance show a slight maximum in the neighborhood of 0.1 millimoles per liter, due to the influence of the impurities in the water, which apparently cause a somewhat greater effect than in the case of iodic acid.
- 3. Comparison with the results of other investigators confirm the conclusions of Kraus and Parker regarding the considerable influence of the impurities in the water and of the alkali in glass cells upon the conductance o dilute acid solutions.
- 4. Values at round concentrations have been interpolated from the results upon hydrochloric and iodic solutions. The data for iodic acid are given from $0.05 \times 10^{-3} \ N$ to $0.5 \ N$.
- 5. The "cell constant" was determined by an intercomparison with 3 standard cells, over a considerable range of concentrations with potassium chloride as the electrolyte. The unusual results of this intercomparison may be explained by assuming the presence of an adsorbed layer (in contact with the electrodes) whose resistance is greater or less than that of the body of the solution, according to whether the electrolyte is negatively or positively adsorbed. One of the intercompared cells apparently has a greater correction for this "adsorbed layer" than the cell used in the measurements with the hydrochloric acid, while the other two have a smaller correction. On the supposition that hydrochloric acid will be positively adsorbed and will consequently have but slight correction for this effect, a value for the "constant" is selected at the minimum point of

the "cell constant" curve, which value is assumed to remain fixed in the measurements with the acid solutions.

6. Extrapolation of the results upon the assumption that the mass-action law is approached as a limiting form at infinite dilution, gives a value of Λ_0 for hydrochloric acid of 425.69. Assuming that the value of Λ_0 for the chloride ion at 25° is 75.8, a value of 349.89 for the hydrogen ion at that temperature is obtained. By comparing this with the value 349.93 obtained by Kraus and Parker for iodic acid, the value 349.89 \pm 0.05 is deduced as the most probable value for the hydrogen ion at 25°—the basis for the "cell constant" being more firmly established in the measurements with hydrochloric acid. The mass-action constant corresponding to this extrapolation has a value of 0.105.

GERMANIUM. VI. METALLIC GERMANIUM. REDUCTION OF GERMANIUM DIOXIDE. PREPARATION OF FUSED GERMANIUM. PHYSICAL AND CHEMICAL PROPERTIES

By L. M. Dennis, Katharina M. Tressler and F. E. Hance² Received June 4, 1923

Material.—The germanium that was used in these investigations was prepared by the reduction of pure germanium dioxide that was practically free from other metals, including arsenic.³

Dehydration of Germanium Dioxide

Since it was desirable that germanium dioxide be thoroughly dehydrated before experiments were made upon its reduction, the lowest temperature at which complete dehydration resulted was ascertained by heating germanium dioxide that had been dried at about 100° to successively higher temperatures until constant weight was obtained. It was found that the dioxide is completely dehydrated when heated to a temperature of 950° for about 3 hours, and that there is no volatilization of germanium dioxide at a temperature of 1250°. The dehydration may be effected rapidly by heating the oxide over a gas-air blast flame, and the product that is formed is not hygroscopic.

- ¹ This article is based upon the theses presented to the Faculty of the Graduate School of Cornell University by Katharina M. Tressler and F. E. Hance in partial fulfilment of the requirements for the degree of Doctor of Philosophy.
- ² The experimental work of this investigation was carried on separately and not jointly by Miss Tressler and Mr. Hance.

Reduction of Germanium Dioxide by Aluminum

The heat of formation of aluminum oxide is far greater than that of silicon dioxide or of stannic oxide, and since germanium lies between silicon and tin in the fourth group of the Periodic Table, it is clearly apparent that metallic aluminum will easily reduce germanium dioxide.

Forty g. of germanium dioxide and 14 g. of granular aluminum were mixed and placed in a small iron crucible that was thickly lined with aluminum oxide. The reaction was started with an ignition mixture of magnesium and barium dioxide and proceeded quietly through the mass. A dense white cloud was, however, given off, and this was found to consist chiefly of germanium dioxide. A button of bright, lustrous metal was obtained, but as this represented a yield of only 61%, further study of this reaction was abandoned for the present.

Reduction of Germanium Dioxide by Hydrogen

Winkler⁴ found that germanium dioxide is reduced by hydrogen at red heat but that the reduction is not always complete.

Müller⁵ stated that the ratio GeO₂:Ge was not suited to the determination of the atomic weight of germanium, both because of impurities in the germanium oxide that he used, and because of loss that he thought resulted from the formation and escape of germanium hydride.

In our study of this reaction, the following procedure was employed. A small sample of germanium dioxide that had been dehydrated at about 950° was weighed into a porcelain boat which was heated to definite temperatures in hydrogen. The hydrogen was first passed through spirals of redhot copper gauze and then through drying towers filled with calcium chloride. A quartz tube drawn out to a fine tip was joined to the exit end of the quartz combustion tube.

After the air in the apparatus had been displaced by hydrogen, the temperature of the combustion furnace was slowly raised. At 500° the surface of the white germanium dioxide began to turn gray, and when the temperature had risen to 540° , the whole surface of the dioxide had taken on this gray color. The temperature was maintained at this point for 45° minutes, the powder changing in that time to a very dark gray. The heat was then turned off, the boat was allowed to cool in hydrogen, and the hydrogen was displaced by air. The weight of the boat showed that reduction was not complete. It was, therefore, re-inserted in the combustion tube and heated in hydrogen for 90° minutes more at from 500° to 540° . The weight of the residual germanium now coincided with the calculated amount (at. wt., Ge = 72.5).

⁴ Winkler, J. prakt. Chem., 142, 177 (1886); 144, 188 (1887).

⁶ Müller, This Journal, 43, 1085 (1921).

	G.
Wt. GeO ₂ taken	0.3498
Heated in hydrogen at 500-540° for 45 minutes, loss	.0909
90 minutes longer, additional loss	.0162
Total loss in 2 ¹ / ₄ hours	.1071
Calculated loss in weight, GeO ₂ —Ge	.1071

The boat and its contents were then heated for $2^{1}/_{4}$ hours longer in hydrogen at 500-540°, and the temperature was finally raised to 900°. No change in weight resulted.

During the reduction of the oxide, a porcelain dish was repeatedly held in the hydrogen flame burning at the quartz tip, but at no time was there formed a mirror of metallic germanium nor did any deposit appear within the quartz combustion tube beyond the boat. The above results indicate that a comparatively small amount of germanium dioxide is quantitatively reduced by about 2 hours' heating in hydrogen at 540° , and that no volatilization of germanium or of any compound of the element takes place under these conditions.

Metallic germanium prepared in this manner is a dark gray powder without metallic luster.

When, however, attempt was made to reduce larger amounts of germanium dioxide that completely filled 4 porcelain boats, there appeared on the walls of the quartz tube beyond the boats a deposit that was black nearest the heated area, and shaded off through brown to yellow toward the cold end of the tube.

Total charges of from 10 to 14 g. always yielded an amount of germanium that was below the calculated quantity.

Preparation of Fused Germanium

A preliminary trial of Winkler's method⁴ of fusing powdered germanium, prepared by reducing germanium dioxide in hydrogen under a layer of borax glass showed that a small amount, about 1 g., could be fused to a bead that was free from boron and sodium. When, however, a larger sample of 26 g. of germanium was heated with 30 g. of borax glass in a covered porcelain crucible over the blast lamp to a temperature of about 930°, the germanium did not coalesce. About 5% of boric acid was then added to a fresh portion of this mixture, and upon fusion there resulted small granules of germanium from 1 to 3 mm. in diameter which were coated with a black powder. The flux also was deep black in color, and when digested in water it yielded a reddish-brown, flocculent residue, consisting chiefly of hydrated germanous oxide.

When the cover of the crucible was lifted during the heating of powdered germanium under borax glass, a white cloud of germanium dioxide rose from the crucible. This misled Winkler into believing that the "vaporization temperature of germanium lies only slightly above its melting point."

As a matter of fact, metallic germanium, as will be shown later, is not volatile at a temperature 300° above its melting point, and the white cloud that rose from the open crucible is doubtless due, as Biltz⁶ has also pointed out. to oxidation of volatile germanous oxide that is formed by the action of molten borax upon germanium.

Powdered germanium was next fused under a layer of anhydrous sodium sulfate. Small samples yielded bright, silvery granules of germanium and a larger sample, about 40 g. of germanium, gave a button of brilliant luster that was distinctly crystalline in character. The button was surrounded by a vellow, transparent, glass-like material that evolved hydrogen sulfide when treated with hydrochloric acid and contained 48.94% of germanium. The weight of the button was only 73.8% of the powdered germanium that was used.

Some of this metal from the first fusion was again fused under sodium sulfate at temperatures rising from 829° at the beginning to 1050° at the end of the 10 minutes' heating. Reduction of the sodium sulfate again resulted and the metallic regulus weighed only 77.7% of the fused germanium that was employed.

These results made it clear that salts of oxy-acids are not suitable as fluxes for this purpose. The compound that is employed as a flux should have a somewhat lower melting point than germanium, but should not appreciably volatilize or dissociate at a temperature that would ensure fluidity of the metal. Sodium chloride seemed to meet these requirements.

Fig. 1.—(Actual size)

A porcelain crucible 7 cm. in diameter was charged first with a layer of pure, dry sodium chloride to a depth of about 15 mm., then with a layer of a mixture of equal parts of salt and powdered germanium that had been ground together, and finally with salt nearly to the top. It was then covered and placed upon a short, perforated cylinder of asbestos board which rested on an iron ring. The crucible was surrounded by 3 concentric tubes of asbestos board through the walls of which passed a long asbestos

tube which permitted the reading of the temperature of the crucible by means of an optical pyrometer. The crucible was heated by the direct flame of 2 blast lamps, and the temperature was brought to from 980° to 1000° and was held there for about 30 minutes. The crucible was

⁶ Biltz, Z. anorg. Chem., 72, 313 (1911).

allowed to cool and was then broken. The germanium was found as a single, brilliant, crystalline button. (Fig. 1.) Adhering salt was removed by digesting the metal in hot water. This solution was alkaline, probably because of the presence of sodium germanate which resulted from the fluxing off of the small amount of the oxides of germanium in the powdered metal. The yields from 3 fusions, in which 24, 38 and 41 g. of powdered germanium were used, were 96%, 96.05% and 96.30%, respectively. Are spectrograms of the preparations showed that they were free from other metals.

Behavior of Germanium when Heated in Hydrogen

Müller states⁵ that germanium dioxide is completely reduced to the metal by heating in hydrogen to 700°, but that there is always loss of weight when the metal is further heated in hydrogen at the above temperature. In a later article⁷ he adds that "metallic germanium is slowly but appreciably volatile in hydrogen at elevated temperatures," and he gives these temperatures as 750–800°. He ascribes the loss in weight to the direct formation of a volatile hydride, the evolution of which was indicated by the formation of a slight black precipitate when the escaping hydrogen was "passed through a solution of a silver salt." He gives no description of his method of preparing metallic germanium, nor of the manner in which its purity was tested.

Since it seemed possible that the loss in weight of germanium when heated in hydrogen, as reported by Müller, might be due to the presence of oxides of germanium in the metal and the consequent volatilization of germanous oxide, detailed experiments were made with the object of first freeing the germanium from all trace of oxide and then heating this product in pure hydrogen to ascertain whether loss in weight and the formation of a volatile hydride resulted.

The germanium that was used was prepared by reduction of very pure germanium dioxide in hydrogen, fusion of the powdered germanium under pure sodium chloride, pulverizing the fused germanium and repeating the fusions under salt until the solution of the flux proved to be neutral to litmus. The final button was pulverized, the powder was digested several times in boiling water to remove the salt, and the product was then heated for 8 hours at 1000° in a current of carefully purified hydrogen.

A sample of this metal weighing 8.93 g. was placed in a porcelain boat which was then inserted in a quartz tube that rested in a combustion furnace. Hydrogen prepared by electrolysis was passed through a purifying chain containing, in the order given, alkaline potassium permanganate, calcium chloride, concd. sulfuric acid, platinized asbestos heated to 260°, soda lime, calcium chloride, concd. sulfuric acid and phosphorus pentoxide.

⁷ Müller, This Journal, 44, 1909 (1922).

The hydrogen then entered a Y-tube, part of it passing through the quartz combustion tube, and the remainder directly through two Wagner absorption flasks containing a $0.25\ M$ solution of silver nitrate. The hydrogen issuing from the quartz tube passed through a small tube with 3 constrictions, and then through 2 Wagner flasks containing a solution of silver nitrate of the above-mentioned concentration.

After the air in the apparatus had been displaced by hydrogen, the germanium was heated to 760–800°. The temperatures were measured by a thermocouple, the hot junction of which was in the quartz tube directly beside the boat.

In the first run, the solution of silver nitrate in both pairs of Wagner flasks was blackened and a small amount of germanium was found in the flasks connected to the combustion tube. The constricted tube was not heated during this first experiment. Since the silver nitrate was reduced not only by the hydrogen that passed over the germanium but also by that which came directly from the purifying chain, 2 spiral gas-washing bottles containing a $0.25\,M$ solution of silver nitrate were inserted at the head of the chain and the metal was then heated in the current of hydrogen on 5 successive days. The introduction of silver nitrate into the purifying chain stopped the reduction of the silver nitrate by the hydrogen that entered it directly from the chain.

The run, each day, consisted in first passing the hydrogen over the germanium at 760-800° for from 2 to 4 hours (see Table I) and through the heated, constricted tube and the solution of silver nitrate beyond, then allowing the furnace to cool, weighing the germanium and the constricted tube and testing the silver nitrate for germanium. The germanium was then replaced in the quartz tube, the apparatus was connected, air was swept out by hydrogen, and the temperature of the furnace was raised to 960-1000° to melt the germanium in the boat. The furnace temperature was then lowered until the germanium solidified, and was then immediately raised again until the metal melted. The metal was in this manner alternately melted and solidified about 10 times each day with the object of repeatedly exposing fresh surfaces of it to the action of hydrogen and thus gradually reducing all oxide of germanium that might be present. During the first 3 days, the germanium lost weight, but the loss steadily became less. There was a correspondingly decreasing amount of germanium deposited in the heated, constricted tube, but no reduction of silver nitrate was observed after the first day. Four hours' heating on the fourth day gave no loss in weight of germanium and no evidence of germanium passing out of the combustion tube. For the fifth day's run, a new quartz tube was used so that the formation of a deposit in the tube beyond the boat, which would be due to the presence of germanous oxide, might clearly be observed. No such deposit was seen, the germanium did not lose weight, no deposit

was formed in the constricted tube, and no reduction of the solution of silver nitrate resulted.

When, however, hydrogen was passed over *molten* germanium the metal invariably lost weight and germanium was found in the flask that contained the solution of silver nitrate.

Table I

Results Obtained when a Sample of Germanium Was Heated in Hydrogen

Day	Duration of heating each day 760-800° Hrs.	Total duration of heating 760-800° Hrs.	Loss in weight of germanium G.	Gain in weight of constricted tube G.	Germanium present in AgNO ₃ solution
1	3	3	0.0090	Tube broke	Trace
2	2	5	.0066	0.0054	None
3	4	9	.0020	.0004	None
4	4	13	.0000	.0000	None
5	4	17	.0000	.0000	None

The above experiments seem to warrant the conclusion that metallic germanium which is free from oxide does not lose weight when heated in hydrogen to a temperature not exceeding 800°, but that volatilization of germanium does take place when hydrogen is passed over the molten metal.

The Physical Properties of Germanium

Melting Point.—Determinations of the melting point were made by melting the metal in a graphite crucible that rested in an electric-resistance furnace, measuring the temperature by means of a platinum-platinumrhodium couple and a potentiometer indicator, and plotting the cooling curve. The metal was purified by several fusions under pure sodium chloride and then repeatedly melting and cooling it in a current of hydrogen. It was finely pulverized and 105 g. of it was packed in the graphite crucible around the quartz protection tube of the thermocouple, being firmly tamped down to exclude air as completely as possible. crucible was next filled to the top with tightly packed sugar carbon, placed in the electric furnace and heated to about 980°. The current was then turned off, and temperature readings were made at 1-minute intervals as the metal cooled. A constant value of 958.5° was obtained over a period of 10 minutes. Repetition of the determination gave the same result. The germanium was then removed from the crucible, pulverized, melted in a current of hydrogen, again pulverized, and its melting point redetermined as above. The results were identical with the first value. An arc spectrogram of the metal was then made and the material was found to be free from impurities.

The Sprouting of Germanium.—When germanium is melted and is then quickly cooled, the "sprouting" of the metal, as noted both by Winkler and by Biltz, 6 is very pronounced. Winkler ascribes the phenomenon to

the great increase in volume of the metal when it crystallizes from the molten condition.

In one of our early experiments, 1 g. of the powdered metal, when fused under borax, solidified to a small button about 4 mm. in diameter, from the top of which projected a cone-shaped protuberance with a needle-sharp point about 3mm. high. When a larger amount, about 30 g., was fused under sodium sulfate and more slowly cooled, there resulted a circular regulus about 40 mm. in diameter and 10 mm. thick, from the middle of the upper surface of which there had been extruded a mass about $^{1}/_{4}$ the size of the main button. The whole surface was beautifully crystalline.

When germanium was melted in a small porcelain boat in an atmosphere of nitrogen, it was found that the sprouting along the surface was very prominent. It was noticed that when the heating was stopped and the asbestos housing around the quartz tube was removed, the metallic germanium retained its redness after the quartz tube and the porcelain boat had resumed normal appearance. The metal then gradually darkened, but suddenly there appeared within the ingot one or two bright spots which rose to the surface and then, with the suddenness of the bursting of a bubble, became dark. This observation seems to support Winkler's explanation of the "sprouting" of germanium. The exterior of the molten metal cools and solidifies first, and when the molten interior solidifies, the resulting expansion of the metal causes it to burst through the surrounding shell. This usually occurs on the upper surface where the shell is thinnest. When the regulus is slowly cooled from the molten condition, the sprouting is much less pronounced and the surface of the metal then shows a beautiful, coarsely crystalline structure.

Since it was possible that the sprouting of germanium might be due to absorption of the gas in contact with which it was melted and the expulsion of this gas upon solidification, as is the case with silver when melted in an atmosphere of oxygen, the metal was melted in a porcelain crucible that rested in a special, closed steel crucible which was exhausted of air. The steel crucible was then cooled as quickly as possible, and although the sprouting was not so marked as when the chilling was more rapid, 3 large protuberances appeared on the sides of the button. Winkler's explanation of the sprouting of the metal, therefore, appears to be correct.

Specific Gravity.—Crystalline germanium that had carefully been purified for the determination of the melting point (see above) was melted in porcelain boats in hydrogen in such a manner as to yield small, compact globules of the metal about 2 mm. in diameter. Two pycnometers were used, one of 10cc. capacity and the other of 25 cc. After the germanium and water had been placed in the pycnometer, the instrument was placed in a desiccator under diminished pressure for several hours. The results of the two determinations were the same, d_{20}^{20} , 5.35. This value agrees very

closely with that obtained by Dr. Albert W. Hull who used a sample of the same preparation of germanium. He wrote: "The density given by X-ray analysis is 5.36. This is correct within one-half of one per cent., and should agree with the density found by other methods for chemically pure germanium free from holes."

Hardness.—Metallic germanium is extremely brittle. However, attempts to determine the hardness of crystalline germanium were kindly made for us by Professor H. Diederichs. Both the Brinell test and the Shore Scleroscope hammer test were separately applied to blocks of polished germanium. In both cases the metal was so thoroughly shattered that even approximate estimation of the hardness could not be made.

A compact specimen of very pure germanium, weighing about 12 g., was then submitted to Professor A. C. Gill, who found that it scratched a well crystallized piece of adularia, but made no mark on epidote. This fixes its hardness number between 6 and 6.5 at, say, 6.25.

Crystal Form.—When a considerable amount of germanium is fused in a large porcelain crucible under a thick layer of salt and is slowly cooled it shows beautiful crystallization on the upper surface. Professor A. C. Gill examined the preparation shown in Fig. 1, and states that it is an aggregate of elongated crystals that are bounded in some cases by octahedral faces. Some of the crystals exceed 3 cm. in length, and occasionally are notched or covered with small dendritic branches. He adds that this particular form of surface crystallization seems to be peculiar to germanium, although it resembles to a certain degree that of antimony.

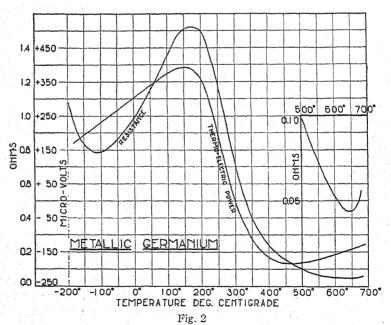

Electric Resistance and Thermoelectric Power.—For the determination of these two values it was necessary to prepare a small bar of germanium about $25 \times 5 \times 5$ mm. This was first attempted by fusion of the metal in a small porcelain boat in an atmosphere of nitrogen. The cool ingot, however, adhered tenaciously to the porcelain, and the bar of germanium could not be removed without fracture because of the very great brittleness of the metal.

To obviate this difficulty, the boat was lined with a paste of germanium dioxide which was then thoroughly dried. The boat was filled with powdered crystalline germanium and was heated in nitrogen in a quartz tube as before. When the temperature of the melting point of germanium was reached, the tube filled with a thick, dark colored vapor. Heating was at once stopped, and examination of the contents of the tube after cooling showed that the germanium dioxide had turned black where it had been in contact with the metal, and that there had been considerable volatilization of this black substance which is most probably germanous oxide. This observation is directly in accord with the statement of Winkler that germanous oxide results when germanium and germanium dioxide are heated together under a layer of borax glass, and contradicts the assertion of

Biltz⁶ that germanium dioxide is not reduced by germanium when a mixture of the two is heated to 1000° in a current of nitrogen.

Since the heat of formation of aluminum oxide is more than twice that of silicon dioxide, and this in turn is undoubtedly greater than that of germanium dioxide, it seemed obvious that germanium might be melted in contact with aluminum oxide without reacting upon it. Consequently a porcelain boat was filled with a paste made by grinding aluminum oxide with a little water, a small bar of wood of the size of the desired ingot was pressed down into this paste and the whole was dried. The piece of wood was then removed and the mould was filled with crystalline germanium. This was melted in nitrogen and a bright bar of the metal was obtained. So far as could be seen, there was no reaction whatever between the germanium and the aluminum oxide. The uneven, upper surface of the bar was smoothed with emery paper and was then used for the determination of the electric resistance and thermoelectric power of the metal.

These determinations were made by Professor C. C. Bidwell of the Department of Physics at Cornell University, and the results appeared in full

in The Physical Review, 19, 447 (1922). They are here shown graphically in Fig. 2. He found that in respect to its electric resistance and thermoelectric power, germanium conforms to its position in the Periodic Table.

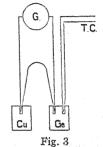

The Molecular Inversion of Germanium.—Bidwell's results cited in the foregoing paragraph show that the thermoelectric power of germanium is a linear function of the temperature, and the resistance is an exponential function of the form, $\log R = \log A + aT + Q/kT$, except in the range 100° to 600°. Between these temperatures there appeared to be a slow, reversible transformation whose completion apparently depended only upon the temperature and not upon the time.

Mr. Hance studied this inversion using the differential method of Roberts-Austen.⁸ This procedure consists in the measurement of the heat effect of the test specimen simultaneously with that of a neutral body.⁹

The general arrangement of the apparatus is shown in Fig. 3. The neutral body was made from a block of pure copper that was obtained

from the United States Mint at Philadelphia. It was cylindrical in shape and of about 2cm. diameter. A hole 4 mm. in diameter was bored into it to half its depth.

Germanium is so brittle that it was impossible to drill holes into it. For this reason it was cast in a special mould in the form of a circular block with 2 holes extending halfway through the block. The weights of the blocks of copper and germanium were made such that the two would have very nearly the same heat capacity. Each block was inserted in a thin-walled graphite shell

which in turn was surrounded by a cylinder of asbestos board. The two were then placed side by side in an alundum electric furnace core of 7.5 cm. bore. In the grooves of this was laid Nichrome wire which was then

covered with refractory cement.

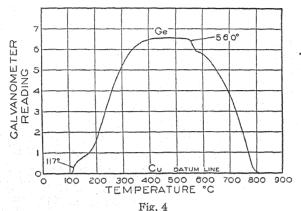

After the wires from the galvanometer G and the thermocouple T.C. were inserted into the openings in the blocks as shown in Fig. 3, the openings and the space around the blocks were tightly packed with asbestos wool. Each block was then covered with a layer of sugar carbon, and the alundum core was next tightly packed to its top with asbestos wool. The cup, thus charged, was placed in a circular box of asbestos board 25cm. wide and 22cm. high, which was then packed with the wool.

After connections with the galvanometer and thermocouple had been made, the heating current was thrown on. The temperature was raised very gradually until 850° was reached, which took about 90 minutes. Readings of the galvanometer deflections and of the temperature of the germanium were made throughout this period at 1-minute intervals. The results are shown in Fig. 4. Inversion began at 117° and reached a maximum at 560°. The experiment was repeated and data concordant with those of the first run were obtained.

⁸ We are greatly indebted to Professor Bidwell for many valuable suggestions during the progress of these determinations.

Hoyt, "Principles of Metallography," McGraw-Hill Book Company, 1920, Part I, pp. 151-156.

It thus appears that germanium passes through a gradual molecular inversion with two or more modifications between the temperatures of 117° and 560° .

Chemical Properties of Germanium

I. Behavior toward Various Gases

Oxygen.—Finely divided amorphous germanium, prepared by the reduction of germanium dioxide in hydrogen, was heated in a porcelain boat in a quartz tube in a current of purified oxygen. The metal was not attacked at 600° even when the temperature was held at this point for 30 minutes. Oxidation began at 605° and proceeded very rapidly at 615° , but was not complete even when the temperature was raised to 900° . The gain in weight at 750° was about 50% of that calculated, and about 90% at 900° . When heated to this latter temperature, the material in the boat was found to be fused to the porcelain and was light gray in color.

These experiments were then repeated with purer germanium that had been fused under sodium sulfate and then finely pulverized. The temperature of the furnace was slowly raised, but no oxidation was observable until the temperature rose to 714° . At this point the powdered metal glowed brightly and white germanium dioxide formed along the edges of the charge and in spots on the top of it. The heating was continued for 30 minutes at 730° and the material was then allowed to cool in oxygen. The product showed a glazed surface and was black in color, with a fine white powder, germanium dioxide, around the edges and distributed irregularly over the top of the mass. The gain in weight of the charge was found to be only 50.8% of that calculated, and the residue in the boat evidently contained germanous and germanic oxides, and metallic germanium. The boat and its contents were then again heated in oxygen, the temperature being gradually raised above 730° . At 900° a white sublimate began to condense in the cool end of the quartz tube. Since germanium dioxide

is not volatile at this temperature, it is evident that the sublimate must be due to the volatilization of germanous oxide which is then further oxidized to the dioxide.

It appears, therefore, to be impossible under the conditions here described, to oxidize germanium quantitatively to the dioxide at a temperature of 730° or lower. At higher temperatures, there is loss of material from the boat through volatilization of germanous oxide.

Hydrogen Sulfide.—Winkler states that when vapor of sulfur is led over germanium that is heated to "incipient redness" (presumably about 600°), the two elements combine to form germanous sulfide, GeS.

Hydrogen sulfide begins to dissociate between 400°10 and 440°.11 To ascertain whether germanium is acted upon by hydrogen sulfide below this dissociation temperature, some of the finely powdered metal was heated in a current of dry hydrogen sulfide at slowly rising temperatures.

No action was apparent up to 290°. At that temperature a slight, yellowish-white deposit appeared in the cool portion of the tube. At 350° this deposit had become heavy. When the temperature dissociation of hydrogen sulfide was reached, the interior of the boat was coated with a yellow deposit and white fumes issued from the tube. At the end of the experiment, 692°, the interior of the tube was so heavily coated with the yellow deposit that the boat was invisible. Minute black crystals were mixed with this yellow coating.

The residue in the boat presented a glazed surface and was of a deep purple color, which persisted when the material was powdered. There was copious evolution of hydrogen sulfide when the material was treated with coned. hydrochloric acid.

The results of the experiment indicate that germanium is not attacked by hydrogen sulfide at temperatures below 200°, and that the action of the gas upon the metal is comparatively slight until dissociation of the hydrogen sulfide begins, when the reaction becomes that between sulfur and germanium with the formation of germanous sulfide as noted by Winkler.

Sulfur Dioxide.—Finely pulverized germanium was heated in a current of sulfur dioxide which had been dried and freed from sulfur trioxide by passing it through concd. sulfuric acid. The temperature was gradually raised to 672° .

When cool, the boat was withdrawn and examined. Its contents were yellowish-gray in appearance, and the end of the boat which was farthest from the sulfur dioxide inlet was covered with a heavy coating of a fine white powder. The cool end of the quartz tube was also coated with a heavy white deposit. When heated with hydrochloric acid, both the white powder and the yellowish-gray material in the boat gave off hydrogen sulfide.

¹⁰ Myers, Ann., 159, 124 (1871).

¹¹ Pelabon, Compt. rend., 124, 35, 686 (1897).

The results show that sulfur dioxide acts upon crystalline germanium at a temperature somewhat below 500°, that this action is rapid between 510° and 530°, and that the disulfide and the dioxide of germanium are formed in the reaction.

II. Behavior in Various Liquid Reagents

Small weighed pieces of fused germanium were immersed in the reagents listed below. They were allowed to stand at room temperature for 1 week, and were then removed, washed with distilled water, dried at 110° and weighed.

Weighed samples were then placed in the same reagents which were maintained at a temperature of 90° for 8 hours. The samples were again washed, dried and weighed.

At room temperature and at 90°, water, a 50% solution of sodium hydroxide, 1:1 hydrochloric acid, concd. hydrochloric acid or 1:1 sulfuric acid did not act upon the metal, which remained bright and lost no weight. The germanium was slightly tarnished by a 10% solution of sodium hydroxide, both cold and warm, and lost about 0.5% in weight. Dilute nitric acid, 1:1, acted upon the metal superficially with the formation of white germanium dioxide, and the loss in weight amounted to about 7% at room temperature and 1.6% at 90° . Concd. nitric acid darkened the surface of the metal, but there was no appreciable loss in weight. The metal was not attacked by concd. sulfuric acid at room temperature, but lost 1% in weight at 90° . Hydrofluoric acid, 19N, caused a loss in weight of only 0.1% at room temperature, and about 0.8% at 90° . Immersion in a 3% solution of hydrogen peroxide at room temperature for 1 week resulted in a loss of weight of about 40%, and at 90° for 8 hours the loss in weight was about 70%.

When finely powdered germanium is digested in a 3% solution of hydrogen peroxide at about 100°, it finally dissolves entirely and the product, germanium dioxide, dissolves in the water present. This solubility of germanium in hydrogen peroxide, which was first observed by us early in 1921, appears to offer an excellent method for determining the atomic weight of germanium by means of the ratio Ge: GeO₂. This will be studied in the near future in this Laboratory.

III. Behavior of Germanium when Fused with Various Solid Reagents

Potassium Hydroxide.—Ten g. of potassium hydroxide was melted in a nickel crucible and was heated until water had been expelled. A small piece of fused germanium weighing 0.0992 g. was then dropped into the molten mass. It began to dissolve immediately with the copious evolution of tiny bubbles. The mass was kept molten and in 10 minutes the reaction ceased and the metal had entirely disappeared. When dissolved in water, the material gave a clear, colorless solution.

Sodium Hydroxide.—The reaction was similar to that with potassium hydroxide.

Potassium Hydrogen Sulfate.—A small particle of germanium weighing $0.1534~\rm g$. was dropped into a platinum crucible containing $10~\rm g$. of molten potassium hydrogen sulfate and allowed to remain there for $10~\rm minutes$. No visible reaction occurred. The sample, however, lost 6% in weight, showing that the metal is slowly attacked by this reagent.

Sodium Carbonate.—Fragments of crystalline germanium were dropped into molten sodium carbonate. The metal was rapidly attacked, with the evolution of gas and with the projection of bright sparks from the surface of the reagent. The metal was eventually dissolved.

Potassium Cyanide.—Molten potassium cyanide was without action. Potassium Chlorate.—Molten potassium chlorate very slowly attacked germanium, and at the end of 30 minutes a small amount of metal had passed into the solution.

Potassium Nitrate.—When small pieces of germanium were dropped into the molten potassium nitrate, there was immediate reduction of the nitrate and evolution of gas. The germanium was oxidized and was found to be present in the water solution of the residue.

Sodium Peroxide.—The reagent was carefully melted and a small amount of germanium was dropped into it. Vigorous reaction at once took place and continued until the germanium had entirely passed into solution.

Germanium Carbide

Preliminary experiments upon the formation of a carbide of germanium analogous to silicon carbide, SiC, led to negative results. When a mixture of finely powdered germanium and sugar carbon was heated in a small electric furnace, part of the germanium vaporized and burned in the air, and part of it condensed on the upper portion of the crucible as brown germanous oxide. The germanium that remained in the crucible was found to have fused into globules, but there was no evidence of combination of the metal with carbon. The experiments will be continued.

Summary

This article deals with the dehydration of germanium dioxide, the reduction of germanium dioxide by aluminum and by hydrogen, the preparation of fused germanium, the behavior of germanium when heated in hydrogen, the melting point, specific gravity, hardness, crystal form, electric resistance, thermoelectric power, molecular inversion and sprouting of germanium, and the behavior of the metal toward various gases, liquid reagents and molten solid reagents.

THE CATALYTIC DECOMPOSITION OF HYDROGEN PEROXIDE IN A BROMINE-BROMIDE SOLUTION. II. RATE MEASURE-MENTS IN DILUTE SOLUTIONS AND IN THE ABSENCE OF SULFATE, AND THEIR INTERPRETATION AS A FUNCTION OF THE ACTIVITY PRODUCT OF HYDROBROMIC ACID

By Robert S. Livingston and William C. Bray Received June 5, 1923

Introduction

In a previous paper on the catalytic decomposition of hydrogen peroxide in a bromine-bromide solution, a series of rate measurements were given for the steady-state condition, and the following kinetic equation was determined.

$$-d(H_2O_2)/dt = K(H_2O_2) (H^+) (Br^-)$$
 (1)

where K is approximately equal to 0.0144 for acid concentrations between $0.2\ N$ and $3.0\ N$. The concentrations used were expressed in moles per liter, and were computed on the assumption that all the electrolytes were completely ionized. It was pointed out at that time that the value of K, obtained from measurements in solutions of potassium bromide and sulfuric acid, increased as the acid concentration was decreased below $0.2\ N$. To determine the nature of this effect, steady-state rate measurements have now been made in still more dilute solutions of sulfuric acid and potassium bromide, and in various acid-bromide solutions that do not contain sulfate.

Experimental Measurements

As before, the reactions were conducted at 25° in the dark. The experimental conditions, methods, and method of computing used were the same as those explained in detail in the earlier paper.

At low acid concentration the decomposition of hydrogen peroxide in the absence of the catalyst introduces a fairly important error. To determine what concentration of acid was necessary to render this effect negligible, three blank solutions were prepared. Each blank contained 0.12 M hydrogen peroxide. To two of them sulfuric acid was added to make them 0.0098 N and 0.073 N, respectively. The first order constant (k) for the neutral solution was 0.176×10^{-4} , a more rapid rate than that at 0.0147 N acid, Expt. 7, Table I. No appreciable loss occurred during a 3-day

¹ Bray and Livingston, This Journal, **45**, 1251 (1923). On p. 1253, fifth from the last line, F_{298} ° is a misprint for ΔF_{298} °.

Recently our attention has been called to a paper by Trifonow: "Eigenschaften und Struktur der Persalpetersäure" (Trifonow, Z. anorg. Chem., 124, 123 (1922)). He mentions the oxidation of bromide and the reduction of bromine by hydrogen peroxide, and states that the former reaction may be retarded by dilution and the latter by the addition of a fairly large quantity of KBr and $\rm H_2SO_4$.

period, in either of the acidified solutions, although these experiments were made in ordinary glass containers. To reduce this effect, wax-lined bottles were used in several of the experiments conducted at low acid concentration (Expts. 7, 8 and 9 of Table II, and 3 and 6, of Table VI).

Steady-State Measurements in the Presence of Dilute Sulfuric Acid

The results of 7 determinations of the steady-state rate in the presence of dil. sulfuric acid are summarized in Table I. The arrangement and conventions adopted are the same as those used in the third table in the preceding paper. In this table (I) the peroxide concentrations marked with an asterisk were made up from "Superoxol," the others from a 3% commercial solution. Since the interest of this table is primarily in the rate constants, the values of "bromine-calculated" and "tribromide-calculated" have been omitted; the "calculated" bromine concentrations were used, however, in computing the values of R listed. The last three columns will be explained later.

Table I
Steady-State Rate Measurements in the Presence of Dilute Sulfuric Acid

	7	. 030	01	.0465	.8	54	.0413	

The value of K is seen to increase as the acid concentration is decreased. It is apparently approaching a limiting finite value, and is not increasing indefinitely, as it would if there were any appreciable catalysis in a neutral bromide solution. To demonstrate this, the ratio of the first order constant to the bromide concentration, $k/(Br^-)$, has been plotted against the hydrogen-ion concentration, (H^+) , Fig. 1. Results from Table III of the first paper, as well as those from Table I, are represented. It is apparent that when this curve is extrapolated to $(H^+) = 0$ (practically identical with neutral solution on this scale) it will pass through or very near the origin; that is, the absolute rate of the catalytic decomposition will be

following form:2

negligibly small. Since the rate of the reaction between bromine and peroxide is very rapid in neutral solution, it follows that the rate of oxidation of bromide by peroxide is negligible under these conditions, for any bromine formed by this reaction would be rapidly reduced with the resultant decomposition of hydrogen peroxide. This is in marked

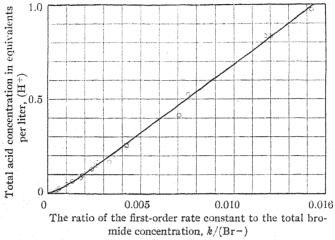

Fig. 1

contrast to the iodide-peroxide reaction, the rate equation for which has the

$$d(I_2)/dt = (I^-) (H_2O_2) [K' + K(H^+)]$$
 (2)

Our results demonstrate that the constant term (K') is unnecessary in the rate equation of the bromide oxidation.

Since the possibility of an independent reaction not involving acid has been eliminated, the most plausible explanation of the increase of K with a decrease in acid concentration is the assumption that the sulfuric acid is not completely ionized. It will be recalled that all values of K and R were computed upon the assumption that sulfuric acid was completely ionized. The assumption of incomplete ionization is in agreement with a series of measurements by Noyes and Stewart,³ who state that singly-ionized sulfuric acid (HSO₄⁻) may be considered as a weak acid, with an ionization constant of 3×10^{-2} in the range $0.1\,M$ to $0.025\,M$ sulfuric acid. It should also be noted that when sulfuric acid is treated as a strong electrolyte the values of the activity coefficients for dilute solutions are very low.

Steady-State Measurements in Hydrobromic Acid Solutions

To discover to what extent the observed increase of the constant in dilute solution was due to the presence of sulfuric acid, a series of steady-state

rate measurements were made in which the only electrolyte was hydrobromic acid. The results of 9 such measurements are summarized in Table II. In all the experiments listed the initial peroxide concentrations were made up to $0.16\,M$ or greater, from a "Superoxol" solution.

9	.0217	.0217	.0217		0.164	.0348		.0217	.889	.0440

The average value of K obtained from these measurements is about twice as great as the average value (0.0144) obtained in sulfuric acid solutions above $0.2\ N$, but is only slightly greater than the average value obtained from measurements in dil. sulfuric acid solution, Table I. Below $0.3\ N$ acid the value of K increases regularly as the hydrobromic acid concentration is decreased. At higher concentrations, for which the rate is very rapid, the values obtained for K were not always concordant and there is some evidence for the existence of a small amount of bromate at the steady state.

Two additional experiments were performed to discover what factor was responsible for the low rates observed in the sulfuric acid-potassium bromide solutions.

Expt.	Initial HBr	conens. Na ₂ SO ₄		Steady-sta Bromide	te conens. Acid	R	K
A	0.1881 M	0.492 M =	= 0.964 N	$0.1880 \ M$	0.1880 N	0.0080	0.0042
		H_2SO_4					
В	.113~M	.976 N		.100~M	1.08 N	.445	.0239

These experiments show that the effect is due to the sulfate ion. Taken in conjunction with the results with solutions of sulfuric acid and potassium bromide and with hydrobromic acid solutions, they show that the value of K increases towards a definite value when the ratio, $\Sigma SO_4/\Sigma$ acid, is decreased without limit, and that it decreases indefinitely when the ratio is increased. The approximate constancy of K in the third table of the preceding paper was due to the constant ratio of sulfate to acid, and therefore the average value of the constant (0.0144) is not fundamental.

The values of R, $(Br_2)/(H^+)^2$ $(Br^-)^2$ vary with the ratio of sulfate to acid in the same direction but more rapidly than the values of K, as is shown in Table III.

Table III
THE Specific Effect of the Sulfate Ion

Expt.	$\Sigma SO_4/\Sigma_{acid}$	K	R
A	2.6	0.0042	0.008
Av. of Table III, Ref. 1		.0144	. 22
B	45	.0239	.45
Av. of Table II		.03	.60

It is evident that these results are in agreement with the assumption that singly-ionized sulfuric acid is a weak acid.

The Rate of Appearance of Bromine in Hydrobromic Acid Solution

As an additional check on the mechanism,⁵ an experiment was performed on the rate of appearance of bromine in hydrobromic acid solution. The results were computed by the second method, explained in the preceding paper.⁶ The smoothed out data and computations are given in Table IV.

TABLE IV

RATE OF	APPEARANC	E OF BROMI	NE IN A	Hypro	BROMIC	ACID So	LUTION
$t-l_0$	c	oncentrations			Rates	\times 104	
Min.	Bromine	Peroxide	HBr -	$d(H_2O_2)/c$	$lt d(Br_2)/$	dt Sum.	$2K_1$
0	0	0.0292	0.294				
5	0.00020	.0290	.294	4.0	3.4	7.4	0.029
10	.00038	.0288	.293	4.0	3.1	7.1	.029
20	.00069	.0284	.293	4.0	2.8	6.8	.028
30	.00099	.0280	.292	4.0	$^{2.4}$	6.4	.027
40	.00122	.0276	.292	4.0	2.4	6.4	.027
60	.00170	.0268	.291	3.8	2.2	6.0	.026
80	.00216	.0261	.290	3.6	1.8	5.4	.025
100	00233	-0254	289	3.1	1.6	4.8	.023

The average value of $2 K_1$ is 0.0273. This is in excellent agreement with the value of K (0.0271) obtained from steady-state measurements, with an initial hydrobromic-acid concentration of 0.286 M. It is not known whether the observed small decrease of $2 K_1$ with time has any theoretical significance or is due to experimental error.

Steady-State Measurements in Solutions of Perchloric and Hydrobromic Acids

Since perchloric acid is a strong non-reactive acid, it was chosen as a substitute for sulfuric acid. A series of experiments, which were performed in relatively dilute solutions containing perchloric and hydrobromic acids, are summarized in Table V.

In only three of these experiments was the bromine concentration measurable; $0.00089\,M$ in 1, $0.000016\,M$ in 2, and $0.00008\,M$ in 5. The corresponding values of R are $0.35, 0.43\,\text{and}\,0.27$, respectively. The values of K obtained are of the same order of magnitude as those obtained in pure hy-

⁵ Ref. 1, pp. 1261, 1270,

⁶ Ref. 1, p. 1266.

drobromic acid solution, and like the latter, they increase as the concentration of electrolyte is decreased.

The Steady State in Solutions Containing Metallic Bromides

Several experiments were performed in solutions containing barium or potassium bromide. The results of these experiments are summarized in Table VI.

TABLE VI

STEADY-STATE RATE MEASUREMENTS IN SOLUTIONS CONTAINING METALLIC BROMIDES

The values of K obtained from measurements in these solutions have the same magnitude and trend as those obtained in hydrobromic acid solutions.

Theoretical Discussion

Substitution of Activities for Concentrations in the Rate Equation

The gradual increase in the specific reaction rate with a decrease in the concentration of the catalyst, 7 at low concentrations, suggests that activi-

⁷ For convenience, the term catalyst has been used to refer to that unit of the catalytic pair, the concentration of which occurs in the steady-state rate equation, in this case hydrobromic acid.

It should be noted that it is not illogical to use steady-state data in determining the effect of activities upon rates. In the present case the steady-state rate (rate of decomposition of peroxide) is exactly twice the rate of Reaction 1 (oxidation of bromide), and the two-rate equations differ only by a factor of 2 in the constant.

ties rather than concentrations should be used in the rate equation. Recently several cases of catalytic-rate measurements have been reported for which fairly accurate constants could be obtained by substituting activities for the concentrations of the reacting ions, in the rate equations. Fales and Morrell⁸ applied this correction to the acid hydrolysis of cane sugar. Harned and Pfanstiel⁹ have used a similar method in studying the acid hydrolysis of ethyl acetate. In both cases the use of activities improved the constancy of the specific reaction rate, but still left much to be desired. A more satisfactory example is the rearrangement of acetylchloro-aminobenzene to p-chloro-acetanilide in the presence of hydrochloric acid, which was investigated by Harned and Seltz.¹⁰ This case differs from the other two cited in that it involves the activity of hydrochloric acid rather than the individual ion activity of hydrogen ion.

The reaction discussed here, like the rearrangement of acetyl-chloroaminobenzene, involves the activity of the halide acid, and not the activity of any individual ion. Assuming that the rate is determined by the product of the activities of the ions of the catalyst, and the concentration of the non-electrolyte (hydrogen peroxide), the rate may be expressed by the following equation.

$$-d(H_2O_2)/dt = \chi(H_2O_2)a_H + a_{Br} = \chi(H_2O_2) (H^+) (Br^-)\gamma^2_{HBr}$$
(3)

It follows from Equation 1 that the relation of the "activity-rate" constant (x) to the "concentration-rate" constant (K) is given by the following expression.

$$K/\gamma^2_{\rm HBr} = \chi \tag{4}$$

Data on the activity of hydrobromic acid solutions are rather meager, but the electromotive-force measurements of Storch¹¹ tend to show that below $0.10\ N$ the activities of hydrobromic and hydrochloric acids are identical.¹²

To correlate the observations in the various solutions used, which involved mixed electrolytes of various valence types, it is necessary to introduce the concept of ionic strength.¹³ Since it has been demonstrated empirically that, in dilute solutions, the activity of a solute is a function of the total ionic strength and is independent of the nature of the other solutes,

- 9 Harned and Pfanstiel, ibid., 44, 2193 (1922).
- 10 Harned and Seltz, ibid., 44, 1480 (1922).
- 11 Lewis and Storch, ibid., 39, 2544 (1917).
- 12 Ref. 4; pp. 335, 336.
- 13 The ionic strength may be defined as half the sum of the products of the stoichiometrical molalities of the ions and the squares of their valences. Thus, for sulfuric acid the ionic strength is 3 times the molal concentration. Compare Ref. 4, p. 373. In the present paper the concentrations in moles per liter have been used instead of molalities, but the resulting numerical difference is not appreciable except in the more concentrated solutions.

we may assume that in the various mixed solutions used the activity coefficient of hydrobromic acid, $\gamma_{\rm HBr}$, is a function of the ionic strength, μ , only.

In the last columns of Tables I, II, IV and V, the values of the ionic strength, μ , the mean activity coefficient, $\gamma_{\rm HBr}$, and the rate constant corrected for the activity effect, χ , are listed. Values of the corrected constant have been computed for ionic strengths below 0.25, although it is hardly to be expected that either the assumption of the identity of the activities of hydrobromic and hydrochloric acids or the ionic-strength principle can be applied over this entire range. With the exception of the measurements in sulfuric acid solutions in Table I, the values of the corrected constants (χ) do not show any marked trend. The average value for pure hydrobromic acid solutions (Table II) is 0.0437 ± 0.0005 . For perchloric-hydrobromic acid solutions (Table IV) the average value is 0.0437 ± 0.0006 . On the other hand, the uncorrected constant (K) for the same experiments varies from 0.0348 to 0.0260, a decrease of 25.3%.

Taking 0.0437 as the average value of χ , values of K for a series of ionic strengths may be computed by Equation 4, from the values of γ_{HCI} given by Lewis and Randall.¹² Table VII lists the values so obtained.

Table VII
The Calculation of K from x=0.0437 and γ

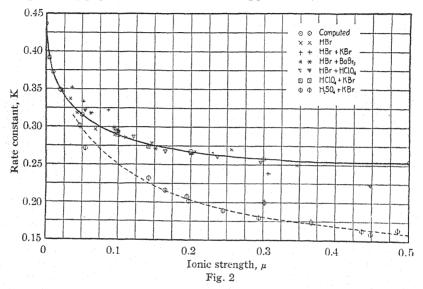

μ	γ _{HCI}	K(Computed)	μ	γ _{HCl}	K(Computed)
0	1,000	(0.0437)	0.100	0.814	0.0289
0.005	0.947	.0392	.200	.783	.0268
.010	.924	.0373	.300	.768	.0258
.020	.894	.0349	.500	.762	.0254
.050	(.850)	.0316			

In Fig. 2, K (computed) has been plotted against μ . The experimental values of K, Tables I, II, V and VI and the first 6 values of Table III (Ref. 1), have also been plotted. At ionic strengths below 0.25, the values of K obtained in pure hydrobromic acid solutions and in perchloric-hydrobromic acid solutions are in remarkable agreement with the theoretical curve.

Although rate measurements cannot be used very generally for the determination of activity coefficients, they may be useful in certain limited cases. The data presented here have been used to obtain an estimate of the activity of hydrobromic acid, in solutions containing various electrolytes, relative to its activity in pure aqueous solutions. The results of such considerations are summarized as follows.

1. The activity of hydrobromic acid in perchloric acid solutions (less than 0.25μ) is almost identical with that of pure hydrobromic acid solutions of the same ionic strength. At higher concentrations there is apparently a small negative departure.

- 2. In all solutions containing metallic bromides the activity seems to be slightly greater below 0.15μ and slightly less above 0.15μ than the activity in pure hydrobromic acid solutions of the same ionic strength.
- 3. If it be assumed, and it is not an improbable assumption, that the presence of sulfuric acid does not depress the specific rate of the catalyzed decomposition, we may use the data given in Table I and in Table III of the preceding paper (Ref. 1) to obtain an approximate estimate of the ac-

tivity coefficient of hydrobromic acid in potassium bromide-sulfuric acid solutions over a wide range of concentrations. The activity coefficient so obtained is practically independent of variations in the ratio (KBr)/(H₂-SO₄) from 2.0 to 0.035. A few averaged values are given in the following table.

TABLE VIII

THE ACTIVITY COEFFICIENT OF HYDROBROMIC ACID IN SOLUTIONS OF SULFURIC ACID AND POTASSIUM BROMIDE

Although the general idea, that activities or "active mass" should be substituted for concentrations in the rate equations, has been discussed for years, one of the first attempts at an experimental test of this principle was made by Bugarsky¹⁴ in 1910. He measured the rate of reaction between alcohol and bromine in 4 different solvents and attempted to estimate the activities by means of partition coefficients. In 1920, Jones and W. C. McC. Lewis¹⁵

¹⁴ Bugarsky, Z. physik. Chem., 71, 705 (1910).

¹⁵ Jones and W. C. McC. Lewis, J. Chem. Soc., 117, 1123 (1920).

studied the acid hydrolysis of sucrose. They obtained their hydrogen-ion activities from cell measurements in the presence of the sugar, but their results are rendered somewhat uncertain by the presence of a diffusion boundary in their cell. This is also true for the results of Fales and Morrell.⁸ The type of equation, used by Jones and Lewis¹⁵ and the more recent workers^{8,8,10} is one in which activities are substituted for the corresponding concentration terms. Following this convention, the rate equation for the bromine-bromide catalysis would be

$$-d(H_2O_2)/dt = K'a_{H_2O_2}a_{H} + a_{Br} - K'(H_2O_2) (H^+) (Br^-)\gamma_{H_2O_2} \gamma^2_{HBr}$$
 (5)

To bring this equation into agreement with the experimental data it is necessary to assume that $\gamma_{\rm H_2O_2}$ is constant in electrolyte solutions whose ionic strengths vary from 0.25 to 0.02. Although there is no definite evidence on this point, it seems an improbable assumption.

Recently Brönsted¹⁶ has pointed out that the substitution of activities for concentrations in rate equations cannot be generally used to obviate "reaction anomalies," for in dilute solutions the activity coefficients of all electrolytes decrease as the total electrolyte concentration is increased, while under these same conditions the rate constants decrease, increase, or are unaffected by a change in the electrolyte concentration. He assumes that all reactions proceed through the formation and decomposition of an unstable intermediate, the valence of which is the algebraic sum of the valences of its components. From these assumptions he shows that it is consistent with thermodynamics and in good agreement with experimental results to represent the rate of any actual reaction as proportional to the product of the activities of the component molecular species divided by the activity coefficient of the intermediate complex. In agreement with this system the law of the bromine-bromide catalysis would be

$$-d(H_2O_2)/dt = \frac{K''}{\gamma_{H_2O_2 \cdot HBr}} a_{H_2O_2} a_{H^+} a_{Br^-} = K''(H_2O_2)(H^+)(Br^-)\gamma^2_{HBr} \frac{\gamma_{H_2O_2}}{\gamma_{H_2O_2 \cdot HBr}}$$
(6)

In order that this equation shall represent the experimental data it is necessary for the ratio of the activity coefficients of hydrogen peroxide and the neutral complex (H₂O₂.HBr) to be constant over the range of concentrations studied. There is no reason to believe this assumption improbable.

The evidence presented here, as well as that presented by Harned and Seltz, ¹⁰ demonstrates that the rate of a catalytic process involving neutral molecules is proportional to a function of the activity of the catalyst rather than of the concentration. If the activity coefficient of the substance undergoing transformation is constant, as Harned assumes, the facts may be expressed equally well by the "activity-rate" theory or by Brönsted's theory. ¹⁷ If this assumption proves to be false, these results may be taken

¹⁶ Brönsted, Z. physik. Chem., 102, 169 (1922).

¹⁷ For a discussion of these theories and additional references, see the paper by Scatchard, This Journal, 45, 1580 (1923), which appeared while this article was in proof.

as a definite confirmation of a special case of Brönsted's theory. We shall continue this investigation by direct measurement of the activities involved and by further rate measurements.

Summary

- 1. The steady-state rate of the bromine-bromide catalysis of hydrogen peroxide has been measured in dil. solutions of sulfuric acid and potassium bromide, and it has been shown that the rate constant approaches a definite finite value as the sulfuric acid is indefinitely decreased.
- 2. The steady-state rate has also been measured in the following solutions: hydrobromic acid, hydrobromic-perchloric acid, hydrobromic acid-potassium bromide, hydrobromic acid-barium bromide, and perchloric acid-potassium bromide. The rate constants obtained from measurements in these various solutions are all slightly larger than those obtained from measurements in dil. sulfuric acid solutions, and are about twice as great as those obtained in sulfuric acid solutions above $0.2\,N$.
- 3. At the steady state, in hydrobromic acid and hydrobromic-perchloric acid solutions of ionic strength less than 0.25 and in 8 out of the 12 remaining experiments in the absence of sulfate, the rate of decomposition of peroxide is represented by the following expression within the limits of experimental error, 1% to 2% (the discrepancy in the 4 excepted experiments lies between 4% and 9%):

$$-d(H_2O_2)/dt = 0.0437 (H_2O_2) (H^+) (Br^-)\gamma^2_{HBr}$$
 (7)

- 4. The activity coefficient of hydrobromic acid in solutions containing sulfuric acid and potassium bromide has been estimated from the rate measurements in these solutions, by the assumption that Equation 7 holds.
- 5. The application of the "activity-rate" theory and of Brönsted's theory to the experiments presented here has been briefly discussed.

BERKELEY, CALIFORNIA

[Contribution from the Chemical and Physical Laboratories of the University of Missouri]

LUMINESCENCE OF ORGANO-MAGNESIUM HALIDES

By R. T. Dufford, S. Calvert and Dorothy Nightingale Received June 7, 1923

Apparently the first notice of luminescence associated with a Grignard reagent dates from 1906, when Wedekind¹ found that phenylmagnesium bromide and phenylmagnesium iodide give a bright light when reacting with chloropicrin. This reaction has become widely known as the "Wedekind Reaction."

¹ Wedekind, Ber., 4, 417 (1906); Physik. Z., 7, 805 (1906); Chem. Zentr., 30, 921 (1906); Z. wiss. Phot., 5, 29 (1907).

Heczko,² in repeating the experiment, noticed that these compounds are luminous when oxidized in air. He thought moisture necessary to produce the light, but this idea was shown to be wrong by Moeller; in fact, tests by the writers have shown definitely that the presence of moisture tends to inhibit the light. Other workers occasionally have noted, incidental to synthetic work, that certain Grignard compounds give light. Thus, Schmidlin³ reports light from diphenylmagnesium bromide, but wrongly reports several other compounds to be non-luminous. Späth⁴ mentions p-chlorophenylmagnesium bromide and m-p-xylylmagnesium bromide as brightly luminescent. These are isolated references that came to the attention of the writers only after most of their work had been done.

Moeller,⁵ in 1914, reported a systematic investigation of 10 such compounds. The original Danish article is practically unavailable in this country, and it has not been adequately abstracted. The growing interest in these compounds makes it seem desirable to give here a summary of his results, although several of his statements have been shown by later workers to be incorrect. The writers, on finally obtaining a photostatic copy of the article, found that they had already rediscovered all but one of the compounds mentioned, and would have recorded their results on that one also within a few days more. It is hoped that others will be saved this experience. The results reported by Moeller are as follows.

"Good"	"Weak"	"No read	ction"
C ₃ H ₇ MgBr (wrong)	C ₂ H ₅ MgBr (wrong)	C ₃ H ₇ Cl)	
C ₆ H ₅ MgBr	C ₅ H ₁₁ MgBr (wrong)	C ₅ H ₁₁ Cl	435
p-BrC ₆ H ₄ MgBr	C ₆ H ₅ MgI	C ₆ H ₅ Cl	and Mg
α -C ₁₀ H ₇ MgBr	C ₆ H ₅ CH ₂ MgBr (wrong)	C ₆ H ₃ Br ₃	
α - α - $C_{10}H_6Br_2$ and Mg			
b-CH-C-H-MgBr			

Moeller also pointed out that oxygen, not moisture, is needed to produce luminescence.

An attack on the problem from quite another angle was made by Lifschitz, whose early work seemed to indicate that differences in the stabilities of the etherates might account for the difference in behavior between aliphatic and aromatic Grignard compound in ether solution. Later work showed that the differences were less than at first was supposed, and that his original explanation was inadequate. The work is, nevertheless, an exceedingly valuable contribution to the chemistry of these compounds. A connection with unsaturation is suggested.

The luminescence of $p\text{-Br}C_6H_4MgBr$ was independently discovered by W. V. Evans, and investigated with one of the writers, who pointed out also that an interesting fluorescence is shown by the product of oxidation of this compound, and that the fluorescence and the chemiluminescence are not identical. The oxidation of $p\text{-}C_6H_4MgBr$ gives about as much light as any of the older classical chemiluminescent reactions. The writers suggest the name "Moeller-Evans Reaction" for it in honor of the discoverers. It has been used frequently in the present work for comparison with other reactions, and the name will be convenient for reference. In the course of this work, all the classical chemiluminescent reactions were repeated for comparison.

An extensive examination of over 60 Grignard compounds has been carried out by the present writers, in which more than 40 luminous compounds have been studied. The effects on the color and the brightness of the chemical nature of have been determined for several factors, such as the chemical nature of the reacting atoms, the position, the mass and the chemical nature of substituents, unsaturation and molecular structure. Certain fluorescent effects have been noted, also. We shall discuss first the chemiluminescence in ether solution on oxidation with oxygen.

Experimental Methods

Where possible, the compounds used were purchased from a commercial source. The majority of the aromatic halogen bodies were synthesized in the Organic Laboratory of the University of Missouri, from materials so purchased. The methods of synthesis chosen were those which seemed calculated to yield the purest products, and in these cases, the products were tested carefully. The results, it is believed, are therefore entitled to confidence in this respect.

In preparing the Grignard reagents, in most cases the attempt was made to use equivalent quantities of material, so that the results would be as nearly comparable as possible with such unstable compounds. With certain of the less soluble compounds it was necessary to work at greater dilutions than usual. The concentrations used were near the optimum.

For studying the spectral distribution of light, the Weiser¹⁰ method of color filters was used, much as in the preliminary work by Evans and Dufford, but with a slightly improved set of filters, as described in Table I. The photographic method is unreliable at the red end of the spectrum and was, therefore, supplemented by visual observations through a second set of filters. The photographs are more reliable than the eye at the violet end of the spectrum, however. For accuracy, both methods are necessary.

For gaging the brightness of the luminescence of the compounds, several methods were used. In the earlier work, compounds were compared with the Moeller-Evans reaction. In later work, the fainter compounds were compared with a set of radio-luminous disks, which were carefully protected from light to prevent phosphorescence. These disks were calibrated by the Bureau of Standards; their brightness ranged from 1 to 8 microlamberts. The brighter compounds were compared by the optical pyrometer method described by Nichols. The ranges of the two methods overlap, so that it is possible to determine, at least approximately, the surface brightness of any luminescence. Another method of estimating brightness is given by Ives. The writers hope to say more concerning such measurements in a later article.

Factors not Determinative of Luminescence

It is very clear, as Lifschitz has pointed out, that reaction velocity is not the factor that determines the luminescence. The oxidations studied are all very slow compared to ordinary ionic reactions, which are not chemiluminescent at all. But if a given Grignard compound is luminescent, increased speed of reaction will brighten the light; for example, pure oxygen gives much more light than air with such Grignard compounds. The quantitative work of Amberson¹³ on luciferin, the luminescent material studied by Harvey, tends strongly to indicate that the brightness is closely proportional to the speed of oxidation. Results of the writers indicate further that the spectral band of a compound widens somewhat when the intensity is high. Thus the radiation from the Moeller-Evans reaction ordinarily photographs as if it were confined to the range 5200–3500, and was so reported by Evans and Dufford. But it is easy to show, when the intensity is high, that the band really extends to about 6200, on the red end, and probably beyond 3000 on the short-wave-length end.

The heat of oxidation of the compounds is also not determinative. Qualitative observations by the writers are in accord with the careful quantitative work of Lifschitz and Kalberer. In certain series of compounds the brightest become hottest during oxidation. But the reverse is more often true; the most of the remarkably bright compounds actually become cooler while oxidizing and radiating, because not enough heat is given off to compensate for the cooling due to the evaporation of ether.

It appears that slight changes in temperature do not affect the brightness of the luminescence appreciably.

Effect of Solvents

While much remains to be done in this line, enough evidence has been secured to establish clearly that the ethyl ether in which such compounds

¹¹ Nichols, Science, 55, 157 (1922).

¹² Ives, J. Franklin Inst., 194, 213 (1922).

¹³ Amberson, J. Gen. Physiol., 4, 517 (1922).

are usually made is by no means necessary. Much evidence indicates that these compounds exist as etherates in such solutions. Other ethers may be substituted, however, without destroying the luminescence; normal ethers appear slightly better than iso ethers, or than diphenyl ether, at least for bromine compounds. Chlorine Grignard compounds are usually best in iso-amyl ether. Dimethylaniline can be substituted for ether, though the light is less intense than with ethyl ether, as was shown by Lifschitz. Toluene containing some ether has been used also. Lifschitz states that the pure, ether-free Grignard compounds, even the aliphatic compounds, give light. The writers have not yet been able to verify this statement, but it is very clear that the nature of the solvent affects the intensity of the light. The writers have failed to find any effect on the spectral distribution, however, though several tests were made. The question should be investigated further before any final decision can be reached.

Effects of Other Oxidizers

The light is brightest when pure oxygen is used; air is much less effective. Other reagents, such as sodium peroxide, hydrogen peroxide, etc., react more violently, but they give no light. Water hydrolyzes these compounds instantly, but without evolution of light. Other gases, such as sulfur dioxide, carbon dioxide, nitric oxide, and nitrogen dioxide also give no light, although some of them react. Lifschitz and Kalberer reported evolution of light with benzene triozonide and also with nitrous oxide, but the writers failed repeatedly to observe light with this gas when particular care was first taken to remove all traces of atmospheric oxygen from the apparatus.

Effect of Other Metals

The magnesium of the Grignard compounds appears to be necessary for chemiluminescence. Several of the analogous zinc compounds, including phenylzine bromide and iodide, and p-bromophenylzine bromide. showed no light. Evans, in a private communication, has stated that he found no light with phenylmercuric bromide. The writers plan to try certain other compounds later.

Effect of Concentration

These compounds evolve most light when the concentration is fairly high; but when the concentration becomes too great, an optimum value is passed. For phenylmagnesium bromide the optimum lies near 2.5 moles per liter. For some other compounds the optimum is at higher concentrations. However, in at least one case, that of the Grignard compound from α -bromonaphthalene, the optimum is lower. This compound has a remarkable tendency to crystallize from solution. When its brightness has died down, successive additions of ether increase the brightness again.

Effect of Reacting Halogen

The identity of the reacting halogen definitely affects both the color and the intensity of the radiation. To test this point, solutions were prepared of the following Grignard compounds: C_6H_5MgI , $p\text{-}CH_3C_6H_4MgI$, C_6H_5MgBr , $p\text{-}CH_3C_6H_4MgBr$, C_6H_5MgCl , and $p\text{-}CH_3C_6H_4MgCl$. In these series the iodine compounds give the faintest light, while the chlorine compounds give the most. Further, the chlorine compounds give light that is distinctly greener than that from the other compounds, while the iodine compounds are bluest, that is, chlorides give off the longest effective wave length, and iodides the shortest. Fig. 1 shows the shift in wave

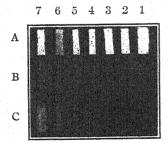

Fig. 1.—Luminescence of Monohalogen benzene Grignard compounds. A, white light; B, C₆H₅MgCl; C, C₆H₅MgBr. The numbers refer to the filters described in Table I

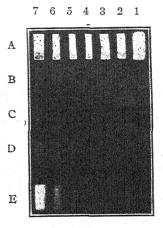

Fig. 2.—Luminescence of Grignard compounds from bromine derivatives of benzene with alkyl side-chains para to the reacting halogen. A, white light; B, C₆H₅MgBr; C, CH₃C₆H₄MgBr; D, C₂H₅C₆H₄MgBr; E, C₄H₉C₆-H₄MgBr

length for phenylmagnesium chloride and bromide; the light from the iodide was too faint to photograph in the same time of exposure. A somewhat similar effect is observed in the dihalogen derivatives, p-TC₆H₄MgI, p-BrC₆H₄MgBr, p-ClC₆H₄MgCl; the same shift in wave length is observed. The same brightness relations exist, except that the dichloro compound gives less light than the dibromo compound. The effect is due partly to the lower yields obtained from the dichloro compound; the point is being investigated further, to determine whether this is the only reason.

Method of Preparing Grignard Compounds Containing Chlorine

None of the chlorine compounds mentioned above can be prepared by the usual methods, in ordinary ether, at least not in any reasonable length of time. The di-iodo compound is also difficult to prepare. Evans⁸ has described a method for preparing the latter, using the analogous dibromo compound as a catalyst; but this method is open to the objection that the catalyst is itself luminescent and, hence, makes the tests unreliable. Hesse¹⁴ patented a method of making chlorine Grignard compounds using pinene hydrochloride as catalyst. The writers found that the compounds formed in *iso*-amyl ether with iodine or ethyl bromide as catalyst; this method works with the di-iodo compound also. The yields are probably somewhat less than with pinene hydrochloride, but the products give a brighter light, as if the pinene hydrochloride tended to inhibit the luminescence.

Effect of the Organic Radical

The character of the radiation during oxidation is profoundly affected by the nature of the organic radical involved. It may be true that ordinary saturated aliphatic compounds give light when crystallized, free from ether, but it is very certain that they do not do so in any ordinary solvent. It was thought at first that the luminescence was confined to aromatic compounds.

Certain theories regard the benzene ring as being in vibration. It appeared possible that the luminescence might be associated with some sort of vibration of the ring. If so, certain effects may be expected: first, that if the ring were loaded with a substituent group, the light should be affected regularly as the mass of the loading group increases, probably in the direction of an increase in wave length; and second, that symmetrical loading should not produce the same effect as unsymmetrical; probably the unsymmetrical (ortho and meta) compounds should show shorter wave lengths than the symmetrical (para) compounds, but without much difference in intensity. Other questions concerning the effect of structure and unsaturation also are suggested. The following paragraphs will show how these compounds actually behave.

Effect of Position of Substituted Group

In order to test carefully the effect of the position of the substituted group, a number of series of compounds were prepared which would form Grignard compounds differing only in the position of the substituted group. They included the *ortho*, *meta* and *para* derivatives of methylphenylmagnesium chloride, bromide and iodide, chlorophenylmagnesium chloride and bromo- and chlorophenylmagnesium bromide. The light

¹⁴ Hesse, Ber., 39, 1147 (1906); Chem. Zentr., 1906, I, 1424; 1908; Ger. Pats. 189,476 and 193,177.

from these compounds was studied carefully, both visually and photographically.

The results show that the para compounds are always very much brighter than the corresponding ortho or meta compounds, though neither of the latter classes is consistently brighter than the other. The differences in wave length are slight—rather less than might have been expected. Indeed, after examining the toluenes, the writers were in doubt whether the observed differences were real at all. The dichlorobenzene derivatives are so faint that their evidence is inconclusive. But the dibromobenzene and chlorobromobenzene derivatives show the same effect as the toluenes, and in so pronounced a form as to be unmistakable. While the differences are small, they are quite regular. Each compound radiates a spectrum made up of a wide continuous band. The spectra of the para compounds always extend farther toward the red than is the case with the other isomeric compounds; the ortho and meta compounds are more nearly alike, but the meta compounds regularly show the shortest wave lengths. Light from para compounds is, therefore, always greener than that from the others, and from meta compounds more violet. The differences show best in the dibromo and chlorobromo compounds; these are illustrated in Figs. 2 and 3, respectively.

Mass and Chemical Nature of Loading Group

Moeller⁵ concluded that the brightness of the luminescence is proportional to the molecular weight of the halogen derivatives. This statement is not true, even of the few compounds which he studied. To test this point, the writers studied a large number of compounds.

When the group added to the benzene ring is an aliphatic side-chain, then the brightness does increase with the weight of the added group or, what is the same thing, with the molecular weight of the compound. Thus, in the series C₆H₅MgBr, p-CH₅C₆H₄MgBr, p-C₂H₅C₆H₄MgBr and p-C₄H₉-C₆H₅MgBr, the brightness increases with the weight and, at the same time, the wave length shifts steadily toward the violet and not toward the red, as might be expected if mass were the determining factor (by analogy with the vibration of a loaded spiral spring). Fig. 4 shows the effect fairly well, except that the exposure for the toluene derivative was too short.

When the loading group is a halogen, however, the result is different. This was tested by studying series in which the loading halogen alone was varied, as in the following: $p\text{-}IC_6H_4MgBr$, $p\text{-}IC_6H_4MgI$, $p\text{-}BrC_6H_4MgBr$, $p\text{-}ClC_6H_4MgBr$, and $p\text{-}ClC_6H_4MgI$. In these compounds, the brightness of the radiation increases in most remarkable fashion as the weight of the loading halogen decreases, and with this, there is an increase in the effective wave length.

In the series p-C₂H₅C₆H₄MgBr, p-ClC₆H₄MgBr and p-(CH₃)₂NC₆H₄-MgBr, the masses of the loading groups are comparable, being 29, 35 and 44, respectively. The brightness shows no regularity; the chlorine derivative is by far the brightest, and the dimethyl-aniline derivative the faintest.

It has already been shown that in the case of Grignard compounds from monohalogen benzene derivatives, the brightness increases as the molecular weight decreases, and the wave length increases at the same time. Certain dihalogen derivatives were shown to behave likewise.

Among diphenyl derivatives, Schmidlin³ reports p-C₆H₆C₆H₄MgBr as giving a bright blue light; the writers find that p-p-BrC₆H₄C₆H₄MgBr gives a bright green light.

These results seem to indicate that mass is not at all the controlling factor in these compounds; if it has any effect, it is so small that it is

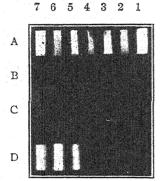

Fig. 3.—Luminescence of Grignard compounds from dihalogen derivatives of benzene. A, white light; B, o-BrC₆H₄MgBr; C, m-BrC₆H₄MgBr; D, p-BrC₆H₄-MgBr

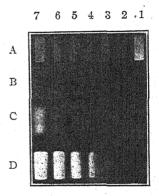

Fig. 4.—Luminescence of Grignard compounds from bromochlorobenzenes. A, white light; B, o-ClC₆H₄MgBr; C, m-ClC₆-H₄MgBr; D, p-ClC₆H₄MgBr

completely masked by other factors depending on the chemical nature of the loading groups. Further evidence on this point will be given later.

In this discussion it has been assumed that in dihalogen derivatives of benzene only one of the halogens reacts with magnesium to form a Grignard compound, and that when the 2 halogens are different, the magnesium reacts with bromine, if present, in preference to the other halogens, or with iodine in preference to chlorine. It is believed that these assumptions are in accord with the experience of most other workers in the field, as well as with many incidental observations by the writers.

Derivatives of Naphthalene, Anthracene and Xylenes

The Grignard compound from α -bromonaphthalene gives a blue light, nearly as bright as that formed in the Moeller-Evans reaction. That from

 β -bromonaphthalene is much brighter, and is at least as bright as that from the Moeller-Evans reaction. By analogy with the benzene derivatives, one might expect the Grignard compound from 1,4-dibromonaphthalene to be still brighter and bluer. In fact, it is much fainter, and greener. The Grignard compound formed from 1,4-chlorobromonaphthalene is, however, much brighter and bluer than that from the 1.4dibromonaphthalene compound. It, also, is about as bright as the light from the Moeller-Evans reaction. α-Chloronaphthalene forms a compound giving a light much weaker than the other compounds just mentioned, and too faint to photograph well.

Some of these effects are shown in Fig. 5.

9,10-Dibromo-anthracene forms a Grignard compound showing a greenish-blue light whose faintness A can hardly be due entirely to poor yields. Since this has a bearing on the probable structure of anthracene we intend to study the matter further.

If Moeller's conclusion as to the effect of mass were correct, the results obtained with the compounds just described would necessarily have been very different. Further, it is n evident that the behavior of these multiplering compounds, and perhaps also of the diphenyl compounds, is not altogether analogous to the behavior of the benzene deriv- E atives. Perhaps a more useful and fruitful point of view is to regard the a-bromonaphthalene Grignard compound as a bromo- nard compounds from naphthabenzene derivative with its ortho and meta positions both loaded; and the β -bromo compound as a similar derivative with the meta E, (1,4) CIC 10 HoMgBr and para positions substituted. According to

5 4 3 2 1

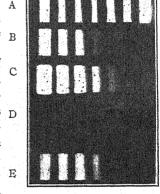

Fig. 5.-Luminescence of Griglene derivatives. A, white light; B, α-C₁₀H₇MgBr; C, β-C₁₀H₇-MgBr; D, (1,4)BrC10H6MgBr;

this view, the Grignard compound from 1,2-dimethyl-4-bromobenzene should be brightly luminescent. The writers were preparing to test this point, but came across the statement by Spath4 that the light from this compound is very bright. Other xylene compounds give less light; for example, those from 1,3-dimethyl-4-bromobenzene, and 1,4-dimethyl-2bromobenzene. It is hoped that other experiments in this direction will be ready for reporting soon.

Effect of Structure and Unsaturation

It will be noted that all the compounds so far mentioned as luminescent are cyclic in structure, and unsaturated. It is of interest to inquire whether the cyclic structure, or the unsaturation, or both, are necessary to produce luminescence.

Further evidence pointing toward unsaturation as being an important factor is the complete failure of saturated aliphatic Grignard compounds to show luminescence in ether solution. The following list of saturated nonluminescent compounds, containing both halogen-substituted and simple aliphatic derivatives, shows how widespread is the lack of luminescence: C₂H₅MgBr, C₂H₅MgI, C₃H₇MgBr, C₄H₃MgBr, *i*-C₅H₁₁MgBr, C₇H₁₅MgBr, ICH₂MgI, BrC₂H₄MgBr, IC₂H₄MgI. If molecular weight had anything to do with luminescence, some of the heavy molecules at the end of the list should give light, for they are comparable with the benzene ring in mass. This is one more reason for thinking that mass has nothing to do with the question, but suggests that unsaturation or cyclic structure may have some influence.

The cyclic structure alone, however, is not sufficient to give luminescence. Several saturated cyclic compounds which form Grignard compounds easily prove to be quite inactive, photochemically. Examples are: cyclo-C₆H₁₁Br, C₁₀H₁₅OBr (camphor), C₁₀H₁₇Cl (pinene hydrochloride).

Unsaturation alone is likewise not a sufficient condition for luminescence. Thus the following substances which are really phenyl-substituted aliphatic compounds give no light, though highly unsaturated: C₆H₅CH₂MgCl, C₆H₅CH₂MgBr, p-ClC₆H₄CH₂MgBr, (C₆H₅)₃CMgCl.

Careful scrutiny of the lists seems to indicate that the determining difference lies in the fact that in the luminescent compounds, the magnesium is attached directly to an unsaturated carbon atom, while in the others it is not. No exceptions to this statement are known at present.

To test this supposition further, the compound ClHC:CHMgCl was prepared, as an aliphatic compound with the supposedly necessary grouping. This compound is faintly but unmistakably luminescent. It is believed to be the first aliphatic compound discovered to be luminescent in ether solution. The analogous bromine compound, BrHC: CHMgBr. shows so much fainter luminescence that it is to be regarded as doubtful. but this is what would be expected if these compounds are like the monohalogen benzene Grignard compounds in their behavior. The Grignard compound from β-bromostyrene, (C₆H₅CH:CHBr), is fairly bright, however, thus substantiating the view. On the other hand, allyl bromide and iodide, which are unsaturated, but which have the halogen attached to a saturated carbon, give non-luminescent Grignard compounds. The final product of this reaction is claimed to be diallyl. As the reaction was in progress, oxygen was passed into the solutions in the dark, so that any allylmagnesium bromide or iodide present as an intermediate product would be oxidized. No light was observed. It is hoped to make other tests later.

Especially Bright Reactions

Several of the compounds are bright enough to be worthy of special mention. The Moeller-Evans reaction has been mentioned already; it is as bright as any of the classical chemiluminescent reactions, except the oxidation of luciferin. The Grignard compounds derived from α -bromonaphthalene, from 1,4-bromochloronaphthalene, and from ρ,ρ -BrC₆H₄C₆H₄Br, are nearly as bright. That derived from β -bromonaphthalene is at least as bright as the Moeller-Evans reaction, and probably brighter at its best. The compound ρ -ClC₆H₄MgBr is much brighter than any other so far found. Careful pyrometric measurements show that it is brighter even than luciferin, except possibly for the bright specks in the luciferin solution and, therefore, probably the brightest case of chemiluminescence on record. The comparisons were made at the wave length corresponding to the maximum of the emission of the luciferin. The light from the luciferin is greenish-blue, while that from the Grignard compound is deep blue. The ease of preparation of this compound and the high intensity of its light make it an ideal demonstration material for illustrating the phenomenon of chemiluminescence.

Reactions with Chloropicrin and Bromopicrin

Many of the luminescent Grignard compounds studied show light also when reacting with chloropicrin or with bromopicrin, as in the well-known Wedekind reaction. These cases are of interest as being probably not oxidations, though the precise nature of the reactions is not known. Thus far, the work of the writers has established several important facts regarding this type of luminescence. (1) No compound has been found to give light in these reactions that does not also give light on oxidation with oxygen. (2) The light obtained from chloropicrin is always stronger than that obtained with bromopicrin. (3) The light from these reactions is clearly not identical with that from the oxidation of the same Grignard compounds with oxygen. It is always of somewhat longer wave length, although its spectrum is always a single continuous band. (4) The order of brightness in these reactions is precisely the reverse of that for oxidation with oxygen; that is, with chloropicrin, iodides are the brightest, and chlorides the least bright.

An attempt was made to determine the part of the chloropicrin molecule that is essential for the production of light. Aliphatic nitro compounds, picryl chloride, chloroform and other compounds were tried, but none of these gave light, although some of them reacted violently with the Grignard reagent. Apparently there is something about the particular chloropicrin grouping that is necessary for the production of light in these reactions.

Fluorescence

A very large number of the oxidation products of these Grignard compounds show fluorescence in "near" ultraviolet light. Apparently little regularity is to be found in most cases. Several new multiple-banded

spectra have been observed. A few of these fluorescences are extremely bright; curiously, these all come from compounds that show very bright chemiluminescence with oxygen. In spectral distribution, the fluorescence is clearly not the same as the related chemiluminescence. These results the writers hope to discuss more fully in a later article.

List of Luminescent Grignard Compounds

Tables II and III give lists of the Grignard compounds studied by the writers, together with 2 or 3 others on which observations have been published by other workers. The list is believed to contain all known luminescent Grignard compounds except certain triple bond compounds investigated by Evans, on which the results have not yet been published. The notes indicate the cases where other investigators have studied any of these compounds, so far as is known. While most of the formulas as written are those generally accepted, they are written in this form here chiefly for reasons of brevity, and not because it is desired to claim that any particular structure has been proved. It may be that such results will come to be of aid in determining chemical structure later.

The spectral distributions, where given, are in terms of the windows listed in Table I. The picture so given is very incomplete, but any other method would require an unreasonable amount of space. Because of the difference in sensibility of the eye and the photographic plate, the apparent maxima as found by both methods are given.

The following substances showed no chemiluminescence with oxygen nor, in those that were tested, with chloropicrin or bromopicrin. Their oxidation products, however, frequently exhibited fluorescence; references to the latter are given for each formula. Where chemiluminescence was tested for only in the presence of oxygen the symbol O₂ is also added.

Summary

- 1. Grignard reagents in ether solution are chemiluminescent on oxidation by oxygen only if the magnesium is attached directly to an unsaturated carbon atom. This rule is shown to hold for both aliphatic and aromatic compounds, in all cases investigated.
- 2. The nature of the solvent affects the intensity of the luminescence, but apparently not the wave length.
- 3. No chemiluminescence is found when zinc or mercury is used instead of magnesium.
- 4. The wave length and intensity of the radiation are affected by the nature of the reacting halogen.
- 5. The wave length and the intensity are affected by the nature of the organic radical involved, and especially by the nature of substituted groups in the cyclic compounds. The effect depends on (a) the position of the substituent group; (b) the chemical nature of the substituent group. It is shown that the mass of the substituent is not the controlling factor.
- 6. Certain cases of very bright chemiluminescence are described; the luminescence of p-chlorophenylmagnesium bromide is believed to be the brightest yet recorded.
- 7. A method (apparently new) of preparing chlorine-containing Grignard compounds is described.
- 8. Many Grignard compounds give light when treated with chloropicrin and with bromopicrin. This light is not the same as that given out on oxidation with oxygen.
- 9. Many Grignard compounds and especially their oxidation-products are found to be fluorescent in ultraviolet light.
- 10. Two tables are given listing the luminescent properties of more than 60 compounds, of which over 40 are luminescent.

THE SEPARATION AND DETERMINATION OF POTASSIUM AND SODIUM. A PERCHLORATE PRECIPITATION PROCESS USING NORMAL BUTYL ALCOHOL.

By G. Frederick Smith Received June 14, 1923

The perchlorate method for the separation and determination of potassium and sodium has been quite generally accepted as a satisfactory substitute for the chloroplatinate procedure. The use of absolute ethyl alcohol in the perchlorate procedure is a pronounced disadvantage. The method has the further disadvantage of being an extraction process. This method of extracting a mixture of salts with a solvent for one of them is necessarily inefficient, since the crystals of one may be more or less sur-

rounded by a coating of the other salt. It would obviously be a considerable improvement if the use of ethyl alcohol and the inefficient extraction type of procedure could be entirely eliminated. The present paper shows how both of these improvements can be accomplished and also simplifies the procedure with consequent increase in accuracy.

Studies in the improvement of the perchlorate separation of potassium and sodium are desirable, as indicated by recent work in the field by several careful observers including those of Baxter and Kobayashi, Baxter and Rupert² and Gooch and Blake. The most complete work on the perchlorate method is that of Morris⁴ which contains an extensive bibliography. Few further references to the literature of the subject are therefore necessary here.

The Method

The process, in brief, consists in the precipitation of potassium perchlorate from solution in warm water, in the presence of sodium perchlorate, by the slow addition of a proportionally large volume of N-butyl alcohol containing $0.5{\text -}1\%$ of perchloric acid dihydrate. The solution together with the precipitated potassium perchlorate is then boiled for 30 seconds, cooled to room temperature and filtered using a Monroe or Gooch crucible. The precipitate is washed with butyl alcohol, dried at $150{\text -}250^{\circ}$ for 1/2 to 1 hour and weighed as potassium perchlorate. The sodium is determined in the filtrate by evaporation of the solvent and conversion of the sodium perchlorate to sulfate, and is weighed as such in the usual manner. The method is best suited to the determination of sodium by difference, after weighing the mixed potassium and sodium chlorides.

Preparation of Materials

Normal Butyl Alcohol.—This material is readily obtainable on the market at the present time at a moderate price. The alcohol used in this research had a boiling range of $112-118^{\circ}$; d_4^{25} 0.8065. It was distilled as received without further treatment, and the first and last 5% discarded.

Perchloric Acid.—The acid used was prepared by the method of Willard.⁵ This material was converted to the true dihydrate,⁶ HClO₄-2H₂O by a method to be described in a subsequent paper. The dihydrate was used to acidify the butyl alcohol employed in this investigation as well as for converting weighed portions of potassium and sodium chlorides to perchlorates.

Sodium and Potassium Perchlorates.—These materials were prepared

from sodium and potassium chlorides that had been twice recrystallized from aqueous solution using hydrogen chloride. The chlorides thus obtained were converted to perchlorates with an excess of pure perchloric acid followed by crystallization of the perchlorates and filtration with centrifugal drainage. The perchlorates thus obtained were dried at 250° and were found to be free from chlorides.

Sodium and Potassium Chlorides.—These were a foreign firm's best product dried at 250° before use.

Solubility Determinations

The solubilities of sodium perchlorate in n-butyl alcohol both at ordinary temperature and at the boiling point of the resulting solutions, in the absence and in the presence of increasing percentages of perchloric acid, are important in connection with the present investigation. Solubility tubes were prepared containing an excess of anhydrous sodium perchlorate together with the pure butyl alcohol or alcohol containing 0.25%, 0.5% or 1.5% of perchloric acid dihydrate by weight. The sealed glass tubes were revolved endwise during 5-6 hours at room temperature of 25° with variation of less than 3°. The temperature coefficient for the solubilities involved was known to be high, but since all experiments were conducted simultaneously and comparative results only were desired, accurate temperature control was not necessary. The saturated solutions thus obtained were allowed to settle, samples were withdrawn from the clear supernatant liquid and the sodium perchlorate was determined as described by Willard and Smith.7 The solubility determinations of the same solutions at the boiling point were carried out in a specially prepared all-glass refluxing apparatus. The solutions in presence of excess of solute were gently boiled for 1/2 to 1 hour and samples were withdrawn from the continuously boiling solution with a special pipet provided with a filtering medium in its lower stem and maintained hot by being inserted through the reflux condenser into the hot vapors over the solution.

The results obtained are reported by graph (Fig. 1) rather than by table to avoid a wrong conclusion concerning their accuracy. The determinations were carried out in duplicate to exclude the possibility of gross error.

By study of the values reported in Fig. 1 it is seen that the solubility of anhydrous sodium perchlorate at 25° in the butyl alcohol employed is approximately 3%. The addition of 0.25%, 0.5% and 1% perchloric acid dihydrate is progressively without appreciable effect, the solubility still remaining approximately 3% in the presence of 1% of acid. The solubility of sodium perchlorate in the pure alcohol at the boiling point of the solution is approximately 7.6% while with addition of perchloric acid dihydrate the solubility increases uniformly until at 1% acid concentration the solu-

⁷ Willard and Smith, This Journal, 45, 291 (1923).

bility of the sodium salt has reached approximately 9%. In addition to the values included in Table I it was found that the butyl alcohol when treated with 1% of water by volume and 1% of perchloric acid dihydrate by weight, dissolved at 25° approximately 4.5% of sodium perchlorate, and this value was increased to approximately 5% for butyl alcohol containing 1% of acid and 3% of water for the same temperature. It has been shown by Willard and Smith⁷ and by Gomberg⁸ that equilibrium for solutions of perchlorates in organic solvents is slowly attained and that there is a pronounced tendency towards supersaturation. This observation was found to hold for the solution of sodium perchlorate in butyl alcohol, so that in actual practice solubilities in excess of those given are

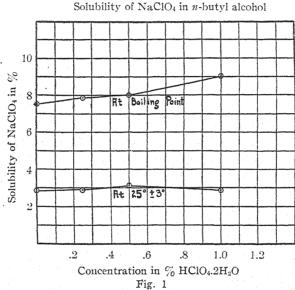

Fig. 1 often obtained. Determinations of solubilities of sodium perchlorate in butyl alcohol containing 1% of perchloric acid dihydrate with 1% and 3% of water at the boiling point were not made but the values are known to be much higher than for the same solutions without water and at the

The solubilities of potassium perchlorate in the same solvent were made omitting determinations for boiling solutions. In these determinations 100 cc. or more of solvent was employed, the solutions resulting from the equilibria attained after 5–20 hours' agitation were filtered through a Monroe crucible and the potassium perchlorate in the weighed filtrates was recovered and converted to potassium sulfate, from the weight of which the potassium perchlorate originally dissolved was de-

boiling temperature.

0.5	3.0	84	.0006	1.2
1.0	5.0	97	.0014	2.3

One-third of these values represents the amount calculated as K₂O.

It will be seen from Table I that for butyl alcohol, as demonstrated for ethyl alcohol by Thin and Cumming⁹ and by Baxter and Kobayashi,¹ the solubility of potassium perchlorate is materially diminished by the addition of perchloric acid. This effect is very pronounced for butyl alcohol containing up to 5% of water. The data of Table I led to the choice of butyl alcohol containing 1% of perchloric acid dihydrate and 3% of water as the best solvent to be used in the separation and determination of potassium and sodium in the manner to be described.

The Precipitation of Potassium Perchlorate and Separation from Sodium Perchlorate

The mixed chlorides of potassium and sodium (free from sulfate) obtained by the J. Lawrence Smith or other method are evaporated to dryness with an excess of perchloric acid. A second evaporation is desirable when the amount is great. Two or three cc. of water is then added according to whether the amount of potassium is low or high, respectively, and the mixed perchlorates are then dissolved by gently swirling the covered beaker over a free flame. The sodium perchlorate is extremely soluble. Potassium perchlorate dissolves to the extent of 20 mg. per cc. at 25° as shown by Willard and Smith⁷ and more than 200 mg. at 99° as shown by Calzolari. Sixty-five or 100 cc. of 0.5–1.0% perchloric acid butyl alcohol solution, according to whether 2 cc. or 3 cc. of water has been added to dissolve the mixed perchlorates, is heated to boiling (using a wire gauze

⁹ Thin and Cumming, J. Chem. Soc., 107, 361 (1915).

¹⁰ Calzolari, Acc. Sci. Med. Ferrara, 85, 150 (1911).

and free flame) and added to the warm, aqueous, perchlorate solution slowly with vigorous stirring. The potassium perchlorate is slowly precipitated as the addition of alcohol continues and after all has been added the solution is boiled gently in the covered beaker for half a minute and cooled to room temperature.

The resulting solution and precipitate are filtered through a weighed Monroe or Gooch crucible, the potassium perchlorate is transferred and the beaker walls are rinsed with the butyl alcohol solution used as precipitant (for precautions involved in the preparation of Gooch crucible asbestos for acid butyl alcohol solutions and other manipulative details, see Willard and Smith).¹¹ The precipitate in the crucible is washed with 8 to 10 portions of 1 to 2 cc. each of precipitant, thus limiting the filtrate and washings to 125–150 cc. It is dried at 150–250°, cooled and weighed. From the weight of the perchlorate obtained, the potassium chloride or oxide present is calculated.

The filtrate and washings from the determination of potassium are diluted with considerable water, forming 2 layers, and the whole is evaporated on the steam bath in such a way as to avoid any condensation on the upper part of the beaker, thus hastening the evaporation. It is well to add 5 to 10 cc. of water at the end of the evaporation to make the removal of organic matter more complete as the solution becomes concentrated. By such treatment a colorless residue of sodium perchlorate and perchloric acid can be obtained. When any brown color remains after this treatment. remove the watch glass supports and heat the beaker gradually on the hot plate until fumes of perchloric acid are evolved. Allow the perchloric acid to continue just at the fuming point until the organic matter is oxidized. Add a few drops of perchloric acid if not enough is present. When the brown color is removed 0.5 cc. of concd. sulfuric acid is added, the watch glass supports are replaced and the acid is fumed off using a wire gauze and free flame. The beaker is cooled, 5-10 cc. of water added and the cover glass and beaker walls are washed. The sodium sulfate solution is then transferred to a platinum crucible, previously weighed with cover, the solution evaporated and the sodium sulfate ignited as usual.

The separation of potassium and sodium perchlorates by the process given was tested by the analysis of 10 mixtures of potassium chloride and sodium chloride and the results are reported in Table II.

Table II shows that small or large amounts of potassium can be separated from large or small amounts, respectively, of sodium by one precipitation, results being obtained which agree excellently with the calculated values. An exceptional compensation of errors accounts for this fact. The amount of potassium perchlorate dissolved which would make results low is counterbalanced by the occlusion of sodium perchlorate.

¹¹ Willard and Smith, This Journal, 44, 2823 (1922).

In all cases except those in which a very small amount of sodium is present no solubility correction for potassium is necessary. Direct determination of sodium in the filtrate from potassium gives results somewhat high in accordance with the higher molecular weight of potassium sulfate than that of sodium sulfate. The average plus and minus errors for the 10 analyses of Table II show the potassium chloride found to be 0.2 mg. low

for an average sample of 0.1441 g. of KCl and the sodium chloride found 0.6 mg. high for an average sample of 0.1603 g. of NaCl.

The use of 2 to 3 cc. of water to dissolve the mixed perchlorates of potassium and sodium followed by precipitation of the former by addition of butyl alcohol, requires more alcohol than the familiar extraction process. It was thought that the use of an excess of water over that required to dissolve sodium perchlorate and partially dissolve potassium perchlorate when present in large amount, would require the use of less alcohol without much decrease in accuracy as compared with the determinations listed in Table II. The determinations reported in Table III were made with 0.75

cc. of water and 25 cc. of butyl alcohol containing 0.5% of perchloric acid dihydrate to precipitate the potassium perchlorate, all other conditions being the same as previously described.

As will be seen from Table III results obtained using less alcohol, while not as good as those included in Table II, are still satisfactory.

Because of the low vapor pressure of butyl alcohol at water-bath temperatures, which must not be exceeded, direct determination of sodium as sulfate is comparatively slow and rather inconvenient. Since the determination of potassium is far more important than that of sodium, which is usually determined by difference following the determination of the mixed chlorides of potassium and sodium, and since by the method given the determination of potassium leaves nothing to be desired as to accuracy, the process is thought to be entirely adequate.

The correction for the solubility of potassium perchlorate to be applied in the absence of sodium was determined by precipitating 3 cc. of a saturated aqueous solution of potassium perchlorate in the manner already described, followed by filtration of the precipitated perchlorate and determination of the potassium in the filtrate. By duplicate analyses this correction was found to be 1.1 mg. of potassium perchlorate or 0.38 mg. of potassium oxide per 100 cc. of solution. This value is somewhat lower than that given in Table I but corresponds more exactly to working conditions.

The method as described has the following advantages: (1) absolute ethyl alcohol is replaced by n-butyl alcohol; (2) purification or dehydration of the alcohol used is not necessary; (3) it is a precipitation process; (4) one precipitation only is required; (5) the errors involved compensate one another exceptionally well.

A method has been devised by Willard and Smith¹¹ for the separation and determination of sodium and lithium using n-butyl alcohol. In this method butyl alcohol, used as received, was found adequate. The sodium was precipitated as chloride from its solution as perchlorate in butyl alcohol. The data described in the present paper indicate that butyl alcohol might be employed advantageously in an extraction process for the separation of potassium from sodium. Butyl alcohol could then be employed in the separation, successively, of potassium, sodium and lithium. The process is now being studied in this Laboratory.

The analyses reported in this paper include all of those carried out in the study of this method, with no omissions. The reliability of the process is thus demonstrated. No violent reactions were encountered throughout this work.

Summary

1. A method has been developed for the separation and determination of potassium and sodium depending upon the precipitation of potassium perchlorate from an aqueous solution by the addition of a comparatively

large volume of n-butyl alcohol, and its accuracy has been shown by its application to known mixtures of potassium and sodium chlorides.

- 2. The solubilities of potassium and sodium perchlorates in *n*-butyl alcohol have been determined.
- 3. The method was successfully applied in the separation and determination of known mixtures of potassium and sodium chloride including 20 determinations duplicating practical working conditions.
- 4. The method is particularly well adapted to the determination of potassium in the combined chlorides, the sodium being obtained by difference.
- 5. The use of n-butyl alcohol in proposed work on the separation and determination of potassium, sodium and lithium is discussed.

THE HEATS OF VAPORIZATION OF MERCURY AND CADMIUM

By Mayor F. Fogler¹ with Worth H. Rodebush Received June 16, 1923

Probably the application of the quantum theory that is of most importance to physical chemists is the calculation of the entropies of the monatomic gases. The expression 1.5 relating the vapor pressure of a monatomic liquid to its heat of vaporization also promises to be an application of considerable significance. While it is probable that the numerical results furnished by the quantum theory in these cases will be more exactly confirmed by more accurate data as in the case of other triumphs of the quantum theory, nevertheless there is always a danger in generalizing from meager or uncertain data.

The two elements that offer the best opportunity for a check upon the equation for the entropy of a monatomic gas are mercury and cadmium. The specific heats of these metals have been determined with considerable accuracy both for the solid and liquid, and the heats of fusion are known. There is, however, no direct determination of heat of vaporization of any metal described in the literature, that appears to be at all reliable. It is possible to calculate heat of vaporization from vapor-pressure data by means of the thermodynamic relation,

$$\frac{\mathrm{d}\ln p}{\mathrm{d}T} = \frac{\Delta H}{RT^2} \tag{1}$$

¹ This communication is an abstract of a thesis submitted by M. F. Fogler in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry at the University of Illinois.

² Tolman, This Journal, 42, 1185 (1920).

³ Lewis, Gibson and Latimer, *ibid.*, 44, 1008 (1922).

⁴ Dushman, ibid., 43, 397 (1921).

⁵ Rodebush, ibid., 45, 606 (1923).

However, the above equation can be used with exactness only at low pressures, which is precisely where the data are subject to the greatest percentage errors. Since it involves the slope of a curve it requires, for an accurate determination, an empirical equation representing the data to be set up and differentiated. In the case of mercury, Smith and Menzies⁶ and Menzies⁷ have set up an empirical equation for which they claim an accuracy of 1% at temperatures above 120°. In their equation. there is no term to take care of the variation of the specific heat of liquid mercury with the temperature and, assuming that the accuracy is no greater than they claim, the heat of vaporization calculated at 298° K., from their equation might easily be in error by some hundreds of calories. 300 calories is one entropy unit at 25° C. and is a great enough amount to invalidate any generalization in regard to the entropy of monatomic gases. Since the heat of vaporization is not only the most uncertain factor in the calculation of the entropy of monatomic gases from the experimental data, but is also the fundamental quantity in the equation of Rodebush⁵ for the vapor pressure of monatomic liquids, it seemed desirable to make as accurate a determination of it as possible for mercury and cadmium.

Experimental Part

Some time was spent upon what promised to be a simple and rapid method of determining heats of vaporization at higher temperatures. This method consisted in dropping an iron plummet of known specific heat and known initial temperature into the vapor of the boiling metal and determining the weight of metal which condensed upon the plummet. It did not appear feasible to weigh the plummet while suspended in the vapor, although this could probably have been done, so that, after sufficient time had elapsed for the plummet to come to the temperature of the vapor, the vapor was swept away by a current of gas and the plummet was withdrawn and weighed. This operation was not difficult to carry out but the amount of metal collected depended on the time that the plummet was left in the vapor, indicating that the plummet was losing heat by radiation. Radiation shields were introduced in an attempt to remedy this difficulty, but the results were still very uncertain and variable. Apparently, at higher temperatures the transfer of heat by radiation is so rapid that the unavoidable slight difference in temperature between plummet and environment caused serious heat losses.

It was then decided to attempt to use for mercury a modification of the method employed so successfully by A. W. Smith⁸ to determine the heat of vaporization of water. In principle, this method consists in determining the difference in the rate of input of electrical energy required

⁶ Smith and Menzies, This Journal, 32, 1434 (1910).

⁷ Menzies, ibid., 41, 1783 (1919).

⁸ Smith, Phys. Rev., 34, 173 (1911).

to maintain a quantity of liquid in an insulated vessel at a constant temperature when vaporizing at a measured rate and when no distillation occurs. Smith maintained the water at a temperature just below its boiling point and controlled the distillation by bubbling a current of air through the liquid. It seemed undesirable to work with mercury near its boiling point because of the difficulty of preventing excessive heat losses due especially to radiation at high temperatures. It seemed better to work at the lowest temperature at which the mercury could be readily vaporized and this temperature was found to be about 140° where the vapor pressure of mercury is slightly greater than 1 mm. At this low pressure, the distillation could not be controlled by bubbling a current of inert gas through the mercury because it would be necessary to pass through so many moles of gas to each mole of mercury vaporized that serious errors would be introduced because of the heat capacity of the gas itself. Accordingly, the vaporization was controlled by distilling the mercury in a closed system maintained at constant pressure. When it was desired to commence the distillation the pressure was lowered until the mercury just began to vaporize; distillation was stopped by admitting gas and raising the pressure. The operation then consisted in bringing the vessel containing the mercury to a constant temperature, measuring the rate of input of electrical energy necessary to maintain this temperature for an indefinite time, then commencing the distillation and again measuring the rate of input of electrical energy necessary to maintain the same temperature as before, and the amount of mercury distilled in a given time.

The vessel containing the mercury to be distilled was placed in a Dewar tube, but in order to make the heat losses as small as possible, it was found desirable to place this part of the apparatus in some sort of a thermostat. An air thermostat was tried using a heating coil, fan stirrer, and an air thermometer regulator. It was not found possible to maintain uniform temperatures throughout this thermostat. Presumably an air thermostat can be kept at a uniform temperature provided the insulation of the walls is sufficiently good, but with our apparatus it was necessary to have so many openings through the walls that the insulation was poor and the regulation of the thermostat very unsatisfactory. A very satisfactory substitute was found in a vapor bath of dibutyl ether, which boils at 142°.

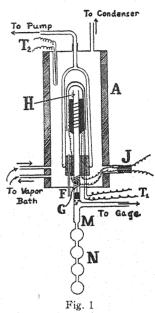

In Fig. 1 the general set-up of the apparatus is shown.

The vapor bath was made of copper with insulation (A) on the outside. H is the tube containing the mercury to be vaporized. The heating coil was wound around this tube, sheet asbestos was placed over the heating coil as insulation, and a sheath of heavy sheet copper was placed over the asbestos in order to equalize the temperature in different parts of the tube. A thermocouple was attached to the middle of this sheath. The tube H was about 10 cm. long by 2.5 cm. inside diameter; the vapor outlet was a tube of about 7 mm. diameter which was sealed through the bottom of the tube containing the mercury with a ring seal. The level of the mercury in the bulb was kept about 1 cm. below the

opening of the vapor tube, and experiments made with the apparatus exposed to view showed that the boiling was not violent enough to throw any drops of liquid mercury into the vapor outlet. The tube H was placed in the Dewar tube which was inverted because it was necessary to maintain the temperature inside slightly higher than the temperature of the vapor bath in order that no vapor might condense inside it. The mouth of the Dewar tube was closed with a loosely fitting cork. In order to make sure that no dibutyl ether vapor might enter the Dewar tube and condense, a very slow current of air was kept passing in through the tube F. To maintain the very highest possible vacuum at all times in the Dewar tube it was connected through a liquid-air trap to a mercury-vapor pump, which in turn was connected to a large evacuated flask, thus eliminating the sup-

porting pump. T_1 and T_2 are thermocouples. G is a magnetic plunger to dislodge any mercury that might condense on the sides of the tube, and N is a series of bulbs in which the distilled mercury was collected, sealed, and weighed. The connections to the heating coil were brought in at J. The source of the heating current was a lead storage battery. The energy input was measured by an ammeter and voltmeter calibrated to 0.1%. Pyrex glass was used exclusively in the apparatus. The mercury was carefully purified.

The arrangement of a Dewar tube inside of a vapor bath as described above gives a maximum of insulation with a minimum heat capacity. This is a very important consideration in an apparatus where it is necessary to maintain steady thermal conditions. It would be possible to decrease the heat losses by the use of insulating material, but such an apparatus would be unwieldy because of the length of time necessary to establish a steady state, and it is more important that the heat loss be constant than that it be small.

The mode of operation was as follows. The apparatus was brought to the temperature of the vapor bath, and the pressure in the tube containing the mercury was lowered until the mercury just began to distil. The heating current was adjusted to maintain a temperature inside the Dewar tube slightly above the temperature on the outside. When steady conditions had been established, any mercury adhering to the sides of the vapor outlet tube was dislodged by the magnetic plunger, collected in the bottom bulb, sealed off, and discarded. At the same time a stop watch was started, and at intervals of 15 minutes the mercury was collected in successive bulbs, sealed off and weighed. In the meantime, the current and voltage were maintained constant. No error was involved in the measurement of the time at which the bulb was sealed off, because after the mercury had been shaken down into the bottom bulb with the magnetic plunger, the next portions of mercury which came over would condense in the upper

part of the tube. As many as 5 bulbs were filled in succession. At the close of a run the pressure was raised to stop the distillation of the mercury and the current was readjusted to maintain the same temperature inside the Dewar tube as before, in order to correct for heat losses. Runs were made with temperatures inside the Dewar tube ranging all the way from 0° to 7° above the outside temperature. The correction for heat loss appeared to vary consistently with the temperature difference, being zero when the temperature difference was zero, and small in all cases. The value obtained for heat of vaporization appears to be quite independent of the correction made for heat loss. The results of 25 con-

secutive determinations range from 14,140 to 14,840 calories. These variations are believed to be due almost entirely to accidental errors, such as variation in the heat loss and the amount of mercury that adhered to the vapor outlet tube. The latter error would tend to be eliminated by our method of sealing off successive bulbs one after the other, since if one contained less mercury, the next would probably contain an excess. No results were omitted in this series of determinations, and it can be

stated with some confidence that the arithmetical mean of the results obtained would not be changed appreciably by any number of additional determinations. The probable error calculated by the method of least squares is about 25 calories. Allowing a possible constant error of 25 calories in the calibration of the instruments, etc., the heat of vaporization of mercury is found to be $14,490 \pm 50$ calories at 142° C. If this value be corrected to 298° K. we obtain 14,670. The value obtained by differentiating the empirical equation of Smith and Menzies at 298° K. is 14,615 cal. While this close agreement cannot be assumed to prove the accuracy of our results it does, on the other hand, indicate a very high order of accuracy for the vapor-pressure data of Smith and Menzies, since a very slight error in vapor-pressure measurements would cause a much greater error in the calculation of heat of vaporization.

Heat of Vaporization of Cadmium

It would no doubt be possible to make a direct calorimetric determination of the heat of vaporization of cadmium using the same method that was employed in the case of mercury. It would be necessary, however, to work at a temperature of at least 350° where the effects of radiation would be very great and the experimental difficulties would probably be considerable. On the other hand, the results in the case of mercury indicate that heat of vaporization can be calculated with considerable accuracy from vapor-pressure data, and this is especially true in the case of cadmium because we have the very elaborate work of Wüst, Meuthen and Durrer⁹ on the specific heats of solid and liquid cadmium at high temperatures. By way of existing data on the vapor pressure of cadmium, there are only the measurements of Egerton¹⁰ on solid cadmium and a measurement of the boiling point of liquid cadmium by Heycock and Lamplough.¹¹

The simplest and most promising method for the measurement of the vapor pressure of a liquid at high temperatures appeared to us to be the measurement of the boiling point at various reduced pressures. This has been done, working over a range of pressures from about 10 mm. up to about 80 mm. with very satisfactory results. It was not possible to measure the pressures below 10 mm. with sufficient accuracy, and the measurements in the direction of higher pressures were limited by the softening point of Pyrex glass.

The apparatus used was modeled after that used by the Bureau of Standards¹² for determining the boiling point of sulfur. A sketch of the apparatus is shown in Fig. 2. The cadmium was boiled in a test-tube

25 cm. in depth by 3 cm. inside diameter, around the bottom of which a heating coil was wound. This tube was mounted inside of a larger tube that formed a closed system connected to a source of supply of nitrogen, and a gage and a pump. The gage was simply a U-tube manometer containing mercury, made from tubing about 2 cm. inside diameter. A vacuum of about 0.002 mm. was maintained in one limb of the manometer by a connection to an oil pump which was kept running while measurements were being made. A leveling bulb was connected to the bottom of the manometer so that the mercury levels could be raised or lowered.

The thermocouple was placed inside a glass tube, the lower end of which was about 3 cm. above the molten eadmium. Around the lower

portion of the thermocouple tube was placed an iron radiation shield which was designed to prevent molten cadmium from running down the thermocouple A platinum-platinumrhodium tube. thermocouple made by Heraeus was used, with a calibration chart furnished by the makers. This calibration was confirmed by checking the thermocouple against the boiling point of sulfur. The thermocouple e.m.f. was read upon a White potentiometer. The heights of the mercury in the manometer were read to 0.02 mm, with a cathetometer. Before each reading the mercury was moved up and down the manometer to free the meniscus and readings taken with the mercury at different heights in the manometer showed no variation due to unevenuess of bore. The outside tube for about 3 cm. above the heating

coil was uninsulated in order to prevent superheating as far as possible. Above this, the tube was covered with asbestos insulation to prevent too rapid cooling and condensation of the vapor around the thermocouple.

In the operation the tube was filled with nitrogen at the desired pressure and the cadmium boiled at such a rate that the vapor rose well above the radiation shield, the thermocouple being immersed about 10 cm. in the vapor. Experiment showed that the temperature did not change when the height of the vapor was changed by varying the heating current. When the temperature and pressure had become constant, two sets of readings were made with the mercury at different heights in the manometer. The first question that concerned us was whether the pressure as read by the

manometer is the same as that under which the vapor condenses on the thermocouple. This question is not easily answered because a very rapid current of vapor flows past the thermocouple when the cadmium is boiling. It is believed, however, that the average variation in pressure from that read by the manometer is negligible. The question of the accuracy of the temperature measurements is more serious. The thermocouple is not likely to be below the temperature of the vapor, but superheating can very readily take place. The first run was made with the cadmium meniscus about 3 mm. above the top of the heating coil. Results were obtained which when plotted with the logarithm of the pressure as ordinate and the reciprocal of the absolute temperature as abscissa gave a remarkably smooth curve that deviated but slightly from a straight line, as the theory would predict. It seems unlikely that any serious error in the temperature measurements could have occurred in this run, because a variation of even 1° in the temperature of an observation would cause noticeable deviation in the plot and if any considerable superheating were taking place it would have been very remarkable if noticeable irregularities in the data

[&]quot; Egerton.

had not appeared. A second run was made with the cadmium surface about 3 cm. above the heating coil. No satisfactory observations were obtained in this run because of the violent bumping and unsteady boiling. A third run was made with the cadmium slightly below the top of the heating coil; in this case, superheating evidently took place and the results when plotted gave a very irregular curve. A fourth run was made with the cadmium surface about 1 cm. above the top of the heating coil, and the results obtained at lower pressures checked very closely the results of the first run. At higher pressures the cadmium began to bump

b Heycock and Lamplough.

and the observations again became uncertain. When the cadmium surface was slightly above the heating coil the boiling was very smooth and the temperature as read by the thermocouple was very constant and responded at once to the slightest change in pressure. It is believed that the temperatures observed under these conditions are not in error by more than 0.5° .

Eleven observations are given in Table II, each observation being the mean of two separate readings taken at the same pressure. The cadmium used was of very high purity.

We should be unable to do better than give a rough approximation of the heat of vaporization of cadmium were it not for the previously mentioned work of Wüst, Meuthen and Durrer⁹ on the specific heat of liquid cadmium. If we use their equation for the specific heat of the liquid and assume $C_p = 4.97$ for the vapor, we then have for the heat of vaporization of liquid cadmium

$$\Delta H = \Delta H_0 - 2.453 \ T - 0.000716 \ T^2 \tag{2}$$

Substituting this in the Clapeyron equation (1) and integrating, we have

$$\ln p = -\frac{\Delta H_0}{RT} - \frac{2.453 \ln T}{R} - \frac{0.000716}{R} T + C$$
 (3)

We thus have only ΔH_0 and C to determine.

The value for the vapor pressure at the melting point determined by Egerton¹⁰ is presumably not of high accuracy. Nevertheless, we shall find that it agrees very well with our determinations. The value for the boiling point obtained by Heycock and Lamplough¹¹ may likewise be in error by 2° or 3°. Furthermore, we can scarcely expect our equation to be strictly applicable at pressures of 1 atmosphere unless cadmium vapor is very nearly an ideal gas in its behavior. Hence, we shall be satisfied if our vapor-pressure equation approximates the value of Heycock and Lamplough. Accordingly, we find that if we assume $\Delta H_0 = 27,060$ cal. and take Egerton's value at the melting point as valid we obtain the final equation for vapor pressure in this form,

$$\log p_{\text{(mm.)}} = -\frac{5910}{T} - 1.234 \log T - 0.000156 T + 12.467 \tag{4}$$

This equation gives excellent agreement with the data and leads to a value for ΔH at 594.1° K. of 25,350 cal. It is believed that the data are not likely to be in error by enough to change the value for ΔH by more than 100 cal.

The Entropy of Monatomic Vapors

We are now in a position to calculate with considerable accuracy the entropy of mercury and cadmium vapors at 298° K. and 1 atmosphere. In the case of mercury the only change that we shall make from the calculation of Lewis, Gibson and Latimer³ is in the slightly greater heat of

vaporization. In the case of cadmium, the specific-heat data of Rodebush¹³ indicate an entropy of 11.97 for solid cadmium at 298.1° K. The data of Wüst, Meuthen and Durrer⁹ on specific heats and heat of fusion and our determinations of vapor pressure enable us to calculate the entropy of the vapor. Sackur, Tetrode, and others² have predicted that the entropies of the different monatomic gases at 298.1° K. and 1 atmosphere would be represented by the equation, $S = 3/2 R \ln M + C$, where M is the atomic weight and C a constant. Lewis has predicted that the constant would have a value of 25.70. The values we obtained are tabulated together with Lewis's theoretical calculations.

TABLE IV

The equation of Rodebush¹⁴ appears to fit the data for mercury and

$$p = \frac{\mathbf{N}RT}{N^2H} \sqrt{2 M \Delta H_0} \ e^{-\frac{\Lambda H_0}{RT}}$$

cadmium remarkably well. It is apparent that we can calculate a very good value of heat of vaporization provided we have only a very rough value for the vapor pressure at one temperature. Thus, for mercury at 298.1° K., we calculate $\Delta H_0 = 14,800$ cal. as against 14,670 found experimentally. For cadmium at its melting point we find $\Delta H_0 = 25,750$ cal. as compared with the experimental value, 25,350. The extraordinarily high specific heat of molten cadmium indicates that a greater deviation between ΔH_0 and ΔH may be expected than in the case of mercury.

From Egerton's value of 1.13 mm. for the vapor pressure of zinc at the melting point we may calculate the heat of vaporization of molten zinc. The value we obtain, 26,800 cal., we may expect to be somewhat high, as in the case of cadmium. We can check this by calculating the entropy of zinc vapor at 298.1° K. and 1 atmosphere, since we have all the necessary data. The result is somewhat high as may be expected, 39.1 entropy units, as compared with a predicted value of 38.2. This is a further confirmation, if any be needed, of the experimental generalizations that suggested the work of this paper.

¹³ Rodebush, This Journal, 45, 1413 (1923).

¹⁴ Here N is the number of molecules per sq. cm. of liquid surface, N is Avogadro's number, h is Planck's constant, M is the molecular weight, and $\Delta H_0 = \Delta E_0 + RT$ where ΔE_0 is the work necessary to remove a molecule from the surface of the liquid which is not in general the same as ΔE , the internal energy of vaporization. In the derivation of this equation (Reference 5) ΔE_0 was assumed to be identical with ΔE , ΔH_0 will usually be larger than ΔH .

Summary

The value of directly measured heat data as a supplement to vaporpressure data is pointed out.

The heat of vaporization of mercury is determined calorimetrically to be 14.670 ± 50 cal. at 298.1° K.

The heat of vaporization of cadmium is found to be $25,350 \pm 100$ cal. at 594.1° K.

The generalizations regarding the entropies of monatomic gases and relating vapor pressures to heats of vaporization are confirmed for zinc, cadmium and mercury.

THE ACTION OF SELENIUM OXYCHLORIDE ON VARIOUS METALS AND METALLIC OXIDES¹

By WARD L. RAY Received June 18, 1923

In his studies of selenium oxychloride, Lenher² has shown that this inorganic solvent reacts with most of the metals to give the chloride of the metal and selenium monochloride; also that many of the metallic oxides are dissolved by selenium oxychloride.

The object of this research was to study these actions in greater detail and to extend the study, in certain cases, to the action of selenium oxychloride on some closely related substances such as the selenides and the selenites.

The temperatures at which the reactions take place have been varied between room temperature, that of a steam-bath (about 90°), and in some cases the boiling point of selenium oxychoride (175°). A few reactions were studied at even higher temperatures.

Manipulation

About 10 cc. of selenium oxychloride, prepared by the interaction of selenium dioxide and selenium tetrachloride and purified by vacuum distillation,³ and from 0.2 to 0.5 g. of the metal of oxide were placed in tubes and sealed, to avoid the access of moisture and the consequent hydrolysis. These sealed tubes were allowed to stand at room temperature or were heated on the steam-bath until reaction was complete, or had progressed sufficiently far for our purposes. In some cases a day was required, in others a year.

¹ Abstract of a part of the thesis submitted to the Graduate School of the University of Wisconsin in partial fulfilment of the requirements for the Degree of Doctor of Philosophy.

² Lenher, This Journal, 43, 29 (1921).

² Lenher, ibid., 42, 2498 (1920).

In the experiments at the boiling point of the selenium oxychloride, the reactants were gently boiled either in small Erlenmeyer flasks or in glass tubes closed with watch glasses, and heated on a sand-bath or an electric hot-plate.

Analytical Procedure

In analyzing the precipitates formed in the various reactions it was necessary to use a non-aqueous solvent to wash out the excess of selenium oxychloride, and selenium monochloride when any was formed. The solvents found most satisfactory were carbon tetrachloride and chloroform.

The general method used to prepare the precipitates for analysis was to pour the selenium oxychloride containing the precipitate into a large excess of chloroform. The precipitate was washed several times by decantation, given a final washing on a filter paper or Gooch crucible, and dried in an air oven at 115° or in a special electrical drying apparatus in a current of dry air, depending upon whether it was easily hydrolyzed by the moisture of the air.

Selenium.—Selenium was determined gravimetrically as elementary selenium. It was precipitated from a hot, 15% hydrochloric acid solution, with a saturated solution of sulfur dioxide.

Selenium Monochloride.—Selenium monochloride reacts with water according to the following equation.

$$2Se_{2}Cl_{2} + 3H_{2}O = 4HCl + H_{2}SeO_{3} + 3Se$$
 (1)

The weight of the selenium precipitated is used to calculate the amount of monochloride that may be dissolved in selenium oxychloride, as the action of water on the selenium oxychloride gives selenious and hydrochloric acids.

Chlorine.—Chlorine was determined gravimetrically as silver chloride, sufficient nitric acid being used to prevent the precipitation of silver selenite.

Metals.—The general method of analyzing the residues obtained from the action of selenium oxychloride on the various metals and their oxides was to use one sample for the determination of chlorine and another for the determination of selenium. The filtrate from the selenium determination was evaporated to dryness and the metal in this residue determined by the most convenient method.

Experimental Part

Copper.—When selenium oxychloride is added to sheet copper at room temperature, the metal gradually becomes covered with a black substance which analysis indicates to be a mixture of cuprous and cupric selenides, Cu₂Se and CuSe. This black coating is gradually changed into anhydrous

cupric chloride. Selenium dioxide and selenium monochloride are formed at the same time. The completed reaction might be expressed as follows.

$$3Cu + 4SeOCl2 = 3CuCl2 + 2SeO2 + Se2Cl2$$
 (2)

The determination of the amount of selenium monochloride formed when a definite amount of copper is acted on by selenium oxychloride substantiates Equation 2.

Cuprous selenide, prepared by heating copper and selenium to 600°, reacts with selenium oxychloride to give cupric chloride, selenium monochloride and selenium dioxide.

A New Selenite of Copper.—When selenium oxychloride and anhydrous cupric chloride are heated together in contact with the air, a green crystalline salt is formed. Analysis shows this salt to be an acid selenite of copper, CuSeO₃.SeO₂, which has not hitherto been reported. Various experiments indicate that the formation of the salt is as follows.

$$CuCl_2 + 3SeO_2 = CuSeO_3.SeO_2 + SeOCl_2$$
 (3)

The selenium oxychloride simply acts as a solvent for cupric chloride and selenium dioxide. Selenium dioxide formed by the hydrolysis of some of the selenium oxychloride by moisture of the air is dissolved in the excess of selenium oxychloride, and when a certain concentration of selenium dioxide is reached the copper selenite is formed. The reaction may be made to go from right to left by adding selenium oxychloride that is not saturated with selenium dioxide.

Anhydrous cupric chloride and selenium dioxide heated together give selenium oxychloride and a selenite of copper.

Oxides of Copper.—Selenium oxychloride slowly reacts with cupric oxide to form cupric chloride and selenium dioxide according to the following equation.

$$CuO + SeOCl2 = CuCl2 + SeO2$$
 (4)

Cuprous oxide heated with selenium oxychloride is oxidized to cupric chloride, while a part of the selenium oxychloride is reduced to selenium monochloride.

CuSeO₃.2H₂O.—Selenium oxychloride reacts at once with cupric selenite CuSeO₃.2H₂O to give anhydrous cupric chloride. Many other copper salts were treated with selenium oxychloride, and in every case anhydrous cupric chloride was formed. The reaction may be expressed as follows.

$$CuSeO_3.2H_2O + 3SeOCl_2 = CuCl_2 + 4SeO_2 + 4HCl$$
 (5)

Silver.—Selenium oxychloride acts very slowly on sheet silver, yet the reaction is similar to that between selenium oxychloride and copper. Black silver selenide, Ag₂Se, which is later changed into silver chloride, is first formed, or at least is formed in such quantities as to mask the silver chloride that may be formed simultaneously. Both the silver selenide and the silver chloride form a coherent film on the silver, and this retards

further action. Silver selenide, prepared by heating precipitated silver with an excess of selenium at red heat for 20 minutes, reacts slowly with selenium oxychloride to give silver chloride.

Precipitated silver is rapidly changed into silver chloride when carefully added to cold selenium oxychloride. Silver leaf added to cold selenium oxychloride turns black at once, and in less than a minute is changed into a sheet of gelatinous silver chloride that floats on top of the selenium oxychloride. If the selenium oxychloride be hot, the reaction is similar, except that the film of silver chloride is thicker.

Silver Oxide.—Selenium oxychloride and silver oxide react with the evolution of light and heat to give selenium dioxide and silver chloride. The heat of the reaction decomposes a part of the silver oxide.

Lead.—Selenium oxychloride reacts more rapidly with lead than with either copper or silver. There is no indication that lead selenide is formed as an intermediate compound. The lead chloride that is formed is granular and drops away from the metal, thus exposing fresh surfaces to the action of the selenium oxychloride.

The Oxides of Lead.—When selenium oxychloride in small amounts is added to lead oxide, red lead and lead dioxide, the reaction is accompanied by the evolution of heat and light. With the last two oxides chlorine is evolved. The following equation represents the action of selenium oxychloride on lead dioxide.

$$PbO_2 + 2SeOCl_2 = PbCl_2 + 2SeO_2 + Cl_2$$
 (6)

Nickel and Cobalt.—Nickel and cobalt are very slowly attacked by selenium oxychloride. These metals in sheet form were placed with selenium oxychloride in sealed tubes and allowed to remain at room temperature for over a year. The selenium oxychloride was slightly darkened by selenium monochloride, while a small amount of the metallic chloride was in the bottom of each tube. The reaction between selenium oxychloride and the finely divided metals is more rapid.

The oxides of these metals slowly react with selenium oxychloride to give the metallic chloride and selenium dioxide.

Iron.—The chlorides of the metals so far discussed are either insoluble, or only slightly soluble, in selenium oxychloride. Thus, when the metal is added to a large excess of selenium oxychloride, the selenium monochloride and the selenium dioxide formed during the reaction are dissolved in the excess of selenium oxychloride, while the metallic chloride separates. A number of other metallic chlorides are more soluble in selenium oxychloride.

Iron dissolves rapidly in hot selenium oxychloride. The ferric chloride formed during the reaction remains in solution, but some of it is precipitated when the solution is repeatedly heated and cooled. In the cold, the reaction is slow and most of the ferric chloride separates from solution as fast as formed.

Ferric oxide is only slowly affected by selenium oxychloride at room temperature, but when selenium oxychloride in the vapor state is passed over ferric oxide heated to 400°, the reaction is rapid. Ferric chloride and selenium dioxide collect on the cooler portions of the tube.

Antimony and Bismuth.—These metals treated with a large excess of selenium oxychloride dissolve completely. A study of the amount of selenium monochloride formed during the reactions shows that bismuth is oxidized to the trichloride. The amount of selenium monochloride formed when antimony is dissolved in selenium oxychloride is more than would be formed to oxidize the antimony to the trichloride, but not enough to oxidize it to the pentachloride.

Tin.—When tin is added to cold selenium oxychloride, action begins at once. The selenium oxychloride becomes dark red from the selenium monochloride formed during the reaction. No precipitate is formed. When sufficient tin is present, the reaction continues until the solution becomes so viscous that it will not run from one end of the tube to the other. The tin is oxidized to stannic chloride.

It was not possible to prepare Weber's⁴ compound, SnCl₄.2SeOCl₂, from the action of selenium oxychloride on tin. The presence of selenium dioxide and selenium monochloride dissolved in selenium oxychloride evidently prevents the reaction between the latter and stannic chloride to form SnCl₄.2SeOCl₂.

The author wishes to acknowledge his appreciation of the inspiration and helpful suggestions received from Professor Victor Lenher, under whose direction this work was carried out.

Summary

- 1. A detailed study has been made of the action of selenium oxychloride on 9 metals, 9 metallic oxides, and 2 selenides.
 - 2. A new selenite of copper has been prepared.

A METHOD FOR PHOTOGRAPHING THE DISINTEGRATION OF AN ATOM, AND A NEW TYPE OF RAYS¹

By WILLIAM D. HARKINS AND R. W. RYAN

Received June 25, 1923

Introduction

In 1915 Harkins and Wilson² published the first definite theory of the composition of the nuclei of atoms in terms of hydrogen and helium. The theory predicted a general difference of stability between the atoms of elements of even and those of odd atomic number. That this prediction is definitely confirmed was shown in a later paper,³ where it was demonstrated that (1) the elements of even atomic number are represented in the meteorites by 70 times as many atoms as those of odd number; (2) every one of the 7 most abundant elements in the meteorites has an even atomic number; (3) every one of the 5 undiscovered elements has an odd atomic number, and (4) there are many more atomic species (isotopes) of even than of odd atomic number.⁴

An altogether different type of confirmation was supplied later by Rutherford.⁵ He was able to disintegrate atoms of the elements 5, 7, 9, 11, 13 and 15, in such a way that they give off hydrogen in every case, while he did not obtain any evidence that atoms of elements of even atomic number disintegrate at all. Now, the theory of Harkins specifically pointed out that the energy of combination of hydrogen to form helium is so great that a disintegration of any atom built up entirely of helium would probably in no case give hydrogen (Table I), but it indicated that elements of odd atomic number contain hydrogen not combined into

helium, and these would thus be capable of disintegration to give hydrogen, as accords with the experimental results.

TABLE I ENERGY OF ALPHA-PARTICLES

Energy of formation of 1 g.-atom of helium from 4 g.-atoms of hydrogen = -2.8×10^{19} ergs. (-4.6×10^{-5} ergs per atom of He)

Source of α-particle	Velocity	Kinetic Per particle × 10 ⁵	energy, Per gram atom \times 10 $^{-18}$
Po	0.0523 c	0.812	4.92
Ra C'	.0641	1.218	7.38
Th C	.0572	0.970	5.88
Th C'	.0688	1.404	8.51

The table indicates that the highest kinetic energy for any of the α -particles listed is less than 1/2 the energy of formation of an α -particle from protons and electrons. "c" is the velocity of light.

The scintillation method as used in these experiments by Rutherford, is capable of detecting disintegration particles which have only a range greater than 30 cm. in air, since hydrogen atoms which are merely released from chemical combination in water, hydrogen, and other compounds, have nearly this range, while H+ particles (protons) released from the nucleus of an atom have a greater range. In the case of the aluminum nucleus, for example, it is 90 cm. However, other disintegrations may occur. Thus, when bombarded by swift α -particles, certain atom nuclei may give disintegration fragments, such as α -particles, H⁺ particles, or electrons, of a shorter range than 30 cm. Since all such particles, of any range down to less than a millimeter, leave visible tracks in the ray track apparatus of C. T. R. Wilson,7 it would seem that a method could be devised which would utilize this apparatus for the detection and study of nuclear disintegrations induced by the impact of swift α -particles, provided the characteristics which such a disintegration would exhibit could be determined, and to do this is very simple.

Photographs of Atomic Collisions. (Collisions of the Nuclei of Atoms)

In order to disintegrate an atom nucleus artificially it is necessary to bombard it with a high-speed helium nucleus (α -particle).⁸ The scintillation experiments of Rutherford,⁹ and of Geiger and Marsden¹⁰ have shown that the α -particle must pass through an extremely great number of atoms

- 6 In the 1915 paper from this Laboratory it was pointed out that the packing effect for hydrogen nuclei in a complex nucleus is smaller in all probability when the hydrogen is not combined in an α -particle. The atomic weight of nitrogen, 14.01, indicates that this is true in the nitrogen nucleus unless the 0.01 in excess over a whole number is due to experimental error.
 - 7 Wilson, Proc. Roy. Soc., 87, 277 (1912).
 - 8 It is of course possible that high-speed electrons may also induce disintegration.

in order to secure a single collision with the nucleus of an atom, and the photographs described in the present paper demonstrate this in a much more direct way.

The writers have taken 21,000 photographs of α -ray tracks in air and a few in helium and ethyl chloride. Of these 10,000 were secured by using polonium, and 11,000 by using thorium C and C' as the source of the α -particles. In all, about 80,000 tracks have been photographed. In each of these the α -particle passes directly through between 100,000 and 200,000 atoms, provided atoms have the dimensions usually attributed to them. In all about 12 billion atoms have been shot through, with the remarkable result that in only 3 cases has the nucleus of an atom of the

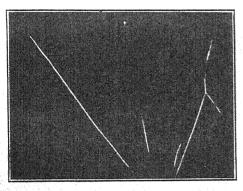

Fig. 1.—Sharp atomic collision with a visible track of the bombarded nitrogen or oxygen nucleus. The fork exhibits conservation of momentum which proves that the nucleus remains stable under the impact

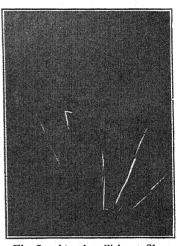

Fig. 2.—Atomic collision. Shows an apparent but not a real, contradiction of the principle of conservation of momentum

gas been hit sharply enough to give a retrograde motion to the α -particle after the collision. Thus for each sharp collision the α -particles have had to shoot through about 4 billion atoms. This fact taken alone would indicate that the radius of the nucleus of an atom of air¹¹ is of the order of $\frac{1}{30,000}$ that of the atom, which would give the nucleus a radius of the

order of a little more than 10^{-13} cm. Since the number of hits is so small, a closer estimate could be secured by a consideration of the numerous cases in which the particle is slightly deflected from its path by the repulsion between its positive charge¹² of 2 and that of 7 on the nitrogen nucleus.

Fig. 1 gives a reproduction of a photograph of the sharpest nuclear

¹¹ An atom of nitrogen or oxygen.

¹² In this paper the charge on the electron is taken as of unit magnitude.

collision ever obtained, with one exception. The α -particle from a polonium source, with an initial velocity of 1.357×10^{10} cm. per second, is turned through an angle of 155° and rebounds for a distance whose horizontal projection is about 5.2 mm. while the nitrogen nucleus is projected forward for a corresponding distance of 3.8 mm. If the track of this

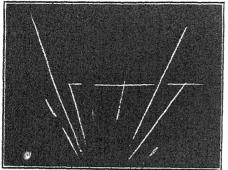

Fig. 3.—Effect of old tracks in the taking up of water vapor

nucleus is projected backward it may be seen that the line thus obtained lies slightly closer to the track of the on-coming, than to that of the retreating α -particle. This is essential in order that the impact shall exhibit conservation of momentum, since the α-particle has much less momentum after the collision than it had before.

The characteristics of an ordinary collision are: (1) the initial track splits into two branches,that is, three lines converge at

one point in space, -(2) momentum is conserved in the collision and (3) the three tracks lie in one plane. In addition, energy is conserved.

provided the presumably small amount of energy radiated is taken into account.

Fig. 2 shows the third sharpest collision photographed, and is presented as an example of an apparent, but not a real, contradiction to the principle of conservation of momentum in an impact. Here the track of the bombarded nucleus does not appear in the photograph. Presumably this is due to a lack of water vapor for the production of the track. This showing old track threading the loop often occurs and is due to a con-

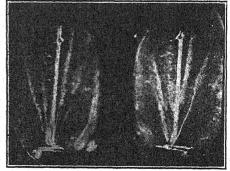

Fig. 4.—Loop formed by two α-ray tracks,

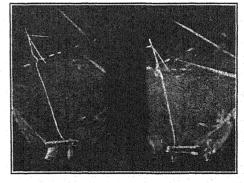

version of the water vapor in a particular region into the minute drops which form a track. These drops are electrically charged and are drawn out of the gas by an electrical field of 500 volts per cm. If a second track passes through this region within a few tenths of a second there is not sufficient moisture to enable water to gather in drops on the ions, so there appears to be a break in the track. In one photograph (Fig. 3) there are two such breaks in a transverse track; one due to a track which has passed so recently that it appears very sharp, while the other is caused by an older track which has become diffuse and has been mostly swept out by the electric field. The transverse track was photographed almost immediately after its formation. If it had remained slightly longer, ions produced by the α -particle would have diffused out (or have been pulled out by the field) of the dry region into a space which contains more moisture, and here an apparent loop somewhat like half of an ellipse cut along its longer axis would have appeared in the track. This bends either upward or downward corresponding to whether the new track lies above or below the old one. In some cases it bends in both directions, and the remnant of the old track is photographed as if threading the eye of a needle. (Fig. 4.)

Characteristics Exhibited by a Photograph of the Disintegration of an

In order to secure the transfer of a large amount of energy to the nucleus to be disintegrated, the incident α -particle should have as high a speed as is possible, and also the collision should be as sharp as can be obtained. The former of these conditions was met in the experiments under discussion in this section, by the use of thorium C and C' as a source. Fig. 5 shows the sharpest collision ever photographed. The angle in space

between the lines representing the tracks of the α -particle is only 15°, so that the particle has been turned through an angle of 165°.

Where a nuclear collision occurs, the initial track splits into two branches. If it should split into three branches, one of these would be due to the rebounding α -particle, one to the forward path of the nucleus which is hit, and a third track, provided it were due to a positively charged nucleus, would indicate a par-

and a third track, provided it Fig. 5.—Sharpest collision of atomic nuclei were due to a positively charged photographed. Shows the number of tracks characteristic of an atomic disintegration

ticle torn off from the bombarded nucleus by a process of disintegration. Now it happens that the tracks of positively charged nuclei are usually easily distinguished from those of negative electrons, since the latter are much fainter, and more highly curved. It might seem that the extra track was caused by the collision of the α -particle with a second nucleus which is not very distant from the first one, but nuclear collisions are so rare that this

is extremely improbable. Even if it should occur, the momentum and energy relations are such as to give a type of double fork which could probably be recognized. Thus, the energy imparted to the nuclei would be taken from that of the α -particle, so the latter should have a shorter range if it gives energy to a second nucleus than if it hits only one. The energy difference can be estimated, within rather wide limits, from the range of the nuclei that are hit. Even at such high speeds as those used in this work there should be no considerable departure from the principle of conservation of momentum in the combined impact and disintegration. Therefore, whenever all of the tracks show, the photograph should exhibit this conservation. However, Fig. 2 demonstrates that the track of even a highly charged positive nucleus may fail to appear. From this point of view it would not seem strange if the faint tracks due to high speed electrons or H $^+$ particles should remain invisible.

If a disintegration should occur, the α -particle and the bombarded nucleus alone would not be expected to exhibit conservation of momentum, though momentum is always conserved in a collision unaccompanied by a disintegration. This indicates that if the tracks of these particles as shown by the photograph are such that momentum is not conserved for the two particles alone, and atomic disintegration has taken place.

In a simple collision it is to be expected that all of the tracks should lie in a plane. If a disintegration occurs this should not be true except by accident.

Fig. 5 shows an α-ray track which splits into 3 branches after the collision occurs, so it has this characteristic to be expected if the bombarded nucleus disintegrates. The extra track is too bright to be caused by an electron, though its extreme brightness is due to the fact that it is photographed almost "head-on." It is evident that the visible tracks do not exhibit conservation of momentum, which may indicate that other particles are emitted at the same time, but do not show. The tracks in the original negative are sharp—much sharper than in the reproduction, and a study of the film under the microscope seems to show that if the third particle is neglected, the remaining tracks do not show conservation of momentum as they should if the collision is a simple one. The question arises, could the extra track have been formed by the disintegration of a radioactive particle exactly at the point of collision at almost exactly the time of the collision? It cannot be stated that this is an absolute impossibility, but it is certain that the probability of such a coincidence is excessively small. At any rate the method used in these experiments will in general photograph atomic disintegrations if they occur.

Zeta (¿) Rays

Delta(δ)-rays were first found in gases by Bumstead, who gave them a sufficient range for observation by causing them to appear in hydrogen

at low pressures. The rays are given off at nearly right angles to the track of the α -ray which produces them. They are very short in air at ordinary pressure, not more than 0.5 mm. in length, and end in a knob which is easily visible. It is supposed that they are produced by low speed electrons removed from the atoms by the passage of the particle.

C. T. R. Wilson has secured beautiful photographs of these rays, and the writers have often observed them, particularly in helium.

Fig. 6 shows a new type of rays, which may be called zeta (t) rays. Their range is very many times greater than that of the δ -rays. They are much rarer, and give faint, but very definite tracks. Their faintness and high curvature makes it seem probable that they are Probably due to electrons due to electrons torn out of the

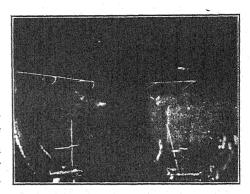

Fig. 6.—Rays of a new type (Zeta Rays).

atoms, possibly from the K level. The figure indicates that the ejection of the first ζ -ray does not materially change the direction of the α -ray track, and this, taken in connection with the length of the tracks shows that the mass of these particles must be low, as would be the case if they are electrons.

These rays present features of extreme interest.¹³ Thus in Fig. 6 the

¹⁸ In a letter in Nature, 111, 463 (April 7, 1923), Bose and Ghosh present three interesting photographs of α -ray tracks in helium. The interpretation of these photographs is difficult, since only one projection was obtained, but it seems that electrons have been ejected from helium atoms by the passage near or through them of α -particles. In this respect there is some similarity to what has been discussed above under the designation of ζ-rays. However, their rays possess quite different characteristics, since they are not projected backward. In order to determine the nature of the rays secured by them two projections should be obtained, since one projection may reveal entirely different characteristics from those exhibited by the other.

Their photographs do not resemble those which depict the collision of 2 atom nuclei, since in each case there seems to be a continuation in a straight line of the initial α -ray track beyond the point where the branching occurs.

Since the nucleus of the argon atom is larger, and the electric field around it is also stronger, than for nitrogen or oxygen, it is much easier to secure photographs of atomic collisions in argon than in either of the two other gases. Blackett [Proc. Roy. Soc., 103A, 62 (1923)] obtained one collision in which the α-particle from polonium was turned through an angle of about 110°, but this is much less sharp than those given in Fig. 1 (125°) and in Fig. 3 (165°).

In addition to the 21,000 photographs of α -ray tracks in air described in the body of the paper, the writers have now obtained about 20,000 photographs of tracks in argon.

2 ray-tracks are practically parallel. Both start upward and give curves that are convex upward. The particles have a considerable retrograde motion, and their range is about 3 mm.

Of these, two are so remarkable that they are presented in Figs. 7 and 8. One of these, Fig. 7, represents by far the most remarkable simple collision yet obtained, in that the

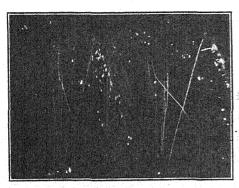

Fig. 7.—Collision of fast α -particle with the nucleus of an argon atom. The hardest hit thus far photographed. The fork exhibits conservation of momentum, which proves that the argon nucleus has not disintegrated

speed of the a-particle is far higher than for any previous case. even after the loss of a considerable fraction of its energy by collision with an argon nucleus, the velocity of the rebounding α -particle is nearly 1/20 that of light, or 18,000 times that of the fastest rifle bullet. The range of the argon nucleus in argon is very high, about 8 or 9 mm. under the conditions of the experiment. The most remarkable feature of this photograph is that it shows that even under this terrific impact the argon nucleus remains intact, so its stability must be of an extremely high order. The α -particle in question has its source in thorium C'. so its initial velocity is 0.688 c.

A nuclear collision which is not simple is represented in Fig. 8. An

 α -particle from a source consisting of thorium C and thorium C' strikes an argon nucleus and is deflected diagonally upward through more than 45°. Two other tracks

spring from the point of collision, as is made evident by the two projections which go more or less downward. As nearly as can be told, there is a total conservation of momentum in the im-The appearance of the two tracks for the bombardment nucleus instead of one indicates that (1) the argon nucleus disintegrates, or (2) the bombarded argon nucleus collides with a second argon nucleus within 0.5 mm. of its starting point. There is a third possibility, that the α -particle hits 2 argon nuclei in direct succession, but the probability of such an occurrence is almost negligible. The angle between the two tracks under discussion is about 80°. From the 20,000 photographs of α -ray tracks in argon, and by a consideration of the stopping power of argon,

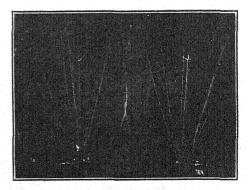

Fig. 8.—Double collision of atom nuclei in argon. The α -particle collides with the nucleus of an argon atom, and probably this in turn collides with a second argon nucleus. Both views of the collision are clear in the original photographs

it has been calculated that the probability that an argon nucleus will hit a second argon nucleus within a distance of 0.5 mm. in such a way as to give an angle as great as 80° between them, is small, possibly about 1 in 1000, the most uncertain factor being that

Experimental Part

The apparatus used is shown in Figs. 9, 10, and 11.

It is essentially a modified Shimizu-Wilson apparatus, 14 and consists of a glass cloud chamber N (Fig. 9) fitted with a piston and provided with a means for securing a sudden expansion. The roof of this cloud chamber is a glass plate K coated underneath with moist gelatin to which copper sulfate has been added. The top of the piston is also coated with moist gelatin blackened with india ink (not waterproof). A source of α -rays is provided at one side of the chamber as shown in Fig. 11 (B). Electrons given off and ions formed by the passage of α -particles through a gas serve as nuclei for the formation of water drops during the expansion and consequent cooling of the nearly saturated gas. A motion picture camera A is provided with a driving mechanism and an optical system such as to take views at right angles at the end of each expansion.

The most important modifications of the original Shimizu-Wilson Apparatus and the method of securing the rays are: (1) the use of a standard

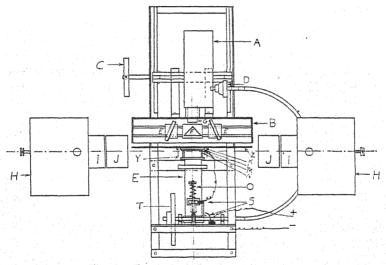

Fig. 9.—Front view of ray track apparatus

motion picture camera driven by a flexible shaft (A, Figs. 9 and 10); (2) a special cam R (Fig. 10) used to secure a sudden expansion (a related to the speed of the argon nucleus. Nevertheless, the characteristics of the tracks around the point of impact suggest that this double collision is probably what has occurred. The shortness of the two tracks, and their approximate equality in length seem to point to the conclusion that in this case a disintegration has not occurred. That the two short prongs are not due to electrons is indicated by the fact that the α -particle is deflected too sharply to give conservation of momentum with such light particles. Thus it seems probable that Fig. 8 represents the first "double collision" of atom nuclei to be photographed, though the possibility that the argon nucleus has disintegrated is not at all excluded. (Received August 9, 1923.)

¹⁴ Shimizu, Proc. Roy. Soc. (London), 99A, 425 (1921).

somewhat similar device is used by Blackett¹⁵); (3) the use of ThC, ThC', and RaC as source of α -rays; (4) the electric field used to sweep out water drops between the expansions is applied by means of brush con-

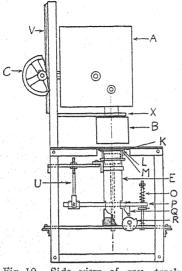

Fig. 10.—Side view of ray trac apparatus

tacts S instead of by a commutator; (5) a variable voltage transformer and a 500 volt kenotron (with a 1mf. condenser) is used as a source of this field; (6) the use of a moving screen prevents α -particles from entering the chamber except during maximum expansion.

The cylinder of the cloud chamber was ground from a well annealed borosilicate glass blank so as to give the uniform small clearance necessary to secure good cloud tracks. A capillary stopcock was provided on one side so that various gases might be introduced. Fig. 11 shows the means of screening α-particles from the chamber except at maximum expansion. A is a copper strip used as a screen to track prevent rays from entering the chamber except at the time of maximum expansion

and B is a Bakelite block holding the copper wire carrying the active deposit. This is so bored that α -particles are able to shoot out in only

a narrow beam; α -particles shot out at other times than at maximum expansion give diffuse tracks.

ThC and ThC' served as the source of the α -particles for much of this work. About 1 mg. of radiothorium is first dissolved in concd. hydrochloric acid. Then a copper wire is coated with wax, except at one end, and immersed in this solution for about half an hour or longer if the solution is weaker. The "active deposit" of thorium, consisting largely of ThC and ThC', deposits (by displacement) on the exposed copper. The end of the wire is then cut off and placed at

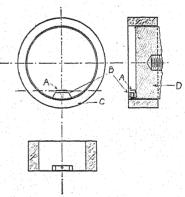

Fig. 11.—Diagram of ionization chamber

the base of the Bakelite block (B, Fig. 11). The very short life of ThC (only a few hours) makes it necessary to prepare this source immediately before use. Polonium sources are prepared in a similar way from solu-

¹⁵ Blackett, Proc. Roy. Soc., 102A, 294 (1922).

tions of RaF in hydrochloric acid but have a life measured in months instead of hours.

The photographic equipment includes a motion picture camera (A, Fig. 9) driven by a flexible shaft which carries a clutch D and thus allows the timing of the shutter with the expansion. This camera is provided with a Taylor-Hobson-Cooke F/2 lens in a focusing mount G, and an optical system which consists of two adjustable surface silvered mirrors E, and a prism F. These mirrors are carried on a 3-point support that slides along a track shown in Fig. 9, while the prism is clamped directly below the lens.

The cloud chamber is illuminated by two d. c. right-angle arcs, each provided with an 11cm. aspheric condenser and a cooling cell. Ammeters are used in both circuits and the current is adjusted so as to afford uniform illumination. Slits are provided on the cooling cell J and at Y in order to prevent the beam of light from striking the lower surface of the glass roof of the cloud chamber or the top of the piston at the moment of expansion.

In both views parts of the frame, the driving apparatus, etc., have been left out so that a clearer view of the essential parts of the apparatus could be given.

For a successful photograph a very sharp expansion is necessary, so that a fairly heavy spring O is used to force down the piston immediately upon its release by the cam R (Fig. 10). Means are provided for varying the length and the height of the stroke at U, and a locknut just below P regulates the expansion ratio. Somewhat exact adjustment is required to give the optimum conditions. A monatomic gas such as helium or argon requires a small expansion to secure the necessary cooling; air (nitrogen and oxygén) and other diatomic gases require a somewhat greater expansion, and a polyatomic gas such as ethyl chloride requires so great an expansion that it is difficult to prevent leakage into the apparatus. In the latter case the leather gasket of the piston must also be lubricated with some material not soluble in ethyl chloride (as glycerol and graphite).

The writers wish to thank the Visual Education Society for the use of one of their motion picture cameras; the Gibb's Fund of the National Academy of Sciences for a grant partly used in this work; Dr. H. N. McCoy for the polonium used and for the loan of radium; Dr. H. S. Miner of the Welsbach Company, for the loan of mesothorium and radiothorium; Mr. Henry Burke, of Burke and James, Chicago, for aid in securing the remarkably fine lens used; and Mr. Paul L. Gross for assistance in the photographic work.

Summary

1. The rarity of a collision between a fast helium nucleus (α -particle) and the nucleus of an atom in a gas through which it is passing, increases

greatly as the directness of the collision increases. At the time of the beginning of the experimental work described in the present paper no photograph of a collision had been obtained sufficiently sharp to give the helium nucleus (α -particle) a retrograde motion after the collision. Thus far photographs have been taken of enough tracks so that the α -particles have passed through about 12 billion atoms in air, with the result that in only 3 cases has such a rebound been obtained. This alone would indicate that the nucleus of an atom of nitrogen or oxygen is of the order of slightly more than 10^{-13} cm. in radius. A more accurate value can be obtained by a mathematical analysis of all of the deflections of the α -particle through smaller angles.

- 2. In an ordinary collision 3 tracks meet in a point: one for the α particle before, and a second for the same particle after the collision. If the bombarded nitrogen or oxygen nucleus should disintegrate, then at least 4 tracks should meet, the additional track being due to a fragment, such as an electron, a hydrogen or a helium nucleus, disrupted from the bombarded nucleus. The chance of such a disintegration increases rapidly with the directness of the collision, and with the speed of the α -particle. For some unknown reasons the tracks of high-speed α -particles have not been photographed in previous work. While using such high-speed particles the writers secured a remarkable photograph of by far the most direct nuclear collision recorded in this way up to the present time, with the result that a fourth track, which should characterize an atomic disintegration, appeared in the photograph. That this track springs from the proper point in space is shown by the two projections obtained simultaneously. These give two views at an angle of 90°. Whatever may be the final decision with respect to this individual photograph, the method presented in this paper will reveal atomic disintegrations to give either helium or hydrogen or electrons, provided they occur during the operation of the apparatus, though the labor and expenditure of funds involved in obtaining such photographs may prove to be very great.
- 3. Rays of a new type, designated by the writers as zeta (ζ) rays, are shown in Fig. 6. Here the α -particle evidently drives particles from 2 widely separated atoms in its path. It is remarkable that the two tracks thus obtained lie in almost parallel planes, both are highly curved and almost parallel lines, and both have a sharp retrograde motion. It seems probable that the ζ -rays are due to electron emission, but this is not certain. The particles must be very light, however, since the direction of the α -particle is not materially affected by the emission, and the tracks of the particles are moderately long, very much longer than those of the previously recorded δ -rays.
- 4. Thus far, 40,000 photographs have been secured, and 3,000 photographs are obtained for each additional hour of operation of the apparatus

with photographic attachments. A number of collisions have been observed visually during periods when the camera is not in use.

5. The method presented in this paper is being used to test experimentally the stability of atom nuclei. Such tests have not been made before. Rutherford's experiments, for example, reveal the disintegration of an extremely minute number of atoms to give long range hydrogen particles, but they do not show whether or not α - or any other short range particles are emitted. The difficulty of the present method lies in the small number of direct hits obtained. Less direct impacts are relatively numerous.

The remarkable feature of the present work is that in no case has any one of these oblique impacts effected a disintegration of the nucleus. Even more remarkable is the fact that the argon nucleus in Fig. 7 remains intact even under the sharp impact of a helium nucleus from Thorium C' (α -particle) with a velocity of 25,000 or 30,000 times that of the swiftest rifle bullet, immediately before impact. This is evidenced by the fact that the visible tracks around the point of collision exhibit conservation of momentum. Fig. 1 illustrates the stability of an atom of air (nitrogen or oxygen) in exactly the same way except that the velocity of the α -particle just before impact is not quite so high.

It may be added that the photographs chosen for this paper have been selected altogether from the standpoint of the importance of the events they represent, even although they may not be so good as some of the others from the purely photographic viewpoint.

THE EQUATION OF STATE FOR PURE NITROGEN, GAS PHASE¹

By Leighton B. Smith and Robert S. Taylor Received June 25, 1923

Following the method of Keyes, pure nitrogen has been investigated by the isometric method. The theoretical work in connection with the equation of state^{2,3,4,5} has made it appear highly probable that in the

¹ This investigation was undertaken by the Research Laboratory of Physical Chemistry at the request of the Bureau of Mines, working in coöperation with the War and Navy Departments. The Bureau of Mines as well as the Massachusetts Institute of Technology contributed liberally in funds needed to carry forward the work.

The present paper is the fourth published by this Laboratory presenting data required in perfecting the processes for the extraction of helium from natural gas.

case of a fluid composed of molecules of invariable type, the pressure should vary linearly with the temperature at constant volume. The truth of this proposition involves the consequence that the potential energy of any given species of molecule or atom should be a function of the volume only. The derivative of the potential energy or the cohesive pressure, as it has come to be designated, may be directly evaluated for each constant volume setting employed in the isometric method. The form of function which represents the cohesive pressure as well as the volume correction term is known and indeed the constants of the equation of state may be easily evaluated directly from the isometric data.

The constants for the equation of state for atmospheric nitrogen based on the data of Amagat have been published by Keyes. Sufficient data, however, for pure nitrogen are not available and the purpose of the present work is to provide accurate data from which the fundamental constants for nitrogen may be deduced. Certain improvements in method and a greater accuracy in the volume control of the apparatus have been attained as a consequence of this study.

Preparation of Pure Nitrogen

The nitrogen was prepared by heating a mixture of ammonium sulfate and potassium nitrite in solution.

Fig. 1 illustrates the apparatus employed for generating and purifying the gas. The flask A was partially filled with a concentrated solution of ammonium sulfate and a solu-

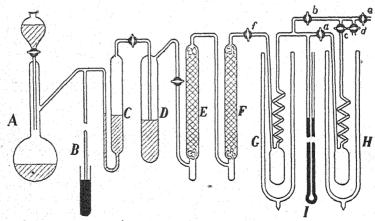

Fig. 1

tion of potassium nitrite was introduced from the separatory funnel, drop by drop. A safety tube and manometer B served to indicate the pressure and to relieve it, if it became excessive. The evolution of nitrogen was readily controlled by the heating and the rate at which the solution was admitted.

The gas first passed through concd sulfuric acid in the wash bottle C, then through a 20% solution of potassium hydroxide in D. E and F contained solid potassium hydroxide

droxide and phosphorus pentoxide, respectively. The gas was next passed through the bulb and spiral G immersed in liquid air which served to freeze and thus remove a large proportion of the impurities. From G the nitrogen passed to a similar arrangement at H which was immersed in liquid air through which hydrogen was bubbled. This so lowered the temperature of the liquid air that the nitrogen condensed to a liquid under a pressure of slightly more than 1 atmosphere. When a sufficient quantity of nitrogen had condensed in the bulb at H (about 20 cc.) the stopcocks a and f were closed and b and d opened, connecting G with the vacuum pump. G was now allowed to warm and the impurities that had condensed there were pumped away. The cock b was now closed and a opened for a short time, thus causing a portion of the liquid nitrogen to boil off and sweep out any fixed gaseous impurities in the vapor at H. The bulb and spiral at G were again cooled with liquid air through which hydrogen was then bubbled. The cock a was again opened and the bubbling of hydrogen at H stopped. As the temperature at H increased to that of liquid air boiling under 1 atmosphere pressure, the nitrogen slowly distilled from H and condensed at G. This process was stopped before all the liquid at H had disappeared and a was closed and C opened so that the residual nitrogen together with the impurities remaining in it were removed by the pump. This process of fractional distillation between G and H was repeated 5 times, and in each case the first and last fractions of distillate were discarded. The resulting liquid nitrogen was water-white and entirely free from particles of solid impurities. Finally, connection was made to the 6-liter Pyrex globe, which had previously been highly evacuated, and the nitrogen allowed to vaporize and fill the globe to somewhat over 1 atmosphere pressure.

The Pressure Gage

The gage was that employed by Keyes, Smith and Joubert⁶ in the work on the equation of state for methane gas phase and was of about 1 cm. in diameter.

It was calibrated against an open top mercury column about 9 meters high. A platinum needle in the short arm of the column for electrical contact with the surface of the mercury was used for detecting the equilibrium of the column. Temperature control of the column was obtained by enclosing it in a channel-shaped support closed on the front side by adjustable pieces of cardboard. The electrical system for detecting equilibrium of the gage consisted of a telephone with an audion bulb in circuit as indicated in Fig. 2. This device made possible the use of very feeble currents in the contact circuit, thus avoiding emulsification of the oil at the surface of the mercury and so insuring very sharp make and break. This emulsification of the mercury and oil is of very great importance in the compressibility measurements as it amounts to removing a small quantity of mercury from the piezometer portion of the system and thus changing its volume.

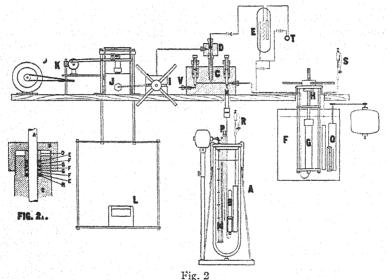

The length of the mercury column was measured on a steel tape, stretched by a load of 7 kg., which had been calibrated under the same stretching load by comparison with a standard meter compared at the United States Bureau of Standards. The complete data for the calibration of the gage have been published in the paper of Keyes, Smith and Joubert. The mean value of the constant is 1.0255 mm./g.

The Compressibility Apparatus and Method of Loading the Piezometer

The general apparatus is shown in Fig. 2, which is a further development of the apparatus used by Keyes and Felsing.⁷

- 6 Keyes, Smith and Joubert, J. Math. Phys., Mass. Inst. Techn., 1, 195 (1922).
- ⁷ Keyes and Felsing, This Journal, 41, 589 (1919).

The floating pressure piston with scale pan and motor for oscillating the piston is represented at J, L and K. The oil injector I serves to adjust the height of the floating piston and to compensate for leak of oil around the floating piston. The steel block C contains a stopcock V for exhausting and an insulated needle D for indicating the mercury level. This contact serves to detect equilibrium of the load on the piston and the pressure exerted by the material in the piezometer. For example, if too great a weight is on the piston the mercury will be depressed, and if too small a weight it will rise and make contact; 1 g. suffices, as a rule, to make or break the contact. A shut-off is provided for closing the piezometer B from the entire apparatus while connection is made from the block C to the mercury volume-displacement piston apparatus G submerged in a constant temperature bath F, whose contents are stirred by means of the motor and propeller apparatus Q. The nut H serves to force the piston into the mercury, driving it through fine steel tubing of small bore into the piezometer. The advance of the piston is indicated by 100 divisions engraved on the under portion of the nut. Whole turns are It is possible with the 16mm. piscounted by a "cyclometer" not shown in the drawing.

ton driven by a screw with 7.1 threads per cm. to estimate 0.001 turn of the nut, corresponding to about 0.00028 cc. The packing of the piston which moves into the cylinder G consists of cotton fabric heated in ceresin wax to 160°, and hard rubber forced into place by means of a steel ring driven by a screw cap.8 The packing is perfectly tight over long

⁸ The diagram, Fig. 2a, shows the method of applying the packing to the piston in the mercury volume injector. The piston is represented by A and the nut driving the packing at B through pressure on the steel ring D. At the bottom of the packing gland is a steel ring H which also is a snug fit to the piston. E, E indicate hard rubber rings and F,F,F the cotton fabric (such as unbleached cotton) impregnated quickly with ceresin wax at 160°. G,G are rings of soft steel. The annular width of the packing gland is about 3 mm. and the depth for moderate pressures (500 atm.) about 3 to 4 cm. The hard rubber ring protects the waxed packing from the kerosene of the bath and serves to wipe the piston as it moves backward and forward, thus minimizing the removal of wax. This latter objective is not as satisfactorily accomplished as desirable, but no better method of wiping the piston has been applied.

periods of use after having been seasoned by exposing it to several hundred atmospheres with successive tightenings of the driving nut. A similar packing is used on the stopcocks of the block C.

The constant temperature bath represented at A, Fig. 2, consists of a Pyrex Dewar tube 6.6 cm. in inside diameter and 40 cm. in length. The disposition of the platinum thermometer, stirrer, heater and mercury in the steel regulator is evident from the figure. For the bath fluid a high-boiling light oil sufficed for the range 50° to 200° , while an ice-bath served to maintain the piezometer at 0° . The cover of the bath is of asbestos wood and carries the bearing for the stirrer and binding posts for the electrical connections of the heater. The Dewar tube bath here represented is very convenient and has been employed to 330° . It possesses obvious advantages due to its permitting a view of the interior at all times, and the heat insulation is excellent. The Dewar tube, however, requires prolonged heating at 450° during exhaustion. Recent tubes silvered in such a manner as to leave a clear strip 2 cm. to 5 cm. in width parallel to the long axis have greater heat-insulating properties, at the same time permitting a view of the interior. The silver will not peel, once it has been slowly and thoroughly baked out during exhaustion.

The piezometer is represented in detail at A, Fig. 3. It was made in one piece from cold rolled steel, the lower end being spun shut and welded with the oxy-acetylene flame.

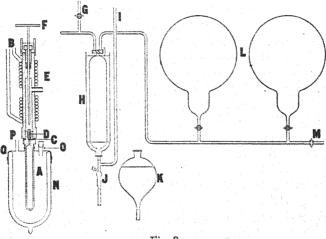

Fig. 3

A left-hand thread was cut on the outer portion, where it screwed into the top piece E surrounded by a cooling coil of copper B. The latter piece carried a screw driver F passing through a packing gland and sealed with mercury. The piezometer was locked by means of the plug D, which had a 0.75 mm. hole drilled throughout its length. The locking of the piezometer was secured by the compression of the gold washer C against a seat in the piezometer by means of the screw D. The purpose of the cooling coil about E was to preserve the packing gland during the exhaustion of the bomb at 350°.

Nitrogen is, of course, above its critical temperature at ordinary temperatures, and it was necessary to place in the piezometer sufficient nitrogen to give a range of volumes per gram from 5 to 23 cc. over the temperature range 0° to 200°. The capacity of the piezometer was 13.3143 cc. at 0° to the under surface of the gold disk. The quantity of nitrogen

employed was about $0.51~\rm g$., corresponding to about $410~\rm cc.$ at N.T.P. and producing about $40~\rm atmospheres$ pressure in the piezometer at ordinary temperatures.

The procedure of loading consisted in first exhausting the buret H connected by means of the 2-way stopcock with the piezometer, the latter being, of course, heated to drive off adsorbed matter. Nitrogen was then permitted to expand into H from the holders L and, when temperature equilibrium had been established, the pressure was read on the mercury column I. The buret was of the constant volume type, with the lower buret mark engraved on a tube of the same diameter as the manometric tube, thereby avoiding corrections for capillary depression. The nitrogen in the buret was transferred to the piezometer by cooling the latter in liquid air and raising the mercury reservoir K, thus liquefying the nitrogen in the piezometer. The vapor pressure of nitrogen at the temperature of liquid air is rather high, so the air was boiled under reduced pressure. For this purpose the Dewar tube containing the liquid air was provided with a spun cap of german silver Q that had an opening for the piezometer and tubes O and P for introducing liquid air and for connection with the vacuum pump. O could be closed with a rubber stopper. The cap was made fast to the Dewar tube and the piezometer by means of soft rubber tape and rubber cement. The air was boiled under a vacuum of 5 or 6 mm. of mercury which made it possible to liquefy the nitrogen under a pressure of 20 or 30 cm. The piezometer was then locked by screwing down the screw D by means of the screw driver F. The nitrogen remaining in the leads and in E above the gold disk was removed by means of a Toepler pump and the volume measured at a known temperature and pressure. To obtain the true mass requires the equation of state for nitrogen, or it suffices for the accuracy obtainable9 to employ the weight of a liter at N.T.P.

The weight of a liter of pure nitrogen was taken as 1.2507 g., or the volume of a gram is 799.55 cc. as given by Moles.¹⁰ Holborn and Otto¹¹ found for their nitrogen 1.2509 g., in fairly good agreement with the above. Later in this paper further reference to the matter of the weight of a liter of pure nitrogen will be made.

⁹ The gas is measured in the buret H, Fig. 3, under other conditions of temperature and pressure than N.T.P., under which the liter is measured. Strictly, one should know the compressibility and coefficient of expansion of the gas to obtain the true weight of the quantity actually measured. The use of the perfect-gas laws with the measured weight per liter leads to no appreciable error, however, in the case of nitrogen, as was proved when the constants of the equation of state were obtained. It will be shown in the present paper that the weight of a liter of nitrogen calculated by the equation of state agrees very well with the experimental determination of Moles.

¹⁰ Moles, J. chim. phys., 19, 283 (1922).

¹¹ Holborn and Otto, Z. Physik, 10, 367 (1922).

The loaded piezometer is connected with a piece of hexagonal steel carrying a steel tubing of 0.75 mm. bore locking against an annealed aluminum washer, and placed inverted in the constant-temperature bath. Referring again to Fig. 2, the piezometer with its steel tube may then be connected with the block C and the steel lead exhausted through V to the gold washer serving to confine the nitrogen in the piezometer. After closing the stopcock in block C at V, mercury may be run in by screwing in the piston of the mercury volume-injector G. It is to be added that a plug replaced the oil lead from I in D during the exhaustion and the oil lead was replaced after filling the block and lead with mercury. The oil lead having been connected, mercury is brought to the needle point by manipulating the oil injector I and volume injector G. By this means a zero setting may be obtained at a definite pressure corresponding to the position of the mercury which is in contact with the gold disk closing the piezometer. After the zero setting is obtained the pressure is increased to several hundred atmospheres and in about 24 hours the gold disk, weakened by amalgamation with the mercury, is punctured, bringing the mercury into contact with the nitrogen. By means of the mercury injector G a setting may be made for a chosen specific volume of nitrogen and a series of pressures and temperatures observed.

It is necessary to know expansion of the mercury with the temperature as well as its compressibility¹² while the stretch of the steel piezometer and apparatus may be obtained by separate blank measurements. For the true expansivity with temperature of the steel piezometer, the data of the Reichsanstalt were correlated as a function of the temperature as follows.

$$V_t^{Fe} = V_0 (1 + 3.25 \times 10^{-5} t + 2.85 \times 10^{-8} t^2 - 1.65 \times 10^{-11} t^3)$$

The equation for the volume of mercury as a function of the temperature, as given by Callendar and Moss, was employed.

$$V_t^{Hg} = V_0 (1 + 1.80555 \times 10^{-4} t + 1.2444 \times 10^{-8} t^2 + 2.539 \times 10^{-11} t^3)$$

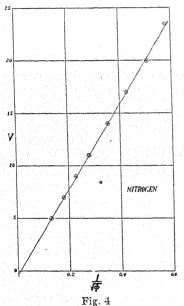

The shifting of the temperature requires, for preserving constancy of the nitrogen volume, a resetting of the mercury injector G to compensate

The compressibility of mercury is a function of both pressure and temperature. Thus Bridgman gives the compressibility at 1 atmosphere as 3.80×10^{-6} at 0° and 3.95×10^{-6} at 22° . The decrease of the compressibility with pressure is given as about 3% for the first thousand atmospheres. The effect of increase in pressure may be neglected in the present work since 400 atmospheres was not exceeded. The temperature effect on the stretch of the piezometer is determined as the sum of that due to the compressibility of the mercury contained in the piezometer and the stretch of the piezometer itself. These direct measurements failed to disclose any pronounced effect on the combined mercury compressibility and piezometer stretch because of the small amount of mercury (13.3 cc.) contained in the piezometer and the smallness of the temperature coefficient of stretch of the piezometer. The value 3.9×10^{-6} was assumed for the mercury compressibility independent of the temperature. The total stretch of the piezometer amounted to 9.73×10^{-6} cc. per atm.

for the combined increase in volume of the mercury in the piezometer and the dilation of the piezometer with temperature and pressure. The method of making this computation is obvious, when the stretch of the piezometer and apparatus with pressure and the expansion of the piezometer and mercury with temperature are known.

The Experimental Data

The data were taken first at 50°, continued to 100°, 150° and 200°, and the observations at 0° were made last, using a Dewar tube filled

with ice. In Table I will be found the absolute temperatures and pressures for the fixed volumes beginning with 23 cc. per g. of nitrogen. A linear equation is given with each volume which has been used to calculate the pressures recorded under each observed pressure.

The equation of state gives, for the tangent of the pressure-temperature lines at constant volume, the expression $R/(v-\delta)$. The magnitude of R per mole is known with tolerable accuracy, ¹³ being 82.058 cc., atm. per degree C., per mole. The molecular weight of nitrogen has been taken as 28.02. The value of R per g. of nitrogen is, therefore, 2.92855.

From the equations for the isometrics the constants for the cohesive pressure term $\Phi = A/(v-l)^2$ may be derived. The constant of the linear equation for each

volume is equal to Φ for that volume. These values were calculated over to $1/\sqrt{\Phi}$ and plotted against v giving a straight line as shown in Fig. 4.

When we represent this by an equation of the form $V = a + \frac{b}{\sqrt{\Phi}}$, we see

To complete the equation of state it remains to obtain the constants for the δ equation. δ was calculated for each observed pressure from the relation $\delta = v - \frac{RT}{p+\Phi}$. The values for each volume were averaged and the mean values log δ were plotted against 1/v. The plot is reproduced in Fig. 5, showing that nitrogen follows the function $\delta = \beta e^{-\alpha/v}$.

The complete equation of state for nitrogen is, therefore,

$$\dot{p} = \frac{2.92855}{v - \delta} T - \frac{1623.6}{(v + 0.2945)^2}, \ \log_{10} \delta = 0.18683 - \frac{0.3113}{v} \tag{1}$$

$$p = \frac{RT}{v - \delta} - \frac{1623.63}{(v + 0.2954)^2} \text{ where log } \delta = 0.18683 - \frac{0.3113}{v}$$

$$R = 2.92855 \qquad \beta = 1.5376 \text{ and } \alpha = 0.716$$

It seems probable that the true form of the cohesive-pressure equation is $\frac{A'}{m^2}e^{-l'/v}$ where A' and l' are constants of similar significance to the constants in the form $A/(v+l)^2$. In the gas phase it is difficult to distinguish between the two forms. Thus $\frac{A'}{n^2}e^{-\nu/\eta}$ for large volumes becomes, with sufficient accuracy, equal to $\frac{A'}{v^2}\left(1-\frac{l'}{v}\right)=\frac{A'}{v^2\left(1+\frac{l'}{2v}\right)^2}\equiv\frac{A}{(v+l)^2}$. Hence, for the gas phase A = A' and 2l = l'. In order to determine the constants of this exponential form, one takes logarithms of both sides,

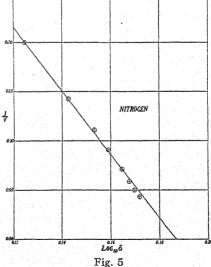

whence one gets $\log \Phi = \log \frac{A}{v^2} - \frac{l'}{v}$. Hence, a plot of $\log \Phi v^2$ against

1/v should give a straight line. Fig. 4a shows that a straight line is all that the assemblage of points will justify. Giving most weight to the

high-pressure points, since they always serve to locate the constants better than low-pressure data, one obtains the following constants: A = 0.286. This is an excellent check and shows that the two forms are interchangeable as far as the present data go. The equation is $\log \Phi = \log \frac{1623.3}{v^2} - \frac{1623.9}{v^2}$. In Table II are also given

the values of Φ calculated from this second form.

Weight of a Liter of Nitrogen at Normal Temperature and Pressure

Moles has most recently measured the normal density of nitrogen¹⁰ obtaining 1.2506 g. per liter as the mean of four volumetric determinations in good agreement with the mean value 1.2507 of 29 determinations by four authors using two different experimental methods with nitrogen produced by eight different reactions. Holborn and Otto¹¹ as a test of the purity of their nitrogen determined the weight of a liter to be 1.2509 g. The equation of state gives 779.40 cc. as the volume of 1 g. at 0° and 1 atm. pressure. The reciprocal of this multiplied by 1000 gives 1.2509 as the weight of 1 liter at N.T.P.

Equation of State for Atmospheric Nitrogen from Measurements by Amagat

Amagat¹⁴ has measured the isotherms for gaseous atmospheric nitrogen. The data are divided into two series, the first set extending over a range of pressure from 100 to 1000 atmospheres and from 0.0° to 199.5°. The second series covers the range of pressures from 1000 to 3000 atmospheres and from 0.0° to 43.6°. The volumes given are relative to the capacity of a manometric tube and are not absolute. Keyes¹⁵ has derived an equation from the low-pressure measurements which he gives as

$$\dot{p} = \frac{2.9138}{v - \delta} T - \frac{1587.2}{(v - 0.007)^2}, \quad \log \delta = 0.2200 - \frac{0.284}{v}$$

He assumes the composition of atmospheric nitrogen to be 1.66% argon and 98.34% nitrogen by weight. The apparent molecular weight is taken as 28.163. The volume of 1 g. is taken as 795.12 cc.

Rayleigh, ¹⁶ Regnault, Von Jolly and Leduc have determined the weight of a liter of atmospheric nitrogen. Regnault's value was corrected by Crafts for contraction of the globe and Von Jolly's was corrected by Rayleigh. Rayleigh's and Leduc's values are the latest available and are in best agreement. The mean of their values, 1.25714 g., was assumed as the best figure for the weight of a liter. This gives 795.46 cc. as the volume of 1 g.

Two methods are available for determining the apparent molecular weight. From the weight of a liter of argon, 1.78094, 17 the weight of a liter of pure nitrogen 1.2507 and the weight of a liter of atmospheric nitrogen, the composition of atmospheric nitrogen may be calculated. This method, which is not very accurate, gives 1.21% of argon.

Guye¹⁸ gives the percentage by volume of oxygen in air as 20.94 and the weight of 1 liter of air as 1.2928 g. Keyes¹³ gives 699.77 cc. as the best value for the volume of 1 g. of oxygen. Therefore, we obtain 23.147% oxygen by weight. Moureu and Lepape¹⁹ give the percentage of argon in air as 1.29 by weight. From this, the composition of atmospheric

nitrogen is 1.679% argon and 98.321% nitrogen by weight. This gives for the apparent molecular weight $\frac{1}{\frac{0.01679}{39.88} + \frac{0.98321}{28.020}} = 28.161 \text{ using the}$

accepted values of 39.88 and 28.020 for the molecular weights of argon and pure nitrogen. The gas constant R per gram is, therefore, 82.058/28.161 = 2.9139, which coincides with that obtained by Keyes.

Amagat's series for 1000 to 3000 atmospheres extends over a very short temperature range. Table V gives his constant volume values

and also the actual volumes in cc. per g. as obtained by multiplying his relative volumes by 795.5. Straight-line equations were passed through the points at 0.0° and 43.6° and are given below Table V. In Col. 6, Table V are given the pressures at 16.0° calculated from the corresponding constant-volume equations. These show that, within Amagat's limits of accuracy, p is a linear function of T at constant volume up to 3000 atmospheres.

In Fig. 6 the line represents the plot of $\log \delta$, as calculated from Keyes' equation, against 1/v. The points represent the observed values obtained from Amagat's high-pressure series. The fact that all of the observed points fall upon one side of the

line indicates that Amagat's low-pressure series is not entirely concordant with his high-pressure series.

Comparison of the Recent Work of Holborn and Otto with the Equation of State for Nitrogen

Holborn and Otto¹¹ have recently measured the products of $p \times v$ for oxygen, nitrogen and helium. They represent their data by equations of the form pv = f(p) and pv = f1/v. For the second form they give equations representing the 0°, 50° and 100° isotherms for nitrogen, which when converted to v in cc. per g. and p in atmospheres are as follows:

$$pv = (pv)_0 \left(1 - \frac{0.4563032}{v} + \frac{2.92858}{v^2}\right) \text{ at } 0.0^{\circ}$$
 (2)

$$pv = (pv)_0 \left(1 - \frac{0.0262332}{v} + \frac{3.06343}{v^2}\right) \text{ at } 50.0^{\circ}$$
 (3)

$$pv = (pv)_0 \left(1 + \frac{0.279970}{v} + \frac{3.18418}{v^2}\right) \text{ at } 100.0^{\circ}$$
 (4)

From the equation of state,

$$pv = RT \frac{v}{v - \delta} - A \frac{v}{(v + l)^2}$$

Expanding this in the form of a series gives

$$pv = RT \, v \left(\frac{1}{v} + \frac{\delta}{v^2} + \frac{\delta^2}{v^3} + \frac{\delta^3}{v^4} + \dots \right) - Av \left(\frac{1}{v^2} - \frac{2l}{v^3} + \frac{3l^2}{v^4} + \dots \right)$$

but

$$\delta = \beta e^{-\alpha/v} = \beta \left(1 - \frac{\alpha}{v} + \frac{\alpha^2}{2v^2} - \frac{\alpha^3}{6v^3} + \dots \right)$$

Neglecting all terms of higher order than $1/v^2$ there is obtained

$$pv = RT \left[1 + \frac{1}{v} \left(\beta - \frac{A}{RT} \right) + \frac{1}{v^2} \left(\beta^2 - \alpha \beta + \frac{2Al}{RT} \right) \right] \tag{5}$$

Since $(pv)_0 = RT$, Equation 5 is seen to be, at constant temperature, of the same form as Equations 2, 3 and 4. Substituting in (5) the constants of the equation of state for 0.0° , 50.0° and 100.0° one obtains the following equations for comparison with those of Holborn and Otto.

$$pv = (pv)_0 \left(1 - \frac{0.49227}{v} + \frac{2.45735}{v^2} \right) \text{ at } 0.0^{\circ}$$

$$(pv)_0 = RT = 799.890$$
(6)

$$pv = (pv)_0 \left(1 - \frac{0.17819}{v} + \frac{2.27236}{v^2} \right) \text{ at } 50.0^{\circ}$$

$$(pv)_0 = 946.317$$
(7)

$$pv = (pv)_0 \left(1 + \frac{0.05172}{v} + \frac{2.13694}{v^2} \right) \text{ at } 100.0^{\circ}$$

$$(pv)_0 = RT = 1092.745$$
(8)

For comparison purposes there are given in Table VI, values of pressures in atmospheres and corresponding volumes in cc. per g. at 0° , 50° and 100° from determinations by Holborn and Otto. These values for volume were converted from the arbitrary units by multiplying the latter by the factor 607.43 which is that given by the equation of state when p = 1 meter p = 1.31579 atm. and p = 1 meter p = 1.31579 atm. and p = 1 meter p = 1.31579 atm. and p = 1 meter p = 1.31579 atm.

Table VI
PRESSURES AND VOLUMES COMPUTED FROM EQUATIONS BY HOLBORN AND OTTO

Press. meters of Hg	Press. atm.	0°	Volumes (cc. per g. 50°	100°
10	13.158	60.449	71.930	83.266
30	39.474	19.993	24.022	27.951
50	65.789	11.943	14.477	16.920
70	92.105	8.532	10.418	12.214

From the equation of state pressures were calculated corresponding to the volumes given in Table VI.

These values are listed in Table VII.

TABLE VII

Pressures from Equation of State using Volumes and Temperatures from

			LABL	E AT			
	0.0		5	0,0	100	100°	
7'		t	21	Þ	? *	Þ	
60.449		13.134	71.930	13.128	83.266	13.135	
19.993		39.270	24.022	39.257	27.951	39.275	
11.943		65.376	14.477	65.275	16.920	65.268	
8.532		91.533	10.418	91.203	12.214	91.142	

The pressures resulting from the present work corresponding to the volumes and temperatures given by Holborn and Otto are seen to be lower at about 90 atm. by 0.6%. It will be pointed out subsequently that until the "pure" nitrogen chemically prepared had been fractionated to remove traces of nitric oxide the higher pressures were obtained.

In Table VII of Holborn and Otto's paper are given values of the pv product at 0° , 50° and 100° for various constant densities. The values of 5, 15, 25, 35, 45 and 55 in their arbitrary units were chosen. Multiplying the pv products by the density gives the pressures in meters. Converting the densities to cc. per g. and the pressures to atmospheres, as explained above, the values contained in Table VIII were obtained.

TABLE VIII
PRESSURES AT CONSTANT VOLUME FROM HOLBORN AND OTTO

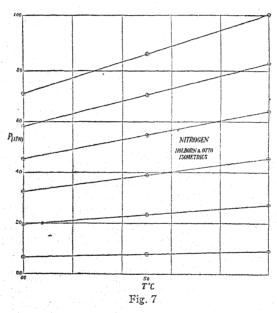

<u>1</u>				
v (arb. units)	(cc. per g.)	0°	—Pressures (atm.)—— 50°	100°
5	121.486	6.564	7.789	9.010
15	40.495	19.596	23.383	27.149
25	24.297	32.535	39.025	45.493
35	17.355	45.416	54.760	64.096
45	13.498	58.261	70.639	83.021
55	11.044	71.105	86.727	102.303

The above values of pressure are plotted against the absolute temperature as shown in Fig. 7. These constant volume lines are straight to within what is believed to be the accuracy of Holborn and Otto's results.

From Equation 5 we see that the coefficient of 1/v in the pv product

equation is equal to $\beta - \frac{A}{RT}$. Taking the coefficients of 1/v in Equations 2, 3 and 4 of Holborn and Otto and solving simultaneously for A we obtain the 3 values 2223.2, 2162.4 and 2197.5, of which the mean is 2194.4. Substituting this mean value of A we obtain for β the 3 values 2.287, 2.293 and 2.288, of which the mean is 2.289.

Holborn and Otto prepared nitrogen from sodium nitrite and purified it by passing it through alkaline pyrogallol and over glowing copper. It is known that alkaline pyrogallol is likely to introduce carbon monoxide and Smyth and Roberts²⁰ have shown that unless the temperature of the copper is kept below 600° the copper oxide will decompose and introduce

oxygen. Also, copper will not reduce oxides of nitrogen unless the temperature is fairly high. The good agreement between the weight of a liter as determined by Holborn and Otto and the accepted value does not necessarily indicate great purity of the gas since, in the first place, the weight of a liter is very difficult to obtain and second, since the molecular weight of carbon monoxide is essentially the same as that of nitrogen and since nitric oxide has only a slightly greater molecular weight, the pressure of appreciable quantities of these gases would not greatly affect the weight of a liter, but would affect the magnitude of the A and β constants greatly. Previous to the work on the equation of state of pure nitrogen as given in this paper an equation was determined for a sample of gas purified by the

²⁰ Smyth and Roberts, This Journal, 42, 2582 (1920).

usual chemical methods. An A constant of about 1860 was obtained, which lies much nearer the value obtained above from Holborn and Otto's work. Subsequently it was found that when this sample of nitrogen was condensed, suspended solid impurities were observed in the liquid. After 5 fractional distillations a perfectly water-white liquid was obtained that was undoubtedly pure. This procedure was used in preparing the gas for the measurements upon which the equation of state was based. Since the impurities mentioned as likely to be present in nitrogen, purified by chemical means, are all less perfect gases than nitrogen, their presence in small amounts would tend to increase the magnitude of the constants.

Compressibility Coefficients

Maverick, 21 both alone and in collaboration with Batuecas, has made measurements on the compressibility coefficients at 1 atmosphere and 0°. Those made by Maverick alone seem to be more consistent than the $\frac{1}{2} \left(\frac{1}{2} \left(\frac{1}{2} \right) \right)$

others. His
$$\lambda$$
 is defined as equal to $-\frac{1}{(pv)_{760}} \left(\frac{\partial (pv)}{\partial p}\right)_T$.

His average value and those of other observers at 0° are Maverick, 0.00044; Chappuis, 22 0.00043; Leduc and Sacerdote, 23 0.00038; Rayleigh, 24 0.00056. Maverick's values for nitrogen prepared from urea were discarded because of impurities in the gas so prepared.

From Equations 2, 3 and 4 of Holborn and Otto values of λ are obtained as follows: 0°, 0.000561; 50°, 0.000023; 100°, —0.000360.

From Equations 6, 7 and 8 derived by the equation of state the following are obtained: 0°, 0.000608; 50°, 0.000216; 100°, —0.000071.

Owing to the extreme accuracy with which an observer must work in order to obtain any percentage accuracy for this coefficient, the agreement is about as good as can be expected. Keyes⁴ has worked over the values for compressibility coefficients of Chappuis, Leduc and Sacerdote, and Rayleigh, comparing them with values obtained from the equation of state for atmospheric nitrogen.

In conclusion it is desired to thank Professor F. G. Keyes for his valuable suggestions and assistance, without which this work could not have been carried out.

Summary

- 1. The p, v, T relationship of pure gaseous nitrogen has been studied by the isometric method over the range of temperatures from 0° to 200° and 30 to 330 atmospheres' pressure. The Keyes equation represented

THE MELTING POINT OF ICE ON THE ABSOLUTE TEMPERATURE SCALE

BY LEIGHTON B. SMITH AND ROBERT S. TAYLOR

Received June 25, 1923

Chappuis,¹ Day and Clement,² Holborn and Henning³ and Eumorfopoulos⁴ have made measurements on the expansion coefficients from 0° to 100° both for the constant volume and the constant pressure thermometers. Keyes⁵ calculated ϵ , the expansion coefficient for a perfect gas, using the data of the above-mentioned workers and the equation of state which he based on Amagat's data for atmospheric nitrogen. Since then Henning,⁶ and Henning and Heuse⁵ have done some work on expansion coefficients for nitrogen and some other gases. It is, therefore, thought worth while to review the above data using the new equation of state of nitrogen⁵ and also the method of obtaining ϵ using the equation of state, since this has never been given in detail before.

Instead of using a constant-pressure thermometer, a constant- π thermometer will be considered where π is defined by the equation $\pi\omega=RT$. From the Keyes equation of state $\omega=v-\delta$ or, for low pressures $\omega=v-\beta$ and $\pi=p+A/(v+l)^2$, which reduces at low pressures to the form, $\pi=p+(A/v^2)$.

 - ⁷ Henning and Heuse, ibid., 5, 285 (1921).
 - ⁸ Smith and Taylor, This Journal, 45, 2115 (1923).

Then ϵ , the coefficient of expansion for a perfect gas, is given by the equation,

$$\epsilon = \left(\frac{\omega_t - \omega_0}{\omega_0 t_{(ab)}}\right)_{\pi} \tag{1}$$

where $t_{(ab)} = T - T_0$ or, in other words, is centigrade thermodynamic temperature. The above equation is, therefore, identical with the following,

$$\epsilon = \frac{v_t \pi - v_0}{(v_0 - \beta) \ t_{(ab)}} \tag{2}$$

where v_0 is the volume measured at 0° and v_t^{π} is the volume at t° when π has the same value as at 0° .

 $\epsilon_{p_0}^t$ is defined by the following equation,

$$\epsilon_{p_0}^{\ t} = \frac{v_t^p - v_0}{v_0 t_c} \tag{3}$$

where v_i^p is measured on the constant-pressure thermometer. The constant- π thermometer has never been investigated experimentally hence v_i^π must be eliminated from Equation 2. By adding and subtracting v_i^p from the numerator of Equation 2 the following is obtained.

$$\epsilon = \frac{(v_t^{p_0} - v_0) + (v_t^{\pi} - v_t^{p})}{(v_0 - \beta) \ t_{(ab)}}$$
(4)

Dividing numerator and denominator by v_0t_c , Equation 4 becomes

$$\epsilon = \left[\frac{v_t^{p_0} - v_0}{v_0 t_c} + \frac{v_t^{\pi} - v_t^{p_0}}{v_0 t_c} \right]_{\pi}$$
 (5)

Substituting from Equation 5

$$\epsilon = \left[\frac{\epsilon_p + \frac{v_t \pi - v_t p_0}{v_0 t_c}}{\left(1 - \frac{\beta}{v_0}\right) \frac{t_{ab}}{t_c}} \right]_{\pi} \tag{6}$$

Since p_t^{π} is very close to p_0 , Boyle's law may be assumed to hold without, in this instance, introducing too great an error, or $v_t^{\pi} p_t^{\pi} = v_t^{p_0} p_0$.

Hence $v_t^{\pi} = v_t^{p_0} \frac{p_0}{p_t^{\pi}}$. Using this relation, Equation 6 becomes

$$\epsilon = \frac{\epsilon_p + \frac{v_t p_0}{v_0 t_c} \left[\frac{p_0}{p_t \pi} - 1 \right]}{\left[1 - \frac{\beta}{v_0} \right] \frac{t_{ab}}{t_c}} \tag{7}$$

Since $\frac{v_t^{p_0}}{v_0} = \left(1 + \frac{\epsilon_p}{0^0}\right)$ and since the pressures are involved only in the correction term, Equation 7 may be written

$$\epsilon = \frac{\epsilon_{\rm p} + \frac{1 + \epsilon_{\rm p}^{t}}{t_{\rm c}} \left[\frac{p_{\rm 0} - p_{\rm i}^{\tau}}{p_{\rm t}^{\tau} \equiv p_{\rm 0}} \right]}{\left[1 - \frac{\beta}{v_{\rm 0}} \frac{t_{\rm ab}}{t_{\rm c}} \right]} \tag{8}$$

Furthermore,
$$\pi_{t} = \pi_{0}$$
; therefore $p_{t} + \frac{A}{(v_{t})^{2}} = p_{0} + \frac{A}{(v_{0})^{2}}$ or $p_{t} - p_{0} = \frac{A}{v_{0}^{2}} - \frac{A}{v_{t}^{2}}$. But $v_{t} = v_{0}(1 + \epsilon_{p}t_{c})$; therefore $p_{t} - p_{0} = \frac{A}{v_{0}^{2}} \left[1 - \frac{1}{(1 + \epsilon_{p}t_{c})^{2}} \right]$.

Therefore, $\frac{p_{0} - p_{t}}{p_{0}} = -\frac{A}{p_{0}v_{0}^{2}} \left[\frac{(1 + \epsilon_{p}t_{c})^{2} - 1}{(1 + \epsilon_{p}t_{c})^{2}} \right] = -\frac{A\epsilon_{p}t_{c}}{p_{0}v_{0}^{2}} \left[\frac{2 + \epsilon_{p}t_{c}}{(1 + \epsilon_{p}t_{c})^{2}} \right]$.

Equation 8 now becomes,

$$\epsilon \left(1 - \frac{\beta}{v_0}\right) \frac{t_{ab}}{t_c} = \epsilon_p - \frac{A \epsilon_p}{p e v_0^2} \left[\frac{2 + \epsilon_p t_c}{1 + \epsilon_p t_c} \right] \tag{9}$$

Since $t_c = 100 - t_{ab}$ and since $p_0v_0 = RT_0$, Equation 9 becomes

$$\epsilon = \epsilon_p + \frac{\beta \epsilon}{v_0} - \frac{A \epsilon_p}{R^2 T_0^2} \left[\frac{2 + \epsilon_p t_c}{1 + \epsilon_p t_c} \right] p_0 \tag{10}$$

or since in the correction term it suffices to say that $\epsilon_b = \epsilon = 1/T_0$,

$$\epsilon_p = \epsilon + \left[\frac{A}{R^2 T_0^3} \left(\frac{2 + \epsilon_p t_c}{1 + \epsilon_n t_c} \right) - \frac{\beta}{R T_0^2} \right] p_0 \tag{11}$$

It is now seen that with the aid of certain approximations which, however, are permissible since they involve only the correction factor, the limitation of the constant- π thermometer has been removed and the resulting formula is general.

In the case of the constant-volume coefficient the same procedure is employed but the derivation is very much simplified, as will be seen. For the constant- ω thermometer

$$\epsilon = \left[\frac{\pi_t - \pi_0}{\pi_0 t_{ab}}\right]_{\omega} = \left[\frac{p_t - p_0}{\left(p_0 + \frac{A}{v_0^2}\right)t}\right]_{\omega},$$

since constant ω is identical with constant volume and A/v^2 is independent of the temperature. By definition,

$$\epsilon_{\rm e} = \frac{p_{\rm e} - p_{\rm o}}{p_{\rm o} \ell}$$
. Hence, $\epsilon_{\rm o} = \epsilon + \frac{A \epsilon}{v_{\rm o}^2 p_{\rm o}}$, or $\epsilon_{\rm v} = \epsilon + \frac{A}{R^2 T_{\rm o}^3} p_{\rm o}$. (12)

From the equation of state of nitrogen, Equation 12 becomes $\epsilon_p = \epsilon + 0.00000029 \ p_0$ (atm.). Since $1/\epsilon = T_0$, the absolute temperature of melting ice can be calculated from measured expansion coefficients.

In Table I are given the measured values of ϵ_p , and calculated values of T_0 . In Table II are the measured values of ϵ_p and calculated values of T_0 .

It is seen from these tables that in no way can the above data be averaged to give a value of 273.20 as the ice point on the absolute centigrade scale as obtained by Henning and Heuse. The data of Henning and Heuse on nitrogen vary from an ice point of 273.130 to one of 273.231.

⁹ In Keyes' paper, This Journal, 43, 1461 (1921), there is a typographical error in this equation, the square term in the denominator of the expression in brackets being omitted.

An average of their data alone, however, gives 273.175°. A consideration of the other data leads one to believe that even this is too high by several hundredths of a degree. Keyes, 5 after a review of the data on coefficients

of expansion for all gases for which data are available, reached the conclusion that $T_0 = 273.14$. Buckingham decided on 273.13. From the above data it is evident that 273.12° is about as good a value as can be

^a Ref. 1. ^b Ref. 4.

obtained from the nitrogen coefficients alone. A paper will soon be forth-coming from this Laboratory dealing with the data on other gases, but for the present it appears that 273.13° is about as good a value for T_0 as can be decided upon.

In conclusion it is desired to thank Dr. Keyes for his valuable suggestions and assistance.

Summary

The value of T_0 , the absolute temperature of melting ice, from the nitrogen volume and pressure expansion coefficients gives a mean value of 273.12° . The mean value obtained by using the data of other gases including the Joule-Thomson coefficient is $273.13^{\circ} \pm .01^{\circ}$.

THE CRYSTAL STRUCTURE OF POTASSIUM HYDROGEN FLUORIDE

By Richard M. Bozorth Received June 25, 1923

Introduction

Crystals of potassium hydrogen fluoride, KHF₂, were prepared by the spontaneous evaporation at room temperature of an aqueous solution of potassium fluoride and hydrofluoric acid. They are known¹ to belong to the tetragonal system and to have an axial ratio a: c = 1:0.601.

The X-ray data were obtained (1) from photographs of line spectra from the principal planes, using rhodium as the target, and (2) from two Laue photographs taken with the beam approximately perpendicular to the (001) planes. The methods of analysis and treatment are the same as those previously employed.²

The Unit of Structure

The data from the spectral photographs are given in Table I; d is the interplanar distance expressed in Ångstrom units and n the order of reflection. The wave length of the rhodium $K\alpha_1$ line was taken to be 0.6121 Å., and that of the unresolved $K\alpha$ line to be 0.614 Å.

Combining the values of d/n with the density of the crystals, determined by a suspension method to be 2.37, it was found that the data are consistent with a unit containing 1 molecule of KHF₂. Examination of the Laue photographs, however, showed that many values of $n\lambda$ calculated for this unit by means of the well-known Bragg equation were smaller

than any wave lengths that could be present at the voltage applied to the X-ray tube, which was about 53,000 volts. The smallest unit that would avoid this difficulty was found to have the dimensions 5.67 imes 5.67×6.81 Å., so this unit was considered to be the true one. The axial ratio is therefore 1.201, and the distance between any two adjacent hkl

planes is 5.67 $(h^2 + k^2 + 0.685 l^2)^{-\frac{1}{2}}$ Å. The density calculated for this unit containing 4KHF2 is 2.35.

The Possible Arrangements

The symmetry of the Laue photographs corresponds to the point group D_{4h}; accordingly, only space groups were considered which are isomorphous with the point groups V_d, C_{4v}, D₄, and D_{4h}. Furthermore, since all the planes reflecting in the first order on the Laue photographs were found to have one index even and two indices odd, it was concluded that the underlying lattice was the body-centered one, and the space groups were considered accordingly.

It was observed (see Table I) that reflections from the (001) planes were extremely weak in the second and sixth orders, and very strong in the fourth order, while odd orders were absent. It seemed reasonable, therefore, to suppose that in the fourth order all the atoms are reflecting in phase, while in the second and sixth order the potassium atoms act in opposition to the fluorine atoms. Therefore, the arrangements were limited to those which place the fluorine atoms in planes 1/2d(001) apart, and the potassium atoms in planes midway between the fluorine atoms. There are three such arrangements³ for the fluorine atoms, as follows.

- $\begin{array}{ll} (1) & u,\frac{1}{2}+u,0; \; \bar{u},\frac{1}{2}-u,0; \; \frac{1}{2}-u,u,0; \; \frac{1}{2}+u,\bar{u},0; \; \frac{1}{2}+u,u,\frac{1}{2}; \; \frac{1}{2}-u,\bar{u},\frac{1}{2}; \; u,\frac{1}{2}-u,\frac{1}{2}; \; \bar{u},\frac{1}{2}+u,\frac{1}{2}. \\ (2) & u00; \; \bar{u}00; \; 0u0; \; 0\bar{u}0; \; \frac{1}{2}+u,\frac{1}{2},\frac{1}{2}; \; \frac{1}{2}-u,\frac{1}{2},\frac{1}{2}; \; \frac{1}{2},\frac{1}{2}+u,\frac{1}{2}; \; \frac{1}{2},\frac{1}{2}-u,\frac{1}{2}. \\ (3) & uu0; \; \bar{u}\bar{u}0; \; \bar{u}\bar{u}0; \; \bar{u}\bar{u}0; \; \frac{1}{2}+u,\frac{1}{2}+u,\frac{1}{2}; \; \frac{1}{2}-u,\frac{1}{2}+u,\frac{1}{2}; \; \frac{1}{2}+u,\frac{1}{2}-u,\frac{1}{2}; \; \frac{1}{2}-u,\frac{1}{2}+u,\frac{1}{2}. \end{array}$

There are two such ways of placing the potassium atoms with respect to the fluorine atoms, namely,

$$\begin{array}{l} (1) \ 0 \ 0^{1}/_{4}, \ 0 \ 0^{3}/_{4}, \ ^{1}/_{2} \ ^{1}/_{2} \ ^{1}/_{4}, \ ^{1}/_{2} \ ^{1}/_{2} \ ^{3}/_{4}. \\ (2) \ 0 \ ^{1}/_{2} \ ^{1}/_{4}, \ 0 \ ^{1}/_{2} \ ^{3}/_{4}, \ ^{1}/_{2} \ 0 \ ^{1}/_{4}, \ ^{1}/_{2} \ 0 \ ^{3}/_{4}. \end{array}$$

³ Wyckoff, "The Analytical Expression of the Results of the Theory of Space Groups," Carnegie Inst. Pub., 318 (1922).

Determination of the Structure

The six ways of arranging the potassium and fluorine atoms were investigated for all values of the parameter u; and it was shown on the basis of qualitative comparisons of intensities of Laue spots that the only arrangement consistent with the data is the combination of (1) for potassium with (1) for fluorine. The intensity data chiefly used in arriving at this conclusion are: $(2\overline{5}1) > (\overline{4}31)$, $(\overline{56}1) > (\overline{7}01)$, $(\overline{56}1) > (\overline{27}1)$, $(\overline{92}3) > (\overline{7}01)$, $(\overline{92}3) > (\overline{38}3)$, $(7\overline{3}4) > (\overline{7}32)$, $(5\overline{7}4) > (\overline{57}2)$. The value of the parameter u in the correct arrangement was determined from these and other intensity comparisons to be 0.14, with an estimated maximum error of 0.01. The data from one Laue photograph are given in Table II. The reflections are in the second order when a 2 is prefixed to the indices of the reflecting plane; otherwise they are in the first order. The last columns in both tables give the structure factor calculated for the correct arrangement when u is 0.14.

For the comparison of intensities, planes may be divided into two classes: (1) those having the last index odd and reflecting in the first order; (2) all other planes. This classification is such that the intensities of the reflections from planes of Class 1 depend only on the reflecting power of the fluorine atoms, while those from Class 2 planes depend on both kinds of atoms. Intensities were calculated in the usual manner, assuming the reflecting powers of the atoms to be proportional to their atomic numbers; however, when only qualitative comparisons are made involving planes of the same class, the validity of comparing calculated intensities with observation is dependent only on the assumption that the reflecting power of the potassium atom is approximately as great as or greater than twice the reflecting power of the fluorine atom.

Discussion of the Structure

The structure is represented diagrammatically in Fig. 1. It may be regarded as an ammonium chloride arrangement of potassium atoms and fluorine dumb-bells. The arrangement may be derived from any of the space groups D_{4h}^{18} , V_{0}^{10} , and D_{4}^{9} . For the hydrogen atoms the only positions consistent with the symmetry are (1) 00u; $00\bar{u}$; $\frac{1}{2}$, $\frac{1}{2}$, $\frac{1}{2}$ + u; $\frac{1}{2}$, $\frac{1}{2}$, $\frac{1}{2}$ + u; $\frac{1}{2}$, $\frac{1}{2}$, $\frac{1}{2}$ 0 $\frac{1}{2}$ 0, $\frac{1}{2}$ 0 0, $\frac{1}{2}$ 0 $\frac{1}{2}$ 1, 0 $\frac{1}{2}$ 1, 0 $\frac{1}{2}$ 1, 0 $\frac{1}{2}$ 1, 0 $\frac{1}{2}$ 3, 1 $\frac{1}{2}$ 0 $\frac{3}{4}$. Of these the first may be discarded; for, if the hypothesis of constant atomic radii is even approximately correct, there is not room for the hydrogen atoms between potassium atoms that are 3.41 Å. apart.

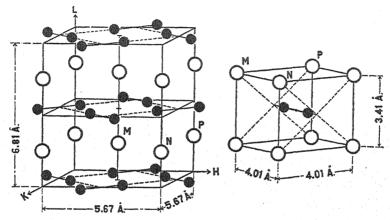

Fig. 1.—The arrangement of the atoms in KHF₂. The potassium atoms are represented by the larger circles and the fluorine atoms by the smaller ones. The larger tetragonal prism represents a complete unit of structure containing 4 KHF₂. The smaller prism contains one KHF₂ and is related to the larger in the way indicated by the letters M, N and P; it shows how the structure is similar to that of ammonium chloride, the K atoms corresponding to N atoms and the F dumb-bell corresponding to Cl atoms

The second arrangement places each hydrogen atom between 2 fluorine atoms that are 2.24 Å. apart, and forms what may be considered an $\mathrm{HF_2}^-$ ion. If the radius 4 0.62 Å. be assigned to the fluorine atom, the radius of the hydrogen atom in this position is 0.50 Å. The third possible position for hydrogen leaves the fluorine atoms much farther apart than the radius usually ascribed to them permits, but permits the same unusually large distances between adjacent negative atoms observed in cadmium iodide, stannic iodide, and molybdenum disulfide.

The distances in Angstrom units between the atoms are given in Table

Summary

The positions of the potassium and fluorine atoms in tetragonal potassium hydrogen fluoride, KHF₂, have been determined by means of X-rays. The dimensions of the unit are $5.67 \times 5.67 \times 6.81$ Å. The structure may be described as an ammonium chloride arrangement of potassium atoms and fluorine dumb-bells, the two atoms of each dumb-bell lying in a plane perpendicular to the tetragonal axis. For the hydrogen atoms there are two possible positions, one of which is in the middle of the dumb-bell, forming an HF₂-ion. The distances in Ångstrom units between the atoms are summarized in Table III.

THE STABILITY OF SODIUM THIOSULFATE SOLUTIONS

By Martin Kilpatrick, Jr., and Mary L. Kilpatrick

Received June 27, 1923

The present investigation was undertaken as a critical study of the stability of $0.01\ N$ sodium thiosulfate under the conditions of its use as a standard solution in an analytical laboratory. It was also hoped that the investigation might throw some light on the mechanism of the decomposition.

Topf¹ in 1887 proved that the carbon dioxide of the air could not account for the deterioration, and concluded that it was to be attributed to direct oxidation: $Na_2S_2O_3 + O \longrightarrow Na_2SO_4 + S$. He also noticed that the fall in normality was greater in summer than in winter. Kolthoff² made an extensive study of the behavior of $0.1\ N$ and $0.01\ N$ sodium thiosulfate solutions under various conditions and in the presence of a great number of substances. He found that sunlight hastened the decomposition; that $0.01\ N$ solutions decomposed much more rapidly than $0.1\ N$; that small amounts of mercuric iodide greatly retarded the decomposition, as did small amounts of alkaline substances; that salts of the heavy metals

⁸ Wyckoff, J. Washington Acad. Sci., 12, 251 (1922).

¹ Topf, Z. anal. Chem., 26, 137 (1887).

² Kolthoff, Pharm. Weekblad, 56, 878 (1919); Z. anal. Chem., 60, 344 (1921).

had various effects; that the sulfur deposit from decomposed thiosulfate solutions accelerated the decomposition, and that carbon dioxide had little influence. He suggested that the decomposition might be due to certain sulfur-consuming microörganisms. He recommended that in preparing the solution 10 mg. of mercuric iodide or 200 mg. of sodium carbonate be added per liter, and that the flasks be sealed and kept in the dark.

Rice, Kilpatrick and Lemkin³ studied the behavior over a period of 52 days of $0.01\ N$ solutions of sodium thiosulfate made up with different grades of distilled water. Using the same method of analysis, the authors have continued this study for some 200 days. The results, which in general are similar to those already given, are summarized in the following table.

Table I
Effect of Different Grades of Distilled Water

	Distilled water	Initial titer, Oct. 3, 1922 N	Final titer, May 31, 1923 N	Fall
1	Laboratory	0.012401	0.009848	20.6
2	Redistilled	.013248	.011810	10.9
3	Redistilled, freshly boiled	.014085	.014016	[0.5]
4	Redistilled, through which CO ₂ -free			
	air had been bubbled	.013111	.012866	1.9

At the same time a fifth bottle was prepared in the same way as in Expt. 1, was sealed, and set aside. Six months later it was opened, fitted with a soda-lime tube and siphon, and a portion was analyzed in the usual way. The normality was found to be 0.012688. In 40 days the normality dropped to 0.012512, a decrease of 1.4%. This is distinctly at variance with the result reported by Treadwell⁴ for a $0.1\ N$ solution.

During the period of investigation, portions were drawn off from the bottles for other experiments. At the end of the work the air spaces above the solutions varied from 4 to 10 liters. (We mention this because it would be the usual case in the laboratory.) Considerable deposits of sulfur formed in Bottles 1, 2 and 5, while no deposit was apparent in 3 or 4. The hydrogen-ion concentration of the solutions, determined colorimetrically from time to time, showed no appreciable change.

The most stable of the solutions, 3, was selected for the purpose of testing the effects of carbon dioxide, of oxygen, and of small quantities of alkali on the titer of $0.01\,N$ sodium thiosulfate solution. Portions of the solution through which carbon dioxide and oxygen, respectively, had been bubbled for several hours were siphoned into glass-stoppered tubes. At intervals a tube was opened and its contents analyzed. In the case of the alkali, a weighed amount of standard sodium hydroxide solution was added to

³ Rice, Kilpatrick and Lemkin, This Journal, 45, 1361 (1923).

⁴ Treadwell-Hall, "Analytical Chemistry," Wiley and Sons Co., fifth ed., 1919, vol. 2, p. 645.

a weighed amount of thiosulfate, and the resulting solution, 0.001 N in sodium hydroxide, was siphoned into tubes, as before. The analysis of the alkaline solution was carried out in a slightly different manner. As Kolthoff⁵ has pointed out, in 0.01 N solution the minimum hydrogen-ion concentration at which iodine oxidizes thiosulfate quantitatively to tetrathionate is 3.16×10^{-7} ; at lower concentrations of hydrogen ion the thiosulfate is partially oxidized to sulfate. Kolthoff showed that the error is much less when the thiosulfate is titrated with iodine than in the reverse procedure. In his work with slightly alkaline thiosulfate, Kolthoff ran the thiosulfate into an excess of acidified iodine and titrated back with thiosulfate. In the present investigation the thiosulfate was run into a suitable buffer and was titrated directly with iodine. The results of the experiments are given in Table III. For purposes of comparison, data for the original solution over the same period are included.

Table II Effects of Carbon Dioxide, of Oxygen and of Sodium Hydroxide

Date		Original solution No. 3	Solution treated with CO ₂ on Mar. 3 N	Solution treated with O ₂ on Feb. 27 N	Solution 0,001 N in NaOH; prepared Feb. 28 N
Mar.	3	0.014005	0.014020	0.013998	(0.013938, calc.)
1	0		.014035	.013987	
1	7	.014014			.013944
2	8	.014005	.014035	.013995	.013931
Apr. 2	8	.014013	.014028	.013955	.013910

It is evident that carbon dioxide, oxygen and sodium hydroxide have very little effect on a stable solution of sodium thiosulfate. The slight effect observed in the case of carbon dioxide is in agreement with the results of Topf and of Kolthoff. It is, however, contrary to the results of Hahn and Windisch, who report an increase of 10% over a period of 51 days in the normality of a 0.02~N solution of sodium thiosulfate, half saturated with carbon dioxide. The same authors, however, report a gain of approximately 9% for a 0.02~N solution of sodium thiosulfate in distilled water. As far as we know, only one other such case appears in the literature, that of Waterman.

During the course of these experiments, a bacteriological examination revealed the fact that the bacterial count of all the solutions was high, and that the solution which was decomposing most rapidly, No. 1, contained by far the greatest number of organisms. In addition, it appeared to give a pure culture. The organism was isolated, as was another organism from Solution 2. Two sterilized portions of Solution 4 were inoculated with these organisms and were kept at 21° for 24 hours. One-cc.

⁵ Kolthoff, Pharm. Weekblad, 56, 572 (1919).

⁶ Hahn and Windisch, Ber., 55, 3163 (1922).

⁷ Waterman, Chem. Weekblad, 15, 1098 (1918).

portions of the inoculated solutions were added to 500-600 cc. of Solution 4 in 2 glass-stoppered liter bottles. The following table shows the changes in normality observed in a month's time.

Table III Changes in Normality in One Month's Time

Date	600 cc. of Soln. $4+1$ cc. inoculated with bacteria from Soln. 1	600 cc. of soln. 4 + 1 cc. inoculated with bacteria from Soln. 2
Apr. 1	1 0.012934	0.012934
1	8 .012921	.012931
May	2 .012284	.012872
1	2 .011848	.012716
	Fall, 8.3%	Fall, 1.6%

During the same period the normality of the original solution, 4, decreased by 0.3%. It is evident that the decomposition is due to the action of bacteria.

The authors wish to thank Dr. E. M. Twiss of Vassar College for her help with the bacteriological work.

Summary

The stability of several $0.01\ N$ solutions of sodium thiosulfate has been studied over a period of 8 months.

Freshly boiled redistilled water gave a solution that was more permanent than that obtained with laboratory distilled water, ordinary redistilled water or redistilled water through which carbon dioxide-free air had been bubbled.

Carbon dioxide, oxygen or dilute sodium hydroxide had very little effect on the stability of the solution.

Decomposition is caused by the action of bacteria.

POUGHKEEPSIE, NEW YORK

NOTE

A Glass-to-Metal Joint.—In a recent note by Merle L. Dundon¹ on a glass-to-metal joint it was claimed that the method of McKelvy and Taylor² of platinizing, copper plating and soldering was tried without success. The failure of the joints by cracking of the glass upon cooling was ascribed to heat strains introduced by the soldering process. Heat strains may be introduced during the platinizing process, if the glass is not cooled carefully, but the temperature of melted tin is not sufficiently

- 8 The organism isolated from Solution I has been identified by Selman A. Waksman, at the New Jersey Agricultural Experiment Station, as *Thiobacillus thioparus*. Its characteristic reaction is the transformation of thiosulfate into sulfate and elementary sulfur.
 - ¹ Dundon, This Journal, 45, 716 (1923).
 - ² McKelvy and Taylor, ibid., 42, 1364 (1920).

high to introduce permanent strains in glass. The only permanent strains introduced in soldering glass to metal joints are due to the fact that a metal with a greater expansion coefficient is shrunk on the glass by cooling. Although the soda glass used by the writer has very seldom cracked upon cooling, Pyrex glass, which has a smaller expansion coefficient, has frequently cracked unless the joint was a small one or the metal part was made very thin so that it stretched instead of cracking the glass. These facts lead one to suspect that Dundon used a glass that contained numerous heat strains originally or which had an expansion coefficient unusually small for soda glass.

The writer has made several platinized soldered joints, but has found that equally satisfactory joints can be obtained by the use of tin or low melting-point solder without platinizing the glass, a method also mentioned in the article by McKelvy and Taylor.

When joints are made without platinizing, both the glass and metal must be very clean. The following procedure has been successful. The glass is cleaned with chromic acid, rinsed with distilled water and dried; the metal part is coated with tin or solder and the surface of the melted tin cleaned with a solution of zinc chloride. The metal part is allowed to cool, is washed thoroughly with distilled water, and if necessary is scrubbed with absorbent cotton or other material free from grease or dirt, and dried. Then the two parts are held together above a flame and as soon as the tin melts, the glass is inserted in the metal without the addition of any flux. When one part is fixed on an apparatus, it may be inconvenient to use a torch, in which case a soldering copper just hot enough to melt the tin may be held to the outside of the metal part and the glass pushed in slowly as the tin melts.

One joint about 5 mm. in diameter has withstood the vapor pressure of liquid carbon dioxide (60 to 70 atmospheres) for 3 years. A joint 41 mm. in diameter, tested with a pressure difference of about 1 atmosphere, was made with a solder melting at 130°. The first attempt was a failure because the flame came into direct contact with the glass and cracked it. Success was attained in the second attempt, however, when precautions were taken to keep the flame from striking the glass. No trouble arose from the fact that the glass did not fit tightly in the metal.

The copper-plated joint mentioned by Dundon is probably satisfactory for moderate pressures, but the process of manufacture requires much more time and labor than for the soldered joint.

THE OCCURRENCE OF POLYPEPTIDES AND FREE AMINO ACIDS IN THE UNGERMINATED WHEAT KERNEL

By S. L. Jodidi and K. S. Markley Received April 23, 1923

Introduction

While we know, from the work of Osborne¹ and his associates, that the wheat kernel contains 5 proteins, we are altogether inadequately informed, to say the least, in regard to the nitrogenous constituents other than the proteins. According to Schulze² the non-protein nitrogenous compounds present in the seed of wheat make up 0.240% calculated on the basis of the dry seed, or 11.2% calculated on the basis of its total nitrogen.

Frankfurt³ is doubtful with regard to the occurrence of amino acids in the wheat embryo, since his attempts to show their presence in alcoholic extracts of the embryo have led to negative results.

Richardson and Crampton⁴ reported the presence of allantoin—a purine derivative in the wheat embryo, while Frankfurt³ showed the occurrence of the bases betaine and choline.

These results were confirmed by the work of Schulze,⁵ who also reported the presence of asparagine in the wheat embryo, stating, however, that the quantity of those nitrogenous compounds is quite insignificant when related to the weight of the seed. Later Schulze⁶ and Castoro reported the occurrence of arginine also, in the embryo, adding that its quantity is very small. In more recent work by Grindley⁷ and his associates as well as by Nollau⁸ very complete estimations of the amino acids in wheat, wheat bran and gluten were reported. Their data, however, refer to hydrolyzed wheat and its by-products.

No mention is made in the literature of the occurrence of polypeptides in the wheat kernel, as far as we are aware, despite the fact that they were discovered and described by Fischer⁹ some 20 years ago. However, from the results reported in the experimental part of this paper it will be seen that the 4 wheat varieties investigated showed the presence of considerable quantities of free amino acids and polypeptides in the ungerminated wheat kernel.

Experimental Part

For our work we have selected the wheat varieties Fultz, Marquis, Kubanka, and Kanred, because of their commercial importance. Fultz¹⁰ represents a soft red winter wheat which is widely raised in the eastern half of the United States. Marquis,¹⁰ introduced into this country from Canada in 1913, has become the leading variety of hard red spring wheat. Kubanka¹⁰ is a widely grown commercial variety of durum wheat, usually outyielding the hard red spring wheats in the northern Great Plains because of its greater resistance to drought and rust. Kanred,¹¹ a pure-line selection from a wheat introduced into the United States from Russia in 1900, is a hard red winter variety extensively grown in the central Great Plains area.

For the experimental work the wheat samples were ordinarily ground in an electric buhr-mill to pass a 40-mesh sieve. Inasmuch as the results in this paper are largely based on the total and the protein nitrogen of the different wheat varieties a number of estimations, including ammoniacal nitrogen, were made. The average of these was taken as a basis for the calculations. It may be mentioned here that the *protein nitrogen* was estimated according to Stutzer's method outlined elsewhere, 12 while the ammoniacal nitrogen was determined in a vacuum according to Grafe's 13 method.

The results obtained are presented in Table I.

¹³ Grafe, Z. physiol. Chem., 48, 300 (1906).

In looking over Table I, in which the average is based in each case on at least three determinations, it will be noticed that the differences in the total nitrogen of the several varieties are rather marked and characteristic, the nitrogen percentage of Fultz being lowest (1.80), that of Kanred considerably higher (2.83), and that of Kubanka and Marquis higher than either of the others (3.03 and 3.04, respectively).

As to the protein nitrogen, the differences between the varieties when calculated to the oven-dried wheat follow about the order indicated in the case of the total nitrogen. However, when the protein nitrogen is referred to the total nitrogen we find that the differences between Kanred (87.01), Kubanka (86.73), and Marquis (87.26), are comparatively small, only Fultz showing a higher percentage (91.76).

With regard to the proportion of the ammoniacal nitrogen, which was estimated because it is formol-titrable along with the amino acids, it will be seen that the differences between the varieties are small, the total proportion of ammoniacal nitrogen for the three varieties examined being generally quite insignificant.

After a few preliminary experiments the methods finally adopted, in order to demonstrate the presence of amino acids in the wheat seed, were as follows.

Several flasks each containing 25 g. of "whole wheat" flour and 400 cc. of distilled water were shaken at room temperature for 2 hours and the contents filtered at once. The residue on the filter contained the undissolved substance, the bran, starch, etc. The clear filtrate, which was apparently free from starch, was concentrated on the waterbath. During evaporation, precipitates formed that displayed the xanthoprotein and biuret reactions and otherwise appeared to consist chiefly of proteins. These precipitates were separated by centrifugation. The supernatant liquid was evaporated on the water-bath to dryness and the residue extracted with 70% alcohol in order to remove the rest of protein and the residue—a yellow sirup—dissolved readily in hot water. The solution was made up to 100 cc., of which 2 portions of 20 cc. each were oxidized according to Kjeldahl's method to ascertain the quantity of nitrogen present. Of the remaining solution, 50 cc. was freed from carbon dioxide, phosphoric acid and coloring matter, and titrated with formol according to Sörensen's method as applied by one'r of us elsewhere (Method A).

The flour extracts ordinarily showed a neutral or a very slightly acid reaction. The probability that the slight acidity could have a hydrolyzing effect upon the nitrogen compounds in the flour extracts seemed to be quite remote. However, in order to remove any doubt the experiment was repeated with the difference that all evaporations took place under reduced pressure. We refer to this modification as Method B.

While operations incidental to the two foregoing methods remove the proteins, they do not accomplish it quantitatively. Inasmuch, however, as proteins containing ly-

¹⁴ Except gliadin, which is soluble in the alcohol.

¹⁵ The very small residue on the filter displayed protein reactions due undoubtedly to some gliadin present.

¹⁷ Jodidi, This Journal, 33, 1236 (1911); 34, 98 (1912); 40, 1031 (1918).

sine, as is the case with glutenin and leucosin occurring in the wheat kernel, have been shown to contain free amino groups which are formol-titrable, 18 the complete removal of the proteins from the aqueous solutions prior to their titration with formol seemed necessary. Method A, therefore, was modified as follows. The dried alcoholic extract of the flour was dissolved in hot water, the solution brought to boiling, carefully acidified with acetic acid, boiled for a few minutes and filtered. To the filtrate freshly prepared lead hydroxide¹⁰ and some lead acetate were added. The mixture was boiled for a few minutes and filtered. The clear filtrate was then concentrated on the water-bath to 100 cc. and treated as outlined in Method A. We refer to the results secured in this way as those of Method C. To do away with any possible changes due to evaporation under ordinary pressure, Method C was further modified so as to concentrate the extracts in a vacuum. This modification is referred to as Method D. For lack of material however, not all four methods could be applied to each variety. Since the reaction of amino acids with formaldehyde is reversible according to the equation, NH₂RCOOH+ CH₂O CH₂ = NRCOOH + H₂O, excess of formaldehyde was applied to make sure that the forward reaction takes place quantitatively. The results obtained are recorded in Table II.

TABLE II
PROPORTION OF AMINO ACID NITROGEN IN THE UNGERMINATED WHEAT KERNEL

Fultz	₹B	.029	.026	1.61	9.72	Kubanka	B	.037	.034	1.21	8.92
	l c	.033	.029	1.85	11.12		D	.039	.036	1.28	9.41
	A	.048	.043	1.56	10.09	77	B	.066	.059	2.32	16.04
Marquis	B	.060	.054	1.95	12.63	Kanred	D	.067	.060	2.38	16.46
	D	. 055	.050	1.81	11.67		•				

The most outstanding feature of the results in Table II, in which the figures represent the average of at least two estimations, seems to us to be the fact that each of the four methods applied, while differing from the others to a certain extent, indicates appreciable quantities of amino acids, the proportions (in round figures) for Kubanka, Fultz, Marquis, and Kanred being respectively 10, 11, 11, and 16% of amino acid nitrogen calculated to the water-soluble nitrogen, and 1.4, 1.8, 1.8, and 2.3%, calculated to the total nitrogen.

Concerning acid amides, it is true that asparagine was reported by Schulze⁶ and Castoro as well as by Frankfurt²⁰ to occur in the wheat embryo. However, these authors failed to give information as to the varieties in which it occurs, nor did they give the percentage in which it is present. It was, therefore, deemed of sufficient interest to obtain data on those subjects. The way we proceeded was as follows.

The alcoholic extract of a definite quantity of flour prepared as described in Method A was freed from alcohol by distillation. The residue was taken up with water and made

¹⁸ Z. physiol. Chem., 81, 274 (1912).

¹⁹ Hoppe-Seyler, "Handbuch der Physiologisch-Pathologisch Chemischen Analyse," A. Hirschwald, Berlin, 1909, p. 393.

²⁰ Ref. 3, p. 453.

up to 100 cc. Of this solution 2 portions of 20 cc. each were oxidized according to Kjeldahl's method to find out the quantity of nitrogen present. To 50 cc. of the remaining solution hydrochloric acid was added to a concentration of 20% and the whole boiled under a reflux condenser for 30 minutes, since it was ascertained that under these conditions asparagine²¹ splits off its amide nitrogen as ammonia quantitatively. Inasmuch, however, as it was noticed that the quantity of ammoniacal nitrogen increases with the duration of the hydrolysis, another extract was treated as described above, except that the hydrolysis was allowed to continue for 12 hours. The evaporated hydrolysate was distilled with magnesium oxide and the ammonia thus obtained titrated with standard acid. The results secured are summarized in Table III.

Table III
Proportion of Acid Amide Nitrogen in the Ungerminated Wheat Kernel

Ammoniacal nitrogen split off by hydrolysis with acid forms Acid amides Compounds other than acid amides (Hydrolyzed for 30 minutes) (Hydrolyzed for 12 Lours)

Variety of wheat	Oven- dried %	Air-dried	Total nitrogen	Water- soluble nitrogen	Oven- dried %	Air-dried %	Total nitrogen	Water- soluble nitrogen
Fultz	0.026	0.023	1.46	8.76	0.006	0.005	0.34	2.08
Marquis	.058	.052	1.91	12.33	.036	.033	1.18	7.63
Kanred	.053	.047	1.88	12.99	.017	.015	0.59	4.12
Kubanka	.052	.048	1.72	12.61	.032	.029	1.05	7.75

The numbers in Table III, each of which ordinarily represents the average of two or three individual estimations, need some explanation. When hydrolyzed for but 30 minutes the flour extract yields the total nitrogen of acid amides as ammonia, which is recorded in Cols. 2 to 5. However, when hydrolyzed for 12 hours it yields as ammonia both the nitrogen of acid amides and that of compounds other than acid amides, such as allantoin, which was shown to be present in the wheat embryo²² and is known to split off ammonia²³ when boiled with acids. it is necessary to subtract the ammoniacal nitrogen obtained on hydrolysis of the extract for 30 minutes from that secured by hydrolysis for 12 hours in order to obtain the ammoniacal nitrogen of compounds other than acid amides. It is this difference that is recorded in the last 4 columns. It will be noticed that the percentage of acid amide nitrogen in Fultz is much lower than in Marquis, Kanred and Kubanka, which show practically no difference among themselves in this respect. Similarly, the nitrogen from compounds other than acid amides (allantoin and similar substances) is lowest in Fultz, higher in Kanred and still higher in Marquis and Kubanka.

The occurrence of polypeptides or substances of a peptide character in vegetable and, generally speaking, in biological materials appears to have been variously reported by a number of investigators.

²¹ Jodidi, Kellogg and True, J. Agr. Research, 15, 398 (1918).

²² J. Landw., **52**, 322 (1904). Ref. 4.

²³ Abderhalden, "Handbuch der Biochemischen Arbeitsmethoden, Urban and Schwarzenberger, Berlin, 1910, vol. 2, p. 514.

Thus, by hydrolyzing gliadin Osborne and Clapp²⁴ succeeded in isolating a dipeptide of proline and phenylalanine. Levene and Wallace²⁵ by the action of trypsin on gelatin, obtained a polypeptide which on hydrolysis yielded proline and glycocoll while Levene and Beatty²⁶ by the action of 25% sulfuric acid on gelatin, managed to obtain peptide-like substances. By the action of pancreatin on different proteins Fischer and Abderhalden²⁷ obtained a polypeptide that was made up of all the proline and phenylalanine, and in part of other amino acids that could be obtained by hydrolysis of the proteins in question. Hart²⁸ reported that the water-soluble nitrogen of feeding stuffs is largely composed of free amino acids and peptide linkings. A few years later the occurrence of peptides in healthy and mosaic-diseased spinach²⁹ and cabbage³⁰ was reported.

A very diligent search of the literature revealed the fact that polypeptides have thus far never been reported to occur in the *ungerminated wheat kernel*.

If the aqueous flour extracts contain polypeptides, they must, when hydrolyzed long enough, yield free amino acids according to the equation,

> $NH_2RCONHR^1COOH + H_2O = NH_2RCOOH + NH_2R^1COOH$ Polypeptide Amino acids

Hence, the increase in amino acids after hydrolysis over that present before hydrolysis must correspond to the free amino groups of the peptides.

The following method was adopted in order to demonstrate the presence of polypeptides in the wheat kernel.

The preparation of the aqueous and alcoholic extracts up to the point where the alcohol is distilled was effected as outlined above. In order to remove the protein matter completely, the dry residue from the alcoholic extract was dissolved in hot water. The solution was brought to boiling, and treated successively with acetic acid, and then with freshly prepared lead hydroxide and a little lead acetate, the mixture being boiled and filtered after each treatment. The final clear filtrate was concentrated in a vacuum and made up to 100 cc. In two 20cc. portions of this the nitrogen was estimated according to the Kjeldahl method. To 50 cc. of the remaining solution hydrochloric acid was added to a concentration of 20%. This solution was boiled under a reflux condenser for 12 hours. The hydrolyzed substance was then evaporated to dryness, transferred quantitatively to a Kjeldahl flask and, in order to remove the ammonia, distilled with one31 g. of magnesium oxide previously reduced to cream with water. The magnesium oxide residue in the Kjeldahl flask was thoroughly extracted with hot water and filtered. The filtrate and washings were concentrated and made up to 100 cc., of which 2 portions of 20 cc. were analyzed by the Kieldahl method, while the remaining 50 cc. was used for formol-titration. The data secured are contained in Table IV.

Examination of Table IV, whose figures represent the average of three or four individual determinations, reveals the fact that the 4 wheat va-

While by the method as outlined for the peptide nitrogen determination the proteins proper are quantitatively removed from the flour extracts, this may not be fully the case with the proteoses present in wheat and with the peptones whose formation during the flour extraction, in minute amounts, is very hard to prevent. It is evident that hydrolysis of these compounds, if present, just as the hydrolysis of peptides, is bound to raise the amino acid content of the flour extracts. It seemed imperative, therefore, to devise a method by which the proteoses and peptones are removed completely before hydrolysis takes place. We proceeded as follows.

The dry alcoholic extract of a definite amount of flour, prepared as already outlined, was dissolved in water and made up to 200 cc. Two portions of 10 cc. each were used for nitrogen estimation. The remaining 180 cc. was made up to 200 cc. and divided into 2 equal parts. To each of those were added 5 g. of sulfuric acid mixed with 30 cc. of a solution containing 20 g. of phosphotungstic acid and 5 g. of sulfuric acid per 100 cc. After about 24 hours the precipitates were filtered off and washed with a solution containing 2.5 g. of phosphotungstic acid and 5 g. of sulfuric acid per 100 cc. Combined filtrates and washings were freed from phosphotungstic and sulfuric acids by treatment with baryta whose excess was precipitated with carbon dioxide. The mixture was then brought to boiling and filtered. The residue on the filter was extracted with ammonia-free water. The filtrate and washings were concentrated under reduced pressure, made up to a definite volume, and the peptide nitrogen was estimated after hydrolysis with hydrochloric acid as outlined above.

By this method in which proteoses and peptones, if present, are completely precipitated by phosphotungstic acid, it was found that Kanred, Fultz, and Marquis contain respectively 27.05, 29.35 and 35.14% of peptide nitrogen as against 26.86, 28.09 and 32.20% recorded in Table IV (last column). It is true that the results obtained by the last outlined method,

³² While the results presented in this paper are based upon standard methods, the complexity of the substances contained in plant materials renders it extremely difficult, if at all possible, to effect a strictly quantitative separation of the various compounds. This should be borne in mind when examining the data in Tables II to IV.

the details of which will be given in a subsequent paper, are not strictly comparable with those of Table IV for the reason that phosphotungstic acid precipitates, in addition to proteoses and peptones, also diamino acids, ammonia, bases like choline, betaine, etc. Broadly speaking, however, the results obtained by the last method fully corroborate the outstanding fact presented in Table IV that the wheat varieties in question contain in their ungerminated kernel considerable proportions of peptide nitrogen. The presence of peptides in the wheat kernel may have considerable physiological significance, such as in protein synthesis and more generally in nitrogen metabolism, because of the fact that they form a necessary link between the amino acids on the one hand and the proteins on the other.

Summary

The results thus far obtained permit drawing the following conclusions.

- 1. The wheat varieties investigated contain peptides in their ungerminated kernels, the percentages of peptide nitrogen for Kanred, Fultz, Marquis, and Kubanka being, respectively, 26.86, 28.09, 32.20 and 37.76, on the basis of the water-soluble nitrogen, and 3.89, 4.67, 4.98 and 5.13, calculated to the total nitrogen.
- 2. The wheat varieties under consideration contain free amino acids in their ungerminated kernels, the proportions (in round figures) for Kubanka, Fultz, Marquis, and Kanred being, respectively, 10, 11, 11 and 16% of amino acid nitrogen, calculated to the water-soluble nitrogen, and 1.4, 1.8, 1.8 and 2.3%, calculated to the total nitrogen.
- 3. The proportions of acid amide nitrogen in the ungerminated kernel of the varieties Fultz, Marquis, Kubanka and Kanred are, respectively, 8.76, 12.33, 12.61 and 12.99%, calculated to the water-soluble nitrogen, and 1.46, 1.91, 1.72 and 1.88% calculated to the total nitrogen.

THE CATALYTIC REDUCTION OF NITRO COMPOUNDS. II. GAMMA-NITRO KETONES

By E. P. Kohler and N. L. Drake Received June 14, 1923

The first step in the reduction of nitro compounds, the transition from nitro to nitroso compounds or, in the case of primary aliphatic nitro compounds, to oximes is as yet a complete mystery. Since γ -nitro ketones on hydrogenation would form substances in which active hydrogen and a carbonyl group are in a relation that is favorable for intramolecular condensation, it seemed possible that they might serve better than simpler nitroparaffins for permitting an insight into this process. With this end in view we have reduced the following 3 nitro ketones.

The results are disappointing, for while the reduction products undergo internal condensation as expected, the condensation products are themselves so easily reduced that it is impossible either to confine the action to a single step or to deduce the successive steps from the products finally obtained. The final result, moreover, depends to such a degree upon factors that cannot be controlled, that both the nature of the products and their relative amounts vary in reductions which are carried out as nearly as possible under the same conditions.

Thus in an experiment with the nitro ketone II in which the operation was interrupted when approximately 2 molecular equivalents of hydrogen per equivalent of ketone had been absorbed, the solution contained unchanged nitro ketone, the amino ketone IV, an hydroxy pyrroline V or VI, and the pyrrolidine VII.

The 3 reduction products, the only ones obtained by reducing this nitro ketone under a variety of different conditions, are here formed side by side long before all of the nitro compounds have disappeared from the solution, and neither the nature of the products nor the rate at which hydrogen is consumed gives any clue as to the stage at which condensation takes place.

The amino ketone IV is the only open chained reduction product that we obtained from any of these nitro ketones. It is also the only γ -amino ketone that is known, all earlier attempts to prepare this type of compound having failed, owing to the ease with which such compounds undergo internal condensation.1 While it readily undergoes this condensation, it is stable in neutral and weakly alkaline solutions. It is unlikely, therefore, that the pyrrolidine derivative VII is formed by way of the amino ketone.

The hydroxy pyrroline also represents a new type of compound. It was isolated with such difficulty and in such small quantities that its

¹ Hielscher, Ber., 31, 278 (1898). Gabriel, ibid., 42, 1242 (1909). Gabriel and Colman, ibid., 42, 1248 (1909).

structure could not be established with certainty; the only facts available are its composition and its ability to form a benzoyl derivative. Its indifference to permanganate in acetone is hard to reconcile with either formula. Since it is always present in the solutions after all absorption of hydrogen has ceased, it cannot be the source for the pyrrolidine derivative. The 3 reduction products, amino ketone, pyrroline, and pyrrolidine, must therefore be reached by separate paths.

The relative amounts of the 3 reduction products vary greatly with the nature of the nitro ketone. The 2 phenyl ketones give but small quantities of pyrrolidine derivatives, but in the case of the methyl ketone this is the principal product. Since the reduction takes place very readily and it is easy to isolate the product without allowing it to come in contact with air, this is at present, doubtless, the best method for getting pyrrolidine derivatives with groups in the 2,5 positions. The yield from the nitro ketone I was 86.5%.

Experimental Part

The reductions were carried out by shaking suspensions or solutions of the nitro ketones in methyl alcohol with hydrogen in the presence of 0.5 g. of Loew's platinum black. As the nitro ketones are only moderately soluble, solutions were used only in attempts to get earlier stages of reduction. The rate at which hydrogen was absorbed was measured but it had little significance beyond indicating whether or not the reduction was proceeding normally. When suspensions were used, the rate of absorption usually remained constant until all of the solid had disappeared, then slowly fell off, and finally stopped when approximately 4 molecules of hydrogen had been absorbed for 1 of the ketones. In the few cases in which a sharper break in the absorption curve was observed, the corresponding quantities of hydrogen did not represent any definite stages of reduction.

During the reduction the catalyst changed into a more compact form, hence was easily removed by filtration. If the reduction to the pyrrolidine derivative was complete, the clear filtrate remained colorless both when allowed to remain in contact with air, and when treated with acid. But if the operation was interrupted before the reduction was completed, the colorless liquid soon became pink and the color gradually deepened to dark red or purple.

I. γ -Nitro- β -phenyl Pentanone

Preparation.—The nitro ketone was made by adding nitromethane to benzalacetone. The addition takes place readily, but the yield is not nearly so satisfactory as that obtained with benzalacetophenone, and even under the most favorable conditions half of the material goes into oily products. The best procedure was as follows.

A paste of sodium nitromethane was made by adding gradually and with constant stirring 15 g. of nitromethane to a well-cooled solution of 5 g. of sodium in 50 cc. of dry methyl alcohol. This was added rapidly to a solution of 25 g. of benzalacetone in 50 cc. of dry methyl alcohol that had previously been heated to near the boiling point. The mixture was kept at this temperature, and shaken vigorously to ensure as rapid addition as possible. As soon as all the solid had disappeared the clear, orange-colored solution was cooled in an ice-and-salt mixture and then acidified very slowly with 20 g. of glacial acetic acid. The nitro ketone slowly separated as a pasty solid. After standing for an hour the crystal mass was filtered, pressed on a suction funnel, washed first with a little alcohol and then very thoroughly with water, pressed as dry as possible, and dissolved in chloroform. The water layer was separated, the chloroform solution dried with calcium chloride, and freed from chloroform by distillation. The residue thus obtained was recrystallized from methyl alcohol from which it separated in lustrous needles. The substance is moderately soluble in cold ether and methyl alcohol; m. p., 99–100°; yield, 48%.

Analysis. Calc. for C₁₁H₁₃O₃N: C, 63.8; H, 6.3. Found: C, 63.7; H, 6.4.

REDUCTION.—A suspension of 40 g. of the nitro ketone in 200 cc. of methyl alcohol was shaken with hydrogen and 0.5 g. of platinum black until absorption ceased. The platinum was then removed from the solution by filtration, the methyl alcohol distilled, and the residue subjected to vacuum distillation. This gave, along with a small quantity of low-boiling product and a tarry residue, 27 g. of a colorless oil which on redistillation boiled at 112° (10 mm.). As this proved to be extremely hygroscopic it was distilled from sodium in preparation for analysis.

Analysis. Calc. for C11H15N: C, 82.0; H, 9.3. Found: C, 81.7; H, 9.4.

2-Methyl-4-phenyl-pyrrolidine, $C_6H_5CH-CH_2-CHCH_3$.—This is a colorless CH_2-NH

liquid which can be kept unchanged in sealed tubes, but which gradually turns yellow when exposed to the air. It is most easily identified by its solid benzoyl derivative.

chloride was gradually added in excess to an ethereal solution of the pyrrolidine derivative which was then shaken with 10% potassium hydroxide until the odor of the chloride had disappeared. The ethereal solution was dried over calcium chloride, the ether removed, and the residue distilled under diminished pressure. It distilled without decomposition at 260–270°, and the colorless distillate solidified in large, colorless tablets melting at 79–80°. When the substance was recrystallized from a mixture of ether and petroleum ether the melting point became constant at 82–83°. The substance crystal-

lizes in large prisms. It is readily soluble in ether or alcohol, sparingly in ligroin.

Analysis. Calc. for C₁₈H₁₉ON: C, 81.5; H, 7.2. Found: C, 82.0; H, 7.2.

1,2-Dimethyl-4-phenyl-pyrrolidine Hydrobromide, C₆H₅CH—CH₂—CHCH₃

CH₂——NCH₃HBr.—

Methylphenyl-pyrrolidine reacts very energetically with methyl iodide, but it is difficult to isolate a pure product even when the reaction is moderated by diluting the reagents with dry ether. It is better, therefore, to methylate with dimethyl sulfate. For this purpose 8 g. of dimethyl sulfate was gradually added to 5 g. of the base suspended in 70 cc. of 10% potassium hydroxide solution which was cooled in ice and salt. The mixture was shaken until all of the sulfate was hydrolyzed, then extracted with ether. The ethereal solution was dried with solid potassium hydroxide and finally with metallic sodium. From the resulting solution dry hydrogen bromide precipitated the hydro-

bromide of the methylated compound in fine, colorless needles. After recrystallization from methyl alcohol ether these melted at 144-146°, probably with decomposition.

Analysis. Calc. for C12H17NHBr: C, 56.3; H, 7.0. Found C, 56.6; H, 7.0.

II. β -(3,4-Methylene-dioxy-phenyl)- γ -nitro-butyrophenone

Preparation and Properties.—The method of preparation was the same as that used in the case of γ -nitro- β -phenyl pentanone, but the yield was much better; 68 g. of piperonal acetophenone condensed with 30 g. of nitro methane gave 61 g. of the nitro ketone.

The substance was purified by recrystallization from methyl alcohol. It separated in fine needles that melted at $95-96^{\circ}$.

Analysis. Calc. for C₁₇H₁₅O₅N: C, 65.2; H, 4.8. Found; C, 65.0; H, 5.1.

REDUCTION.—A solution of 31.3 g. of the nitro ketone in 200 cc. of methyl alcohol was reduced in the presence of 0.5 g. of platinum. The solution began to absorb hydrogen at a rate of about 2.3 cc. a minute. This rate was maintained with little change until somewhat more than the quantity of hydrogen had been absorbed which was calculated for reducing the nitro to the amino group. It then dropped sharply to nearly a third of this value and remained constant at the new level until absorption ceased.

A colorless solid separated from the solution during the reduction and remained mixed with the catalyst when the operation was stopped. This was filtered off, washed with ether, and dissolved in boiling dry methyl alcohol. It crystallized in colorless needles, but the melting point was less sharp than it had been before solution. It was, therefore, recrystallized from dry ether and ligroin before analysis.

Analysis. Calc. for C₁₇H₁₇O₃N: C, 72.1; H, 6.0. Found: C, 72.4; H, 6.0.

 β -(3,4-Methylene-dioxy-phenyl)- γ -amino-butyrophenone, IV.—The amine is readily soluble in chloroform and acetone, moderately soluble in methyl alcohol and in ether, slightly soluble in ligroin. It crystallizes in colorless needles or plates and melts at 129–130°. When it is perfectly pure and dry it is stable; but in solution and when moist it changes more or less rapidly into gummy, discolored condensation products. It appeared to form a hydrochloride, but this was not adapted either for purification or identification.

2-Phenyl-4-(3,4-methylene-dioxy-phenyl)phenyl Sulfone,

CH₂-N—SO₂C₆H₅.—When the amine is treated with benzene sulfone chloride and alkali it undergoes both acylation and condensation. The product is a sparingly soluble sulfone which crystallizes well and serves to distinguish between the amine and all other substances except the corresponding pyrrolidine. The substance is very sparingly soluble in ether, somewhat more readily soluble in methyl alcohol, readily soluble in chloroform. It was purified by recrystallization from chloroform-petroleum ether. It crystallizes in minute plates, begins to turn brown at 220°, and melts with decomposition at 225–227°.

Analysis. Calc. for C23H19O4NS: C, 68.1; H, 4.7. Found: C, 68.6; H, 4.9.

PARTIAL REDUCTION.—Since the preceding experiment showed a fairly sharp drop in the rate of reduction after 2 molecular equivalents of hydrogen had been absorbed, we repeated it as nearly as possible under the same conditions, but interrupted the operation when the solution which contained 31.3 g. of ketone had absorbed 4.97 l. of hydrogen. The liquid contained no solid other than platinum. This was removed and the

filtrate concentrated and set aside. It deposited $7.0~\rm g$. of unchanged nitro ketone which was identified by a mixed melting point. After further concentration it deposited $3.3~\rm g$. of a mixture of nitro ketone and amine, and later $4.5~\rm g$. of a new product that melted at $144-145~\rm c$. Finally, when all the alcohol was removed, there remained a gummy residue that could not be induced to crystallize.

1-Hydroxy-2-phenyl-4-(3,4-methylene-dioxy-phenyl)-pyrroline, VI.—The solid that melted at 144-145° was purified by recrystallization from methyl alcohol or ether. It crystallizes in colorless needles, is moderately soluble in alcohol, ether or benzene, is not changed by contact with air, and does not reduce permanganate in acetone.

Analyses. Calc. for C₁₇H₁₅O₂N: C, 72.6; H, 5.3. Found: C, 72.5, 72.4; H, 5.6, 5.6.

2-Phenyl-4(3,4-methylene-dioxy-phenyl)pyrrolidine Hydrochloride, VII.—The gummy mass left after all of the alcohol had been removed turned dark red or purple on treatment with hydrochloric acid. On cautious dilution with a mixture of methyl alcoholic hydrogen chloride and ether it deposited a solid that crystallizes from alcohol and ether in beautiful, long, thin, white needles. The color of the solution was doubtless due to the presence of the amino ketone, because the solutions of the pyrrolidine hydrochloride in methyl alcohol and in ether are colorless, and remain so when left in contact with air. The salt melts with decomposition at about 208°.

Analysis. Calc. for C₁₇H₁₇O₂NHC1: C, 67.2; H, 5.9. Found: C, 67.2; H, 5.8.

III. β -Phenyl- γ -nitro-butyrophenone

The nitro ketone III gave only oily products that could not be distilled under diminished pressure. By indirect methods it was possible to prove that these oils contained an hydroxy pyrroline, which was isolated as benzoate VIII or IX, and the pyrrolidine X which was isolated as hydrochloride and oxalate.

2,4-Diphenyl-pyrrolyl Benzoate, VIII or IX.—A small quantity of the oil, left after distillation of the methyl alcohol in which the nitro ketone had been reduced, was mixed with 5 times its weight of benzoyl chloride and an excess of 10% potassium hydroxide. The mixture immediately turned to a deep purple. It was shaken until the odor of benzoyl chloride had disappeared, then diluted with water and separated. The oil was washed with water and dissolved in methyl alcohol. This solution deposited a solid which was recrystallized from methyl alcohol. It separated in colorless needles; m. p., 179–180°.

Analysis. Calc. for C23H19O2N: C, 80.9; H, 5.6. Found: C, 80.5; H, 5.4.

2,4-Diphenyl-pyrrolidine Hydrochloride.—A methyl alcoholic solution of the oil obtained by reducing phenylnitro-butyrophenone was saturated with dry hydrogen chloride, then cautiously diluted with dry ether until a slight cloudiness appeared, and set aside. It deposited thin, colorless needles which were recrystallized from dry methyl alcohol and ether; m. p., 171–172°.

Analysis. Calc. for C₁₆H₁₇NCl: C, 74.0; H, 6.9. Found: C, 73.9; H, 6.9.

Di(2,4-diphenyl)pyrrolidine Oxalate.—A solution of 5.4 g. of the nitro ketone in 50 cc. of methyl alcohol was reduced in the presence of 0.9 g. of oxalic acid and 0.5 g. of platinum black. A colorless solid began to separate long before all of the nitro compound had disappeared from the solution. As it was impossible to dissolve the sparingly

soluble salt without decomposing it, the mixture of salt and platinum was thoroughly dried and analyzed, the amount of platinum in the sample being determined by weighing the boat after the analysis.

Analysis. Calc. for C₃₄H₂₅O₄N₂: C, 76.1; H, 6.7. Found: C, 75.7; H, 6.8.

Both the pure hydrochloride and the pure oxalate were decomposed with alkali in the hope of getting a solid pyrrolidine, but the product in each case was a colorless oil.

Summary

- 1. When γ -nitro ketones are reduced with hydrogen in the presence of Loew's platinum black there is a succession of reduction and condensation reactions that overlap to such a degree that the rate at which the hydrogen is absorbed is represented by a smooth curve.
- 2. The principal reduction products are the amino ketone, hydroxypyrroline and pyrrolidine, corresponding to the nitro ketone that is reduced.
- 3. These products do not represent successive stages in the reduction; they are formed, simultaneously, along different routes.

DETERMINATION OF FORMALDEHYDE IN PRESENCE OF SUBSTANCES FOUND IN FORMALIN

By P. Borgstrom Received June 15, 1923

The object of this paper is to present the results of a study of certain methods for the determination of formaldehyde in the presence of some of the organic substances that may be present in a formalin solution. The substances whose effect will be noted are methyl alcohol, ethyl alcohol, sodium formate, acetone and methylal.

The methods chosen are (1) iodimetric, (2) "alkali-peroxide" and (3) neutral sulfite. These methods have been studied in previous work, and as the procedure used in this work is the same no detailed explanation of the procedure will be given.

The paraformaldehyde used is the same as in previous work, and gave by the Liebig combustion method 96.8% of formaldehyde and 3.2% of water. Sodium formate was

¹ The determination of formaldehyde, methyl alcohol, and sodium formate in the same solution was attempted by the oxidation with permanganate and the absorption of the carbon dioxide produced. The method used is that suggested by Messinger [Ber., 21, 2910 (1888)]. By this method the purity of the methyl alcohol was determined to be 95.35% and the sodium formate 100%; 0.2466 g. of paraformaldehyde and 0.7510 g. of sodium formate produced 0.8284 g. of carbon dioxide; calc., 0.8352 g.; 0.1170 g. of paraformaldehyde, 0.2722 g. of sodium formate and 0.2270 g. of methyl alcohol produced 0.6448 g. of carbon dioxide; calc., 0.6397 g.

² Borgstrom and Horsch, This Journal, 45, 1493 (1923).

used as a source of formate ion due to the ease of purification. The methyl alcohol was acetone-free but no attempt was made to have it absolute. The ethyl alcohol was absolute but no special purification was attempted to free it from traces of aldehydes. The acetone used was from the bisulfite compound. The methylal was used as purchased. From the odor of iodoform given off during use in the iodimetric method it may have had a trace of either acetone or ethyl alcohol and because of this no extensive investigation was made with it.

The substance whose effect was to be studied was added to the weighed paraformaldehyde.³ With liquids, especially with methyl alcohol and methylal, the materials to be added were sealed in small tubes of known weight. Most of the work was done by weight except in a few cases in which a micro-buret calibrated to 0.02 cc. was used.

Iodimetric Method.—No difference could be detected in the ratio of iodine to thiosulfate due to the presence of sodium formate in amounts ranging from 0.003 to 0.044 molecular equivalent.

The average net consumption of $0.0803\ N$ iodine was $0.140\ {\rm cc.}$ per g. of methyl alcohol. Using this value, one mole of methyl alcohol reacts with an iodine equivalent of $0.0066\ {\rm g.}$ (or $0.00022\ {\rm mole}$) of formaldehyde. This means that when both are present in the same concentration the determination will be 0.022% high.⁴

To show the actual effect of sodium formate and methyl alcohol nine determinations with a ratio of moles of HCOONa to moles of HCHO ranging from 1.24 to 4.26 gave an average value of 96.72% with an average deviation of 0.28. Seven determinations with the ratio of moles of CH₃OH to moles of HCHO ranging from 4.9 to 46.1 gave an average value of 97.0% with an average deviation of 0.18. Twelve determinations with a ratio of moles of HCOONa to moles of HCHO of 2.72, 8.84, 3.64, 5.65, 1.07, 3.55, 2.73, 4.78, 4.16, 4.19, 3.69 and 2.82 and the corresponding ratio of moles of CH₃OH to moles of HCHO of 20.6, 11.4, 14.1, 21.7, 16.2, 11.1, 7.0, 13.9, 31.7, 11.2, 7.8, 23.0, gave the percentage of formaldehyde as 96.90, 97.52, 96.47, 96.79, 96.23, 96.80, 97.19, 97.00, 97.39, 96.83, 96.86, and 97.25, respectively, with an average value of 96.93 and an average deviation of 0.28. This shows that the concentration of methyl alcohol and sodium

- ³ A paper by F. Mach and R. Herrmann has just appeared [Z. anal. Chem., 62, 104 (1923); C. A., 17, 945 (1923)] on "A Comparison of the Most Useful Methods for the Determination of the Formaldehyde Content of Formalin Solutions." The conclusions drawn by them differ somewhat from the results found in the present work and may be due to the fact that they used a formalin solution, while in this work paraformaldehyde was used as a standard.
- ⁴ L. F. Goodwin [This Journal, **42**, 44 (1920)] has found that "0.5 cc. methyl alcohol causes an error of nearly 0.5 cc. in the amount of 0.1 N iodine solution used." This value is higher than that found by the author and may be explained by the difference in quality of the methyl alcohol. If the alcohol be very carefully purified and used when fresh it probably will have no reaction or but very slight with alkaline iodine solutions.

formate in an ordinary formalin solution has no effect on the titration by the iodimetric method.

As both acetone⁵ and ethyl alcohol⁶ react rapidly with an alkaline iodine solution, error in the results would be dependent upon the concentration of these present and, therefore, no further work was done in connection with this method.

With methylal there was a reaction with the alkaline-iodine solution, and a strong odor of iodoform developed and in some cases even a precipitate. This may be due to either ethyl alcohol or acetone. The consumption of iodine $(0.0759\ N)$ per gram of the methylal was $11.07\ cc.$ as an average for 5 trials. Because of this no direct determinations were made with methylal present.

Hydrogen Peroxide Method.—The previous work was repeated; 7 determinations gave an average value of 96.86% with an average deviation of 0.23%. An attempt was made to use cresol red (o-cresol-sulfon-phthalein) as an indicator in place of litmus but the results were 98.71 and 98.01%, showing that under this condition this indicator was not satisfactory. When litmus was used as an indicator and the solution allowed to stand for an hour as recommended by Mach and Herrmann³ the purity found was 97.34% (5 determinations) with an average deviation of 0.20%. When cresol red was used under the same conditions the average value was 96.92% (7 determinations) with an average deviation of 0.21%.

When 5 cc. of methyl alcohol (calculated to be about 3.93 g.) was heated for 5 minutes, the net consumption of 1.0 N sodium hydroxide solution as calculated for per mole of methyl alcohol was 0.250 cc. or a negligible error. When 5 cc. was heated for 10 minutes the calculated consumption per mole was 2.304 cc. of N alkali. Mole for mole the error would not be over 0.25% even if the methyl alcohol were heated for 10 minutes.

When 1.9883, 1.4544, 1.1735 and 2.2280 g. of ethyl alcohol were heated with "alkaline peroxide" the net consumption of N alkali per mole of alcohol was 0.16, 1.53, 4.48 and 7.92 cc. for time of heating 5.5, 6, 8.5 and 27.5 minutes, respectively. The error is very small when the solution is molar, in formaldehyde and ethyl alcohol, and time of heating 5 minutes but with 8 minutes' heating the error is about 0.5%.

Three trials were made with methylal using 0.2379, 0.1799 and 0.2789 g. heated for 5 minutes and then cooled rapidly. The ratio of the acid and alkali used in these experiments was 1.1672, with an average deviation of 0.0005 in 8 trials. The trials with methylal showed a difference from this mean of 0.0017, 0.0003 and 0.0011 or an average of 0.0010. This is twice the error found without methylal. There is a trace of acetone or ethyl

⁵ Messinger, Ber., 21, 3366 (1888).

⁶ Luben, Ann. Spl., 7, 218, 377 (1870).

alcohol in the methylal (as shown by the iodimetric method) and this probably accounts for the difference. The actual difference as found is -0.04, +0.01, -0.02 cc. for the three runs. In one trial in which 0.4137 g. of methylal was allowed to stand for 45 minutes and gradually cool after heating for 5 minutes, the result was a net consumption of 0.11 cc. of N alkali; if both methylal and formaldehyde were molar the results on this account would be 2% high.

The action of alkaline peroxide on acetone is greater than on methyl or ethyl alcohol. When the mixture was heated for 5 minutes and then rapidly cooled the consumption of N alkali was 0.10, 0.05 and 0.15 cc. for 0.270, 0.320 and 0.410 cc. of acetone. Using the density of 0.78637 for acetone one mole reacted, therefore, with 27.32, 11.53 and 26.93 cc. of N alkali, respectively, giving thus an error of 2.7, 1.15 and 2.7%, respectively, if the concentration of each is molar.

Table I shows the actual effect of these substances on the determination of formaldehyde by the peroxide method. No attempt was made to cool

⁷ Krug and Elroy, Z. anal. Chem., 32, 106 (1893).

Runs 5, 6 and 7, while 8 was placed in water at about 20° for cooling. Runs 22 and 26, inclusive, show the effect of acetone. Evidently, if present in traces acetone should not have an effect when this method is used. Omitting Runs 5, 6 and 7, and 22 to 26, inclusive, the average value obtained was 96.94% with an average deviation of 0.20%, or about 0.1% higher than that found in the absence of these materials.

Neutral Sulfite Method.—No color change was noted on the addition of 1.5 g. of anhydrous sodium formate to 25 cc. of 4 N sulfite solution neutralized to rosolic acid by $0.498\ N$ sulfuric acid.

In 3 experiments the average alkalinity produced on the addition of 5 cc. of methyl alcohol to 25 cc. of neutralized sulfite solution was 0.41 cc. of 0.498 N sulfuric acid, using rosolic acid as an indicator. Assuming 5 cc. of methyl alcohol to be about 0.12 mole, the same amount of formaldehyde would require 240 cc. of 0.498 N acid for the neutralization of the base liberated by the reaction. This shows that for equal concentrations methyl alcohol causes an error of 0.16% when no correction is made for the effect of dilution.

The values given in Table II show that methylal, ethyl alcohol and methyl alcohol have no appreciable effect in the determinations by the neutral sulfite method.

Acetone and neutral sulfite react, liberating alkali just as formaldehyde does. Assuming the density of acetone to be 0.8, the amount of base liberated per mole of acetone was 407.5, 410.0 and 408.0 cc. as determined by neutralization with N sulfuric acid, working with samples of 0.235, 0.310 and 0.135 cc., respectively. This substance, then, would cause an error of 40% if the concentration of formaldehyde and acetone were the same.

Paraformaldehyde in the presence of acetone, as determined by this method, gradually decreased in purity with increased time of contact

before neutralization of the alkali liberated. With the addition of 0.060 cc. of acetone to samples of paraformaldehyde of 0.45 to 0.52 g. the purity determined was 97.66, 97.03, 96.27, 96.00 and 93.70% with time intervals of 5, 10, 15, 20 and 30 minutes, respectively. When 0.4466, 0.5283 and 0.5194 g. were mixed with 0.250, 0.235, and 0.240 cc. of acetone, respectively, the purity determined was 101.34, 95.23 and 94.45% with time intervals of 5, 10 and 15 minutes, respectively.

These data show that the determinations when made within 5 minutes' time may be high but not additive. The larger the amount of acetone, the greater will be the error. The cause of the change may be due to (1) the addition of sodium sulfite to the acetone and resultant liberation of sodium hydroxide; (2) the condensation of acetone and formaldehyde under the influence of the base present, thus freeing 2 molecules of sodium sulfite; or (3) the reaction of formaldehyde with the base, forming sodium formate and methyl alcohol. The first cause would be responsible for the first increase, and the second and third causes would tend to lower the values with time, as found. No attempt was made to determine the actual cause of this variation.

Summary

- 1. The iodimetric method can be used for the determination of formaldehyde in the presence of methyl alcohol and formic acid. Methylal, if pure, should have no effect. When acetone and ethyl alcohol are present this method cannot be used.
- 2. The peroxide method as outlined can be used for the determination of formaldehyde in the presence of methyl alcohol, ethyl alcohol, formic acid and methylal. When acetone is present in equal concentrations, the determination will be about 2% high.
- 3. The neutral sulfite method can be used for the determination of formaldehyde in the presence of methyl alcohol, ethyl alcohol, formic acid and methylal. Acetone introduces an error that cannot be readily corrected.

SOME PREPARATIONS FROM MALEIC AND FUMARIC ACIDS

By Harold G. Oddy Received June 16, 1923

Pechman¹ and Gabriel and Coleman² have prepared β -benzoyl-acrylic acid from maleic anhydride, benzene and aluminum chloride, and Pechman and Kosniewski and Marchlewski³ prepared β -toluyl-acrylic acid from maleic anhydride, toluene and aluminum chloride. This work has been repeated and the conditions for better yields determined. In the preparation of β -benzoyl-acrylic acid a yield of 95% (crude) was obtained by using 3 g. of maleic anhydride, 25 cc. of benzene, and 9 g. of aluminum chloride. This was kept cool for 20 minutes and then heated to 60° for 1.5 hours. Longer heating reduces the yield. In the preparation of β -toluyl-acrylic acid the same method gave a yield of 77%. Naphthalene, anthracene and diphenyl have been used in this experiment, giving the corresponding unsaturated keto acids, and various addition compounds of these acids have been prepared.

Rubidge and Qua's⁴ method of preparing diphenylphthalide from phthalic anhydride, benzene and aluminum chloride by using an acid anhydride on the intermediate compound has been shown to have quite general application. If maleic anhydride were substituted for phthalic anhydride in the reaction the product should be diphenyl-croton lactone but although the conditions were varied considerably the results of an attempt to effect this reaction were negative.

Since Pechmann⁵ prepared diphenylphthalide from the mixed anhydride of benzoyl-benzoic acid and acetic acid, the anhydride of β -benzoylacrylic acid and acetic acid, m. p. 113–114°, was prepared and treated with benzene and aluminum chloride but no diphenyl-croton lactone was obtained.

Fumaryl chloride, benzene and aluminum chloride have been used to prepare dibenzoyl-ethylene and instead of benzene, other hydrocarbons such as toluene, *m*-xylene and diphenyl have been used and the corresponding 1,4-diketones obtained. Since this work was done, Conant and Lutz⁶ have described the preparation of 1,4-diketones by this method using benzene, toluene, chlorobenzene and mesitylene. Paal and Schulze⁷ had prepared dibenzoyl-ethylene (*trans*) from dibenzovl-malic acid and

- ⁷ Paal and Schulze, Ber., 33, 3795 (1900).

changed it to the *cis* form by exposure to sunlight. The author found that ditoluyl-ethylene (*trans*) and di-2,4-xylyl-ethylene (*trans*) prepared from fumaryl chloride were changed, on exposure to sunlight, to the colorless *cis* form. Conant and Lutz also changed their *trans* 1,4-diketones to the *cis* forms by this method but my results in the case of ditoluyl-ethylene do not quite agree with theirs.

Paal and Schulze noted that the bromine addition compounds of the trans and cis forms of dibenzoyl-ethylene were identical. The author found this to be true also for the bromine addition compounds of di-p-toluyl-ethylene and di-2,4-xylyl-ethylene.

The melting points given in this paper were taken with a mercury thermometer which was calibrated by Professor J. B. Ferguson against a standard platinum-platinumrhodium thermocouple by means of a precision potentiometer.

Experimental Part

Identification of β -p-Toluyl-acrylic Acid.—One g. of the toluyl-acrylic acid was boiled with 10% sodium hydroxide solution for a few minutes; the methyltolyl ketone separated as an oil. This oil was oxidized in a cold alkaline solution of potassium ferricyanide, giving p-toluic acid. Previous experimenters had assumed that this acid was the para derivative.

Methyl β -p-Toluyl-acrylate.—Six g. of the toluyl-acrylic acid was dissolved in methyl alcohol and the solution saturated with hydrogen chloride. The oil remaining on the evaporation of the methyl alcohol was dried and most of it distilled at 240–245° under 115 mm. pressure. After recrystallization from acetic acid it formed long, colorless crystals, m. p., 45.5–46° and was readily soluble in ether, chloroform, benzene or ethyl alcohol.

 β -p-Toluyl- α -chloropropionic Acid.—One g. of the toluyl-acrylic acid was allowed to stand with 25 cc. of concd. hydrochloric acid in a closed flask for 60 hours. The product, which was colorless, was washed with water, dried and freed from the original acid by warming it with a small amount of toluene. It was then recrystallized from a large volume of toluene; m. p., 144–144.5°. It is quite soluble in acetone or ethyl alcohol and less so in ether or chloroform. Since, in the analogous compound, β -benzoyl-chloropropionic acid, prepared by Bougault, β the chlorine was in the α -position, this compound is β -p-toluyl- α -chloropropionic acid.

Analysis. Cale. for C11H11O3C1: Cl, 15.65. Found: 15.45.

 β -p-Toluyl- β , α -dibromopropionic Acid.—In cold acetic acid solution the toluyl-acrylic acid immediately reacted with bromine. Very pure material was obtained by recrystallizing the product from 75% methyl alcohol. It is soluble in chloroform, benzene, acetone or ethyl alcohol.

Analysis. Calc. for C11H10O3Br2: Br, 45.67. Found: 45.25.

 β , β -Naphthoyl-acrylic Acid.—Five g. of maleic anhydride and 7 g. of naphthalene were dissolved in 35 cc. of benzene, and 15 g. of aluminum chloride was slowly added. After 30 minutes the flask was warmed to $60-70^{\circ}$ for 4 hours. After decomposition of the intermediate compound with hydrochloric acid and removal of the benzene and excess naphthalene by distillation with steam the crude product was dissolved in sodium hydroxide solution and the solution gradually acidified, the first precipitate being re-

⁸ Bougault, Ann. chim. phys., [8] 15, 499 (1909).

jected. A small amount of benzoyl-acrylic acid was removed by washing the crystals with benzene and the material was further purified by recrystallizing it from a large volume of 10% hydrochloric acid; it seemed to be principally one product. By making the methyl ester of this material and hydrolyzing the ester, a pure acid, m. p., 189–190°, was obtained. It is easily soluble in acetone, ether, acetic acid, alcohol or chloroform and slightly soluble in benzene. In one preparation a small amount of a second product, m. p., 158–159°, was obtained which seemed to be more soluble in benzene, and the methyl ester was an oil. The acid, m. p., 189–190°, did not react with bromine in cold acetic acid solution, and in hot acetic acid hydrogen bromide was evolved.

Analysis of silver salt. Calc. for C14H9O3Ag: Ag, 32.5. Found: 31.9.

Identification of the Acid Melting at 189–190°.—One g. of this acid was dissolved in acetic acid and 6 g. of sodium dichromate added. The flask was kept on the water-bath for 6 hours and after it had then cooled the contents were diluted with thrice their volume of water. A brown precipitate formed that on sublimation gave β -naphthoic acid. The acid is, therefore, β , β -naphthoyl-acrylic acid.

Methyl- β , β -naphthoyl-acrylate.—Five g. of the acid was dissolved in methyl alcohol and the solution saturated with hydrogen chloride. The ester crystallized in plates, m. p., 94-95°, and is soluble in acetic acid, chloroform or benzeue.

 β -p-Phenyl-benzoyl-acrylic Acid.—Five g. of maleic anhydride and 8 g. of diphenyl were dissolved in 50 cc. of benzene and 15 g. of aluminum chloride was added. The temperature was kept at 60–70° for 4 hours. Only a small amount of diphenyl and no benzoyl-acrylic acid were recovered and practically no tar was formed. Recrystallization from acetic acid gave yellow needles; m. p., 167–168°; yield, 80%. The acid is quite soluble in acetone, ether or ethyl alcohol and insoluble in cold benzene or toluene. The sodium salt is only slightly soluble in water.

Analysis of silver salt. Calc. for C₁₆H₁₁O₃Ag: Ag, 30.05. Found: 29.75.

Methyl β -p-Phenyl-benzoyl-acrylate.—Four g. of the acid was dissolved in methyl alcohol and after treatment with hydrogen chloride the solution was boiled for $^{1}/_{2}$ hour. The ester on recrystallization from ethyl alcohol melted at 73.5– 74° and is readily soluble in benzene, acetone or ether.

 β -p-Phenyl-benzoyl- α , β -dibromopropionic Acid.—Five g. of β -p-phenyl-benzoylacrylic acid was dissolved in hot acetic acid and bromine slowly added. It was immediately absorbed. The powder obtained by evaporating the solution was recrystallized from toluene; m. p., 180–181°. It was readily soluble in alcohol, acetone or ether and difficultly soluble in benzene or toluene.

Analysis. Calc. for C₁₆H₁₂O₂Br₂: Br, 38.8, Found: 38.35.

Identification of β -p-Phenyl-benzoyl- α , β -dibromopropionic Acid.—One g. of this acid was fused with 2 g. of potassium hydroxide for 10 minutes at 160° and p-phenyl-benzoic acid obtained from the product. This gives the formula for the original acid and for the bromine addition compound.

Methyl β -p-Phenyl-benzoyl- α , β -dibromopropionate.—Two g. of the acid was boiled for 30 minutes with methyl alcohol and hydrogen chloride. The ester on recrystallization from ethyl alcohol was white, m. p., $120-121^{\circ}$, and soluble in acetone, ether, acetic acid or benzene.

β-meso-Anthroyl-acrylic Acid.—Eight g. of maleic anhydride and 16 g. of anthracene were dissolved in 100 cc. of benzene and 24 g. of aluminum chloride was added slowly There was little action in the cold and the flask was warmed for 5 hours at 60–70°. After addition of hydrochloric acid, the solid was separated from the liquid and washed with benzene, yielding 15 g. of a light green product, which after recrystallization from acetic acid gave 10 g. of colorless crystals; m. p., 261°. This acid is soluble in acetone or chloro-

THE RELATION BETWEEN MOLECULAR STRUCTURE AND ODOR IN TRI-SUBSTITUTED BENZENES. I. DERIVATIVES OF PARA-METHOXY-ACETOPHENONE

By Marston Taylor Bogert and Leo Patrick Curtin Received June 23, 1923

Introductory

So many well-known perfume substances among the tri-substituted benzenes possess the 1,3,4 arrangement that this has been called by Georg Cohn the "ideal configuration." Borneol, menthol, carone, fenchone, thujone, menthone, pulegone, camphor, carvacrol, thymol, eugenol, isoeugenol, safrol, piperonal, vanillin, acetovanillone, certain of the synthetic musks, and many others might be cited as illustrations of the fact that such an arrangement of the osmophore groups is of remarkably frequent occurrence in compounds possessing strong, agreeable odors.

In following this observation further, we have investigated various derivatives of p-methoxy-acetophenone, a substance which itself has a fine floral odor, and whose m-hydroxy derivative (2-hydroxy-4-methoxy-acetophenone), also known as peonol, occurs in the roots of the tree peony ($Paeonia\ moutan$) and has been employed in the perfume industry on account of its pleasant aroma.

Our purpose was to throw some additional light upon the connection between odor and structure in compounds of this type, by preparing new 1,3,4 derivatives and noting their odor.

One of the products we had in mind was the isomer of peonol, iso-acetovanillone (3-hydroxy-4-methoxy-acetophenone), but while our experiments were in progress, the article by Schneider and Kraft¹ appeared, describing the preparation of this compound by the action of sulfo-acetic acid upon guaiacol. As the authors make no mention of its possessing any noteworthy odor, the inference is that it has none.

The following derivatives of 4-methoxy-acetophenone were synthesized carrying an additional osmophore group adjacent to the methoxy: 3-nitro, 3-amino, 3-iodo, 3-cyano and 3-azido. Of these, all but the nitro derivative are new. All proved to be practically odorless.

In addition to the above, other new derivatives, carrying non-osmophores in Position 3, were prepared in the course of the investigation, as follows: aceto-amino, iodochloride, iodoso, *p*-nitrobenzalamino, sodium sulfonate, diazo perbromide, diazo-amino, amino-azo and 4-hydroxy-3-iodoso-acetophenone. These likewise were odorless, as might have been expected on account of their nonvolatility.

A tri-substituted benzene containing 3 osmophore groups in 1,3,4 re
Schneider and Kraft, Ber., 55B, 1892 (1922).

lation, therefore, is not because of that reason a perfume, even though its physical constants, such as boiling point, solubilities, etc., may be favorable. The connection between odor and constitution is not so simple then, and other factors must be involved which we hope may be discovered by a continuation of this investigation.

While p-methoxy-acetophenone itself is very stable and can be distilled at 258° without decomposition, its derivatives noted above are much more sensitive to the action of heat, especially in the presence of acid or alkali, and tarry by-products often seriously diminished the yields.

In carrying out reactions upon groups *ortho* to the methoxy, we encountered the well-known obstacle of steric hindrance.^{2,3,4} Thus, it was found impossible to hydrolyze the 3-cyano derivative to the corresponding amide or acid, or to obtain therefrom an imino ester; nor could we convert the 3-amino derivative into the phenol.

Many years ago, Victor Meyer⁵ pointed out that the hindering effect of the interfering group increased with its molecular weight. Our own observations lead us to suggest the following supplementary hypotheses.

- 1. The hindering effect of an interfering group diminishes as the molecular weight of the reacting group in the *ortho* position increases.
- 2. The hindering effect of an interfering group diminishes as the molecular weight of the foreign reacting molecule increases.

These tentative hypotheses are based upon the simple physical considerations of mass and inertia and are, of course, of a qualitative nature only. None the less, they may prove of service to others, as they have to us.

As an illustration of Hypothesis 1, the formation of the azido derivative from the diazo perbromide and ammonia may be cited. The methoxy group, with a molecular weight of 31, is crowded out to such an extent by the heavy diazo perbromide group (molecular weight, 268), that the azido compound is formed practically instantaneously in excellent yield, although the foreign attacking molecule has a molecular weight of only 17.

In confirmation of the second hypothesis are the failures to hydrolyze the cyano derivative by water or hydrogen dioxide, or to change it to an imino ester by anhydrous methyl alcohol and hydrogen chloride, and the inability to hydrolyze the diazonium chloride. In all these cases, the molecular weight of the reacting group was not far from that of the interfering one (methoxyl). On the other hand, reactions involving heavier foreign molecules were particularly satisfactory; as, for example, those with hydrogen iodide, tin, copper, potassium cyanide, and those participating in the formation of Schiff bases or diazo-amino derivatives.

Experimental Part

The p-methoxy-acetophenone used in these experiments was prepared from anisole by a combination of the methods of Gattermann, Ehrhardt and Maisch⁶ and of Charon and Zamanos. The yield of pure product (m. p., $38-39^{\circ}$) was 61%. Charon and Zamanos report that their yields were those calculated. We were not so successful, as some unsymmetrical bis(p-anisyl)ethylene, small amounts of other products and considerable tar were always formed, although the acetyl chloride was added very slowly (2 hours) and the temperature was maintained below 10° . When petroleum ether was employed as solvent, in place of carbon disulfide, the yield was only 8%. With excess anisole as solvent, the yield was 30%, calculated to the anisole consumed in the reaction.

p-Methoxy-acetophenone Sodium Sulfonate.—p-Methoxy-acetophenone is not attacked by 95% sulfuric acid at 80°. Even fuming acid containing 15% of sulfur trioxide attacks it but slightly at laboratory temperature. It can be satisfactorily sulfonated, however, by great excess of stronger acid.

One hundred g. of fuming sulfuric acid containing $30\,\%$ of sulfur trioxide was cooled to $5\,^\circ$ and 25 g. of p-methoxy-acetophenone was added very slowly (30 minutes) with efficient stirring. After all the p-methoxy-acetophenone had been added, the stirring was continued for another half hour at low temperature, and the mixture then poured into 5 times its volume of ice-cold saturated salt solution. The sodium sulfonate soon began to separate, and after 20 minutes' further stirring the voluminous precipitate was filtered out; yield, nearly that calculated.

The salt formed large, snow-white, fatty leaflets, that turned pink when exposed to direct sunlight while still moist. Both the salt and the free acid were easily soluble in water.

Analysis. Calc. for C9H9O5SNa: S, 12.69. Found: 12.82.

Fusion of this sodium salt for 3 minutes with a low-melting mixture of sodium and potassium hydroxides completely destroyed it. The insignificant amount of phenolic product appeared to be mainly a catechol derivative, since with ferric chloride solution it gave immediately a deep green, turning red upon the addition of sodium carbonate. Evidently, the ether linkage was also ruptured in the fusion.

METHYL ESTER.—This was a colorless liquid prepared from the sodium sulfonate and dimethyl sulfate.

3-Nitro-4-methoxy-acetophenone has been described already by Stockhausen and Gattermann, who obtained it from o-nitro-anisole by the Friedel-Crafts reaction. Their yield was less than 9%. We find that high yields may be secured by the direct nitration of p-methoxy-acetophenone.

Fifty g. of p-methoxy-acetophenone was dissolved in 200 cc. of concd. sulfuric acid at laboratory temperature and the solution cooled to 0°. This solution was nitrated by the gradual (1 hour) addition of an ice-cold mixture of concd. nitric acid (containing ½ mole of nitric acid) with an equal volume of concd. sulfuric acid. Stirring was continued for 15 minutes after the addition of the mixed acids, and the solution was then poured into a liter of ice water. After standing for an hour, the precipitated nitro derivative was collected and crystallized from alcohol; yield, 95%. It formed slender, lemon-yellow, odorless needles; m. p., 99.5° (corr.). Stockhausen and Gattermann found this same melting point for their product.

Although it has been observed that o-methoxynitro derivatives are not readily reduced to the corresponding hydrazo compounds, the reaction was attempted with the

⁶ Gattermann, Ehrhardt and Maisch, Ber., 23, 1201 (1890).

⁷ Charon and Zamanos, Compt. rend., 133, 741 (1900).

⁸ Stockhausen and Gattermann, Ber., 25, 3521 (1892).

above nitromethoxy-acetophenone, following the procedure of Starke. Only tarry products resulted, nor could any benzidine derivative be isolated after treatment of the crude reaction product with coned. hydrochloric acid.

3-Amino-4-methoxy-acetophenone was prepared by reducing the above nitro derivative with tin and hydrochloric acid; yield, 74%. It crystallized from alcohol in large, flat, colorless, odorless hexagonal prisms; m. p., 102° (corr.); it was easily soluble in benzene, and moderately soluble in ether.

Analysis. Calc. for C₉H₁₁O₂N: C, 65.45; H, 6.67. Found: C, 65.68; H, 6.77.

ACETYL DERIVATIVE.—This was obtained by dissolving the amine in a slight excess of acetic anhydride and allowing the solution to stand for 2 or 3 days. It crystallized in colorless, rhombic prisms; m. p., 122.5° (corr.).

Analysis. Calc. for C₁₁H₁₃O₃N: C, 63.75; H, 6.33. Found: C, 63.68; H, 6.25.

Boiled with water, it was partially hydrolyzed. On crystallization from water, therefore, it showed a lower melting point, due to contamination with the free amine.

Benzal Derivative.—This was a sirupy substance that solidified only after long standing. When warmed slightly, it reverted to the sirupy form.

p-Nitrobenzal, Derivative.—This was obtained when the amine and p-nitrobenzaldehyde were heated at 110° for 15 hours.

Although a solid at laboratory temperatures, this product was not a crystalloid but a supercooled liquid. At room temperature, it was hard and brittle, but softened above 135° and was completely melted at 160°. The color ranged from deep red to yellow, depending upon the degree of subdivision of the solid. It was purified by dissolving it in boiling alcohol, in which it is but moderately soluble, and on cooling it separated in small droplets which soon solidified.

Analysis. Calc. for C₁₆H₁₄O₄N₂: C, 64.43; H, 4.70. Found: C, 64.18; H, 4.69.

Attempts to obtain the phenylhydrazine from the amine failed, in part due probably to intermolecular condensations of hydrazine and acetyl groups with formation of complex hydrazone types, leading finally to tars.

Similar lack of success attended our experiments for the production of a quinoline from the amine. Arsenic acid¹⁰ was used as the oxidizing agent, but the yield of the quinoline was exceedingly poor, and tars were the main products.

Before the publication of the article by Schneider and Kraft¹ reporting the preparation of iso-acetovanillone from guaiacol, we had made a number of futile attempts to produce the same compound from the above amine. The diazonium salt was boiled in aqueous solution, it was dropped cold into a mixture of sulfuric acid and sodium hydrogen sulfate at 140° and at 160°,¹¹¹ and it was added to a boiling solution of equal parts by weight of copper sulfate and water;¹² but no iso-acetovanillone was isolated in any of these experiments, only tarry substances being formed.

3-Iodo-4-methoxy-acetophenone, prepared from the amino derivative, through the diazo reaction, was purified by repeated crystallization from 50% acetic acid, after decantation from tarry by-products; yield, 55%. It was obtained as yellow, feathery, odorless needles, m. p., 103.6° (corr.), that rapidly became brownish in the light and were easily soluble in alcohol, chloroform, ether or glacial acetic acid.

Analysis. Calc. for C9H9O2I: C, 39.13; H, 3.26. Found: C, 39.29; H, 3.36.

When it was boiled for several hours with alcoholic potassium hydroxide solution, no phenol was formed.

⁹ Starke, J. prakt. Chem. [2] 59, 210 (1889).

¹⁰ Kueppel, Ber., 29, 704 (1896).

¹¹ Ger. pat., 95,339; Winther, I, 216.

¹² Ger. pat., 167,211; ibid., I, 211.

3-Iodochloride-4-methoxy-acetophenone, (ICI₂)(CH₃O)C₆H₃COCH₃.—When the iodo derivative was dissolved in chloroform and the solution saturated with dry chlorine, an unstable iodochloride was obtained in fine, bright yellow crystals.

This compound lost its chlorine so easily that it could not be obtained pure. In a closed vessel, the chlorine liberated displaced hydrogen of the molecule, and the only gas then found present was hydrogen chloride. The result was a mixture of products, which is now awaiting further examination, and which probably contains some of its chlorine in Position 6.

3-Iodoso-4-methoxy-acetophenone.—The freshly precipitated iodochloride was treated with 5 M potassium hydroxide solution. The product was a grayish white, putty-like, amorphous mass that decomposed suddenly when heated. Efforts to purify it by crystallization from various solvents were unavailing, as it always separated in a slimy, amorphous form.

3-Iodoso-4-hydroxy-acetophenone.—In the preparation of the above iodosomethoxy derivative, the clear alkaline filtrate was made acid by passing into it a current of sulfur dioxide. A precipitate resulted that was believed at first to be the iodonium iodide, ¹³ an assumption which was shown to be untenable because of the ready solubility of the substance in dil. aqueous alkali and the analytical results. The precipitation of the compound from its alkaline solution by sulfur dioxide also indicated the presence of a phenolic hydroxyl group, presumably formed by the action of the strong alkali used in attacking the iodochloride, the ether being saponified thereby, due to the acid groups ortho and para to it.

From 50% alcohol, the compound crystallized in long, pale yellow needles, that melted without decomposition at 243° when carefully heated, but decomposed suddenly when heated rapidly. It was easily soluble in alcohol or benzene, and moderately soluble in ether.

Analysis. Calc. for $C_8H_7O_3I$: C, 34.55; H, 2.54. Found: C, 33.58, 34.26; H, 2.62, 2.68.

3-Cyano-4-methoxy-acetophenone (3-Acetyl-6-methoxy-benzonitrile) was prepared from the amine by the usual Sandmeyer method; yield, 70%.

The product crystallized from alcohol in fine, pale yellow, odorless needles, m. p. 159.5° (corr.), that soon changed to a light orange-yellow color. It was moderately soluble in alcohol or ether, and dissolved readily in benzene.

Analysis. Calc. for C₁₀H₉O₂N: C, 68.55; H, 5.18. Found: C, 68.35; H, 5.27.

An attempt to prepare the amide from this nitrile by the action of alkaline hydrogen dioxide¹⁴ proved unsuccessful, the nitrile being recovered unchanged.

Efforts to saponify the nitrile to the corresponding acid were almost equally disappointing. Heating it with 70% sulfuric acid for several hours gave mainly tarry products, but a very small amount of a carboxylic acid was isolated, insufficient for purification, which melted with decomposition at 255°. Boiling the nitrile with concd. hydrochloric acid for 10 hours, heating it with 5 M potassium hydroxide solution for several hours, or fusing the sodium sulfonate with sodium formate, alike failed to yield the acid sought and gave only decomposition products.

Experiments were also conducted for the conversion of the nitrile into the imino ester by the action of dry hydrogen chloride and anhydrous methyl alcohol, but no reaction occurred, and the nitrile was recovered unaltered.

2-Methoxy-5-acetyl-diazobenzene Perbromide was precipitated at once when the calculated amount of bromine dissolved in hydrobromic acid was added to the diazonium chloride; yield, nearly that calculated.

¹³ V. Meyer, Ber., 27, 1592 (1894).

¹⁴ Radziszewski, *ibid.*, **18**, 355 (1885).

The compound formed pale yellow, flat needles (from cold alcohol), m. p., 68-70°, that decomposed on standing or on heating them with alcohol.

2-Methoxy-5-acetyl-azidobenzene, (CH₃O)(CH₃CO)C₆N₃.N₃.—Ammonium hydroxide solution was added with vigorous stirring to a fine suspension of the diazo perbromide in water.¹⁵ The azido compound was precipitated instantly as a mahogany-red mass which, after decolorization and recrystallization from dil. alcohol, was obtained in long, delicate needles of a peculiar faint pinkish buff color that darkened on standing and melted with decomposition at 87° (corr.). When heated rapidly, the substance exploded slightly above its melting point. It was freely soluble in alcohol or benzene, and also dissolved easily in ether; yield, 75%.

Analysis. Calc. for C₉H₉O₂N₃: C, 56.53; H, 4.74. Found: C, 56.33; H, 4.65.

The method of Culmann and Gasiorowski¹⁶ for the synthesis of azidobenzenes by the action of hydrochloric acid and stannous chloride upon the diazonium chloride was tried and found to be unsuitable for the production of this azide.

Griess¹⁷ has shown that certain azidobenzenes with a free para position rearrange to p-aminophenols when heated with 50% sulfuric acid. The azido derivative of p-methoxy-acetophenone described above, however, decomposed to a tar after only 15 minutes' heating with 25% acid.

2,2'-Dimethoxy-5,5'-diacetyl-diazo-aminobenzene, $(CH_3O)(CH_3CO)C_6H_3.N:N.NH.$ $C_6H_3(COCH_3)(OCH_3)$.—Ten g. of the 3-amino-4-methoxy-acetophenone was dissolved in 50 cc. of water and 20 g. of concd. hydrochloric acid, and the solution was well cooled and diazotized with the exact amount of sodium nitrite. To this diazo solution was added a solution of 10 g. of the same amine in 20 cc. of water and 6 g. of concd. hydrochloric acid, followed by a saturated aqueous solution of 35 g. of potassium acetate. The diazo-amino compound precipitated immediately. It was purified by boiling it in alcoholic solution with a decolorizing carbon, filtering the solution while it was still boiling hot, cooling quickly in an ice pack and filtering it promptly with suction. When the pale yellow solution was allowed to cool slowly, orange-colored needles formed that were contaminated with the isomeric amino-azo derivative described below; yield, 95%.

The pure product formed small, pale yellow needles, m. p. 178° (corr.), but was sparingly soluble in boiling alcohol and nearly insoluble in cold.

Analysis. Calc. for C₁₈H₁₉O₄N₃: C, 63.34; H, 5.57. Found: C, 63.10; H, 5.46.

2,2'-Dimethoxy-5,5'-diacetyl-4-amino-azobenzene.—The diazo-amino derivative was suspended in water and an equivalent amount of hydrochloric acid¹⁸ added. After standing at laboratory temperature for 3 days, the mixture had changed mainly to tarry products and only a small amount of the aminoazo derivative was secured. It formed dark red microscopic crystals (from 50% alcohol), m. p. $198-200^{\circ}$ (corr.), and proved to be an extremely feeble base, being insoluble in 10~M hydrochloric acid, but soluble in 13~M with a greenish blue color.

Analysis. Calc. for C₁₈H₁₉O₄N₃: C, 63.34; H, 5.57. Found: C, 63.18; H, 5.44.

Summary

- 1. Tri-substituted benzenes carrying osmophores in 1,3,4 arrangement are not always odorous, even when sufficiently volatile.
 - 2. Although 4-methoxy-acetophenone is itself a perfume substance

THE KETENIC DECOMPOSITION OF METHYLETHYL KETONE

By Charles DeWitt Hurd and Cyril Kocour Received June 25, 1923

It has recently been demonstrated that ketene can be prepared in excellent yields¹ merely by heating acetone vapors in a suitable apparatus. With this in view, methylethyl ketone was put to the same test. It can evidently decompose in two ways: $CH_3-CO-C_2H_5 \longrightarrow CH_2:CO + C_2H_6$; or $CH_3-CH_2-CO-CH_3 \longrightarrow CH_3-CH:CO + CH_4$. If ketene were formed, it would not be a profitable process unless the yield were better than that obtained in the decomposition of acetone.² However, if methyl ketene were formed, the reaction would be one of great interest regardless of the yield, inasmuch as methyl ketene is unusually difficult to prepare.

The literature that deals with methyl ketene is very limited. Staudinger³ prepared it in ethereal solution in 6 to 8% yield from α -bromopropionyl bromide and zinc shavings. No other positive statements are on record, although a few negative items bear witness to the difficulty of its isolation. One such is given by Ott.⁴ In his discussion of the ketonic decomposition of β -lactones, he observed that $(CH_3)_2C-C(CH_3)-COOH$ de-

composed at 110-113° into acetone, carbon suboxide, and an oil in approximately 80-

¹ Hurd and Cochran, This Journal, 45, 515 (1923). A repetition of the experiment was made in this Laboratory by Mr. J. W. Kern who obtained 18.5 g. of purified acetanilide from 28 g. of unrecovered acetone, a yield of 28.3%, in contrast to the yield of 17.5% reported in the original article. The only change in the apparatus was the use of tight-fitting rubber stoppers in place of corks, wherever possible; where corks were used they were well softened and painted with water glass inside and outside 1 day before use. As in the original report, the gas burners were giving their full blast. It is now thought that the temperature 600°, which was originally reported, is somewhat lower than the true temperature of the furnace.

² Methylethyl ketone is nearly as inexpensive as acetone.

³ Staudinger, Ber., 44, 535, 541 (1911).

⁴ Ott, Ann., 401, 159 (1914).

85% yield. Methyl ketene was reported to be absent. This was interesting, inasmuch as the lower homolog, (CH₃)₂C—CH—COOH, also formed acetone, and carbon sub-

oxide at its melting point. In this case, acetic acid was also isolated.

Very few data are obtainable concerning the behavior of methylethyl ketone at high temperatures. At least, it is stable at temperatures that do not exceed 450°. Other ketones, such as acetone, diethyl ketone, dipropyl ketone and methylpropyl ketone behave similarly.⁵

Poma and Nesti⁶ have studied the action of the silent electric discharge upon the vapor of methylethyl ketone. Of the gaseous decomposition products, they reported 43.6% of methane (or ethane), 32.8% of carbon monoxide, 12.5% of ethylene (or acetylene) and 10.2% of hydrogen. The liquid products were not analyzed completely, but sym-dimethyl-acetonyl acetone was shown to be present.

Ketene was found in our experiments, but we obtained no evidence of the formation of methyl ketene. This seems to be direct evidence that only the first of the two possible reactions mentioned above takes place. However, it is entirely possible that methyl ketene is also formed, and that it decomposes at the high temperature of the experiment. This problem is being studied further and will be discussed in a later paper.

Condensation products of methylethyl ketone were to be expected. We found that they constituted between 4 and 5% of the distillate. The remaining 95% was unchanged methylethyl ketone. The work of Bodroux and Taboury and of Becker and Thorpe would lead us to expect that methyl-5-heptene-4-one-3, C₂H₅-CO-CH: C(CH₃)-C₂H₅, would be contained in this mixture. No attempt, however, was made to determine the exact nature of the small amount of higher-boiling material obtained in our experiments.

Because of the fact that both ketene and methyl ketene are gases that polymerize easily, no attempt was made to isolate them but, instead, reagents were sought that would differentiate between the two. The following were used: aniline, toluidine, and water.

Experimental Part

Commercial methylethyl ketone was purified by several fractional distillations. The portion that was finally used, distilled almost completely¹⁰ between 79° and 80°.

The apparatus was similar in its essential features to that described by

- ⁵ Senderens, Compt. rend., 149, 996, footnote, (1909); Bull. soc. chim., [4] 5, 484 (1909).

- ¹⁰ Brunel [This Journal, **45**, 1338 (1923)] reported that very pure methylethyl ketone boils at 79.37° at 755 mm.

Hurd and Cochran. It is of fundamental importance that all joints be made as free from leaks as possible. Rubber stoppers were used in the cooler parts of the apparatus, where they were not in contact with methylethyl ketone. The corks used elsewhere were selected ones, well softened, and carefully fitted. They were painted with water glass, inside and out, and allowed to stand for some time before use in order to permit the water glass to harden before pressure was applied to it. Another difference in the apparatus was the use of an oil-bath, heated to about 120°, in place of the boiling water-bath. This was found necessary in order to effect immediate vaporization of the ketone as it dropped into the 500cc. flask. The burners beneath the combustion furnace were adjusted for a flame about $^3/_4$ the size of the full blast. The temperature, roughly measured in the middle of the furnace with a quartz thermometer, was 600° .

About 80 g. of methylethyl ketone was used in each run. The duration of the experiment ordinarily ranged between 1.5 and 2 hours. The ketone was added at such a rate that between 50 and 60 g. of distillate was recovered. The yields of ketene, based upon the methylethyl ketone that was not recovered, varied between 1 and 3.5%. In the report that follows, all duplicate runs that did not contribute essentially independent data have been omitted for purposes of brevity.

Reaction with Aniline

Eighty g. of methylethyl ketone was passed through the combustion tube; 56 g. of distillate was collected; therefore, 24 g. of the ketone may have decomposed. Ten g. of freshly distilled aniline was placed in the reaction flask with 50 cc. of absolute ether. At the end of the experiment the excess of aniline was removed by distillation with steam. The water solution of the non-volatile portion was evaporated, and the residue was recrystallized from a mixture of ethyl acetate and ligroin. About 0.8 g. of acetanilide, m. p., 112°, was isolated.

There was no indication of the presence of propionanilide, which indicates that no methyl ketene reached this part of the apparatus. However, a very small amount of material that melted at 79° was isolated. As yet it is unidentified, but further work with this compound is in progress. It is best recrystallized from hot ligroin (100–110°). It possesses about the same degree of solubility in hot water as acetanilide, for no separation by fractional crystallization from this solvent could be effected.

Reaction with para-Toluidine

About 10 g. of p-toluidine (m. p., 44-45°) was dissolved in absolute ether and placed in the reaction flask. A second reaction bottle containing aniline was placed in series to ascertain whether or not any ketene escaped reaction in the first flask. Only a trace of acetanilide was found, which proved that the reaction of ketene with toluidine is nearly instantaneous.

Of the 80 g. of ketone used originally, 60 g. was recovered. At the completion of the run, the excess of toluidine was removed by distillation with steam. The non-volatile portion was filtered while still hot, and the filtrate was then cooled in ice. A

¹¹ Ref. 1, p. 519.

voluminous white precipitate appeared which was collected and dried. Without further purification, it melted at 142°; yield, 0.8 g.; this represents a 2% yield of ketene. This product was resolved into 2 fractions by fractional crystallization from ligroin in which was dissolved a little ethyl acetate. The more insoluble fraction melted at 145°. Its identity was proved without question to be p-acetotoluidide by comparison with a known sample. The latter was prepared by the action of 1 cc. of acetyl chloride upon 1.5 g. of p-toluidine. The resultant product was heated to about 150° for a time, then cooled, washed with water, collected and dried; m. p., 145°. After one recrystallization from a mixture of ethyl acetate and ligroin, it melted at 146–147°. A mixture of this and the ketene product melted at 145–146°.

From the more soluble fraction was resolved a small quantity of a white crystalline compound that melted at 106°. This is probably similar to the compound that melts at 79° formed during the reaction with aniline. Work is being continued with both compounds.

At first, it was thought that it was o-acetotoluidide, but a mixed melting-point determination with a known sample showed the incorrectness of such an assumption. The mixture melted between 70–80°. The known sample was prepared by the action of 5.2 g. of acetic anhydride upon 10.7 g. of o-toluidine. The mixture was heated with a small flame for 2 hours, cooled, and recrystallized from a mixture of benzene and ligroin. It was then recrystallized from ligroin (100–110°), a solvent that fails to dissolve the para compound. The pure crystals melted at 109–110°.

Reaction with Water

A mixture of an excess of water with ether was placed in the first reaction flask. The second contained aniline and ether. Of the 80 g. of methylethyl ketone used, 52 g. was recovered. The slowness of the reaction between ketene and water was evidenced when 0.87 g. of acetanilide was isolated from the second reaction flask.

After the evaporation of ether from the mixture in the first flask a little phenolphthalein was added and the acid solution neutralized with 0.05~N sodium hydroxide solution. The solution of salt was then evaporated and dried. It weighed 1.144~g. To determine whether this salt was sodium acetate or sodium propionate, 1~g. of it was treated in 63% alcoholic solution with 1~g. of p-nitrobenzyl bromide. The product which resulted was p-nitrobenzyl acetate; after 2~ecrystallizations from alcohol it melted at 73-75°.

The total yield of ketene in this run was 3.5%, based upon the ketone that was not recovered.

The Distillate

One hundred and sixty g. of distillate, which was collected by the vertical condenser, was fractionated thrice; 43 g. boiled between 75° and 77°; 82 g. between 77° and 80°; 28 g. between 80° and 85°; 3.5 g. between 85° and 125°; 2 g. between 125° and 150°; and a foully smelling liquid which weighed 1.5 g. remained. The 7 g. of material that boiled above 85° represents 4.4% of the total. The rest was methylethyl ketone.

The two U-tubes that were placed between the condenser and the first reaction bottle collected but a small quantity of liquid that possessed an exceedingly pungent odor.

Summary

When methylethyl ketone is passed through a tube at 600°, ketene is formed in small yields. The presence of methyl ketene could not be demonstrated.

12 Two values for the m. p. of p-acetotoluidide are listed. Riche and Berard [Ann.,
 129, 77 (1864)] give 145°, whereas Feitler [Z. physik. Chem., 4, 76 (1889)] gives 153°.
 13 Reid, This Journal, 39, 126 (1917).

Ketene reacts much more slowly with water than with aniline or with toluidine.

PLATINUM OXIDE AS A CATALYST IN THE REDUCTION OF ORGANIC COMPOUNDS. III. PREPARATION AND PROPERTIES OF THE OXIDE OF PLATINUM OBTAINED BY THE FUSION OF CHLOROPLATINIC ACID WITH SODIUM NITRATE:

By Roger Adams and R. L. Shriner²
Received June 28, 1923

In two previous papers³ the platinum oxide obtained by the fusion of chloroplatinic acid and sodium nitrate has been shown to be an excellent catalyst in the reduction of organic compounds. This method for the preparation of an oxide of platinum is new. The chemical nature of this oxide and a quantitative study of the best conditions for its preparation have not yet been described.

This communication discusses (1) the best fusion temperature for preparing the platinum oxide of highest catalytic activity; (2) the quantitative analysis of various samples of the catalyst prepared at different temperatures; (3) the general chemical properties of the oxide; (4) a comparison of the activity as a catalyst of the oxide of platinum prepared from chloroplatinic acid by fusion with sodium nitrate and by fusion with the nitrates of other metals; (5) a comparison of the catalytic activity of the oxide made by the sodium nitrate fusion method with the oxides of platinum prepared by methods which have already been described in the literature.

The Temperature of Fusion

The best qualitative conditions for preparing the oxide of platinum have been described; a large excess of nitrate is advisable, and a rather high temperature of fusion gives a more active catalyst. During the fusion fumes of nitrogen dioxide are evolved and the oxide of platinum is precipitated. It is probable that the following reactions take place: $6NaNO_3 + H_2PtCl_6 \longrightarrow 6NaCl + Pt(NO_3)_4 + 2HNO_3$; $Pt(NO_3)_4 \longrightarrow PtO_2 + (NO_2)_4 + O_2$.

- ¹ Part of the chloroplatinic acid used in this investigation was purchased with the aid of a grant from the Bache Fund of the National Academy of Sciences. For this aid the authors are greatly indebted.
- ² This communication is an abstract of a thesis submitted by R. L. Shriner in partial fulfilment of the requirements for the Degree of Master of Science in Chemistry at the University of Illinois.

 - (b) Carothers with Adams, ibid., 45, 1071 (1923).

The standard procedure used to determine the temperature of fusion that gives the most active catalyst was similar to that previously used. A solution of 4.2 g. of chloroplatinic acid in 10 cc. of water was mixed with 40 g. of c. p. sodium nitrate and evaporated to dryness in a casserole or beaker. The mass was then heated with an ordinary Bunsen or Meker burner until fusion took place. The mixture and melt were stirred continuously with a thermocouple encased in a Pyrex glass tube and the temperature was read on a pyrometer. After the fusion was complete, the melt was allowed to cool and treated with water until the filtrates were free from nitrates and nitrites. The oxide was then dried in a desiccator and weighed in order to determine the yield. Portions of this dried material were weighed for the reduction experiments.

The temperatures used in the fusion for the preparation of the oxide ranged from 310°, the lowest possible temperature, to 700°, a temperature which is bright redness and cannot be reached with two Bunsen burners; it is necessary to use at least one Meker burner and one Bunsen burner.

In the first experiment the mixture was heated, during the course of 5 minutes, to 270–280° at which temperature melting began. The temperature was gradually raised, the reaction mixture reaching 300° at the end of about 8 minutes, and evolution of nitrogen dioxide commenced. The heating was continued until at the end of 10 minutes it reached 310°, then it was increased rapidly to 320° where it was held until the end of 20 minutes, after which the mixture was allowed to cool. Gas was evolved slowly from the time a temperature of 300° was reached and at the same time a brown precipitate gradually appeared. The reaction mixture was then worked up as described and the yield of 0.3 g. (1.69 g. is the theoretical amount) of platinum oxide was obtained. It is obvious that under these conditions the reaction was not nearly complete.

In the second experiment, the mixture was heated more rapidly, the fusion reaching 350-370° in 10 minutes. At this temperature a very vigorous evolution of oxides of nitrogen took place. The temperature was raised to 400° by the end of 15 minutes, by which time the evolution of gas had slackened. The temperature was then held at 400° until 20 minutes had elapsed when heating was discontinued. Evolution of gas had practically stopped at the end of this time. The precipitation of the oxide of platinum was rapid from 350° on. The yield of dry product was 1.4 g.

In the subsequent experiments sufficient heat was applied so that a temperature of 350–370° was reached in 10 minutes. The temperature was then raised and controlled over the period between 10 and 25 minutes. In each case, at the end of 15 minutes the evolution of gas had almost stopped. In Expt. 3, a temperature of 400° was reached at the end of 15 minutes and a temperature of 490–500° at the end of 20 minutes, at which point it was maintained until 25 minutes had elapsed.

In Expt. 4 the temperature was about 500° at the end of 15 minutes, 580° at the end of 20 minutes, and was maintained at 590-600° until 25 minutes had elapsed.

In Expts. 5 and 6 the conditions were similar to those in Expts. 3 and 4, except that in Expt. 5 a temperature of 650°, and in Expt. 6 a temperature of 700° was reached at the end of 20 minutes and maintained at this point until 25 minutes had elapsed. At a temperature of 650° and higher the melt boiled.

The yield of oxide in Expts. 3, 4, 5, 6 was practically quantitative. The only difference in the oxides obtained at the different temperatures

was in their appearance, the color changing from light brown in Expts. 1 and 2 to a very deep brown in Expt. 6.

In order to determine the relative activity of the various samples of oxide as catalysts, standard experiments were carried out with each sample in the reduction of two different types of organic compounds, benzaldehyde in the presence of a trace of ferrous chloride, and maleic acid. The procedure was to dissolve 20 g. of benzaldehyde or 20 g. of maleic acid in 150 cc. of 95% alcohol. To the benzaldehyde solution in each case, was added 1 cc. of 0.0001~M ferrous chloride. The solutions were reduced with 0.25~g. of catalyst in exactly the same manner as described in a previous paper. Table I gives the time for the reduction in each case.

Table I

Comparison of Catalytic Activity in Reduction Experiments of Samples of
Oxide made at Different Temperatures

Catalyst sample	Maximum temperature of fusion °C.	Time for reduction in minutes after reduction starte Benzaldehyde Maleic a		
1	310-320	40		
2	390-400	22	10	
3	490-500	10	11	
4	590-600	11	19	
5	650	20	17	
6	700	20	16	

The lag in the conversion of the platinum oxide to platinum black differed in each sample of the catalyst. It has not been taken into account in Table I but is shown in Table II. To find the total time, therefore, which is necessary for the reduction of benzaldehyde or maleic acid from the time the platinum oxide catalyst was added, it is necessary to add to the time given in Table I the corresponding lag time given in Table II.

Table II

Comparison of Time of Reduction to Platinum Black of Samples of Oxide Made at Different Temperatures

Catalyst sample	Maximum temperature of fusion ° C.	Time elapsing before was reduced to pla Benzaldehyde Min.	platinum oxide tinum black Maleic acid Min.
1	310-320	10	
2	390-400	5	2
3	490-500	1	1
4	590-600	2	3
5	650	7	5
6	700	11	17

These experiments show that a temperature of about 500° is most satisfactory for the fusion in order to obtain a catalyst of maximum activity and minimum lag. For this temperature one Bunsen burner turned on as high as possible was necessary. They also show that any sample

of catalyst may have a slightly variable lag depending upon the compound to be reduced; it may be possible, however, that this is due to slight changes in the conditions of the experiment. It is difficult to determine the lag accurately so that little importance can be given to slight differences in these values. In the previous papers describing the use of this catalyst, reactivation with air has been recommended in order to get the maximum speed of reduction of the organic compounds. It has been found since the publication of the first two papers that reactivation of the catalyst with oxygen instead of with air, as suggested by Willstätter⁴ has a much greater effect than had been anticipated. It is advisable, therefore, whenever using this catalyst, to reactivate by the latter method just mentioned. It is conceivable that in the reduction of a few types of organic compounds this would not be possible, but in the large majority it is possible, and will greatly cut down the time of the reaction.

The results on the activity of the platinum oxide catalyst made at different temperatures differ from those described in the first paper by Voorhees and Adams. This discrepancy in regard to the proper temperatures of preparation and speed of reduction is due to the fact that the reduction of benzaldehyde was chosen as a standard for the determination of the efficiency of the catalyst. At that time the tremendous effect of small amounts of certain metallic salts upon the activity of the platinum catalyst in the reduction of aldehydes was not known and consequently care was not taken to use platinum catalyst from the same source in every experiment.

Quantitative Analysis

Qualitative tests showed that the oxide of platinum obtained in the manner described contained a certain amount of water which probably was taken up during the washing to remove the alkali salts; the oxide also contained small amounts of alkali salts which were included and could not be washed out. The quantitative analyses showed the oxide to be PtO₂.H₂O.

The general procedure for the quantitative analyses was to heat weighed samples (about $0.5~\rm g$.) that had been previously well dried in a vacuum desiccator, to bright redness in a porcelain boat in a glass tube heated by an electric combustion furnace. Carbon dioxide was passed through continuously during the heating and the water that was driven off was absorbed in a sulfuric acid tube. After about 1 hour at bright redness no more moisture was evolved, the bulb was removed and the weight of water determined. The carbon dioxide was now stopped and hydrogen was passed over the red-hot residue in order to reduce the oxide to metallic platinum. This procedure was continued for 1.5 hours when no more moisture was formed. The boat was then allowed to cool and was weighed.

⁴ Willstätter, Ber., 54, 113 (1921).

The value thus obtained represented metallic platinum plus any alkali salts which were present. The residue was boiled with dil. sulfuric acid,⁵ the platinum filtered, dried and weighed. This treatment extracted practically all of the alkali salts.

It was found also that the catalyst contained a small amount of glaze from the porcelain casserole when such a vessel was used for the fusion. This was determined by dissolving a sample of the oxide in constant boiling hydrobromic acid, filtering the solution through a Gooch crucible and weighing the insoluble residue. This glaze averaged about 0.0025 g. in each 0.5g. sample and did not vary appreciably in the various samples of oxides.

The completed results on the analysis of each of the samples of catalyst, prepared at the various temperatures, are given in Table III.

Table III

Quantitative Analyses of Samples of Oxide Made at Different Temperatures

Temperature °C.	% Pt	% H ₂ O	% Alkali salts
390-400	78.90	7.13	2.22
490-500	79.80	7.37	1.72
590-600	78.00	9.16	3.56
650	79.80	8.83	3.66
700	79.40	8.06	4.80

Calc. for PtO2.H2O: Pt, 79.95; H2O, 7.34.

It may be seen that the amount of alkali salts varied with each preparation and particularly that the amount of alkali salts increased with the higher temperatures. Moreover, it is noticeable that the moisture content was somewhat higher with the oxides made at the higher temperatures. Although the analyses vary somewhat from the calculated results, they check much more closely with the theoretical values than many of the analyses of the oxides of platinum prepared by other investigators. The analyses leave no doubt as to the constitution of the oxide.

Properties of the Oxide

The physical and chemical properties of this oxide of platinum are interesting. It has already been mentioned that the color varied with the temperature at which the fusion was made. At the lowest temperature it was a very light brown and darkened gradually until at the highest temperature it was a very deep brown. It is probable that the difference in the color is due merely to a difference in the size of particles. A microscopic examination showed that the oxide is in every case non-crystalline in character and is composed of amorphous, approximately round granules.

The oxide dissolved only slightly in hot aqua regia even after long heating. It was insoluble in boiling coned. nitric acid and only slightly, or

⁵ Wöhler and Martin, Z. Elektrochem., 15, 132 (1909).

at least only slowly, soluble in boiling concd. hydrochloric acid. On the other hand, constant boiling hydrobromic acid dissolved it completely and instantly in the cold with the evolution of bromine and the formation of bromoplatinic acid which could be readily precipitated as the red potassium salt.⁶ By boiling it with 10% hydrobromic acid, solution was readily effected. It seems probable that the hydrobromic acid first reduces the dioxide to the monoxide which is dissolved with the formation of platinous bromide and then reoxidized by the bromine to the platinic bromide. Dilute or concd. hydrochloric acid had very little effect alone, but when a very small amount of sulfur dioxide was bubbled through dilute hydrochloric acid this mixture dissolved the platinum oxide rapidly and completely upon warming. In this case the reduction of the dioxide to the monoxide undoubtedly took place first before solution resulted. Other reducing agents with the dilute hydrochloric acid would undoubtedly produce the same effect.

The oxide caused the immediate decomposition of hydrogen peroxide without itself being apparently changed. When boiled with ethyl alcohol out of contact with air, the oxide was gradually reduced and acetaldehyde was formed.

Effect of the Nature of the Nitrate on the Activity of the Catalyst

All of the nitrates of the other alkali metals and of the alkaline earth metals fuse below 650°. These were, therefore, substituted for sodium nitrate in the fusion of the chloroplatinic acid. The oxides thus obtained were compared as catalysts by studying the reduction of benzaldehyde in exactly the same manner as previously described.

The procedure for these fusions was essentially the same as with sodium nitrate except that 3 g. of chloroplatinic acid and 20 g. each of the nitrates were used. The temperature was determined in a similar manner and the melt also treated similarly. The yields of product were quantitative in every case. In Table IV the results of these experiments are given.

Table IV

Comparison of the Catalytic Activity in Reduction Experiments of Samples of
Oxide by the Use of Various Nitrates

Nitrate	М. р. °С.	reduction of T benzaldehyde after reduction started Min.	Time for reduction of oxide to platinum black Min.	Temp. of fusion ° C.
LiNO ₃	253	12	9	490-500
NaNO ₃	312	10	1	490-500
KNO ₃		25	3	490-500
Ca(NO ₃) ₂	561	80	58	500-530
$Ba(NO_3)_2$	575	135	28	600-630
Sr(NO ₃) ₂	645	No reduction		630-640

⁶ Biilmann and Anderson, Ber., 36, 1566 (1903).

The lithium nitrate worked very satisfactorily in the fusion and yielded an active catalyst. It is noticeable, however, that the oxide produced is reduced to platinum black more slowly than that obtained by fusion with sodium nitrate.

The potassium nitrate was not so satisfactory as sodium nitrate. During the evaporation of the mixture of chloroplatinic acid and potassium nitrate to dryness, excessive foaming took place caused probably by the precipitate of potassium chloroplatinate. The oxide of platinum was produced in good yields but was not so active a catalyst as that obtained by the use of sodium nitrate.

Calcium nitrate itself decomposes just above its melting point into calcium nitrite and then into calcium oxide so that during the fusion with chloroplatinic acid the melt became very thick and viscid. The catalyst produced was very light yellow in color and did not resemble the oxide obtained by the fusion with the alkali metal nitrates. It was rather fluffy in appearance. It seems probable that this was an oxide of the formula PtO₂.2H₂O, since it resembled in appearance this substance as made by a method described in the literature and also in its catalytic activity in reduction experiments. The production of this substance could be explained by the primary formation of the calcium oxide which would precipitate the platinum oxide just as sodium hydroxide precipitates it from the chloroplatinic acid.

Both barium and strontium nitrates melt at so high a temperature that the platinum chloride, for the most part, is decomposed to metallic platinum before the fusion occurs, and hence the products from these fusions would not be expected to be so active as catalysts. That obtained from the barium nitrate caused the reduction of benzaldehyde only very slowly, and that from the strontium nitrate caused no reduction at all.

Comparison of this Catalyst with Platinum Oxides Made by Other Methods

A discussion^{3a} has already been made of the reasons for attempting to use the oxides of platinum as catalysts in the reduction of organic compounds. None of the oxides is as conveniently prepared as the oxide prepared by the fusion of sodium nitrate and chloroplatinic acid. Wöhler and Martin⁵ gave explicit directions for the preparation of a number of the oxides and these directions have been followed. These investigators, however, did not mention yields, a point of considerable importance when the oxides are to be used as catalysts. Most of the methods consisted in wet precipitation, and as slight changes in condition might make a considerable difference in the activity of the product as a catalyst, two different samples of each oxide were prepared.

In Table V a summary of the results of the use of PtO2, PtO2.2H2O,

 Pt_2O_3 , Pt_3O_4 and $Pt(OH)_2$ in reduction experiments is given. Since the majority of the oxides were comparatively non-active catalysts, smaller amounts of maleic acid and benzaldehyde were reduced than when the oxide catalyst prepared by fusion was used.

TABLE V

Comparison of Catalytic Activity in Reduction Experiments of Fusion Oxide and Various Platinum Oxides Made in Other Ways

					duction includi	
	% of oxide			ction of oxide	to platinum b	lack
	ostained from				enzaldehyde (1	
	the chloro-	oxide	(1)	0 g.)	(9.5 g	g.)
	platinic acid	used	Sample	Sample	Sample	Sample
Oxide	used	G.	1	2	1	2
Fusion oxide	100	0.25	10 m.		7 m.	
PtO_2	51	.24	4 h.	1.25 h.	50 m.	69 m.
$PtO_2.2H_2O$	60	.30	5.66 h.	5.0 h.	40 m.	60 m.
Pt_2O_3,\ldots	6	.23	5.5 h.	No red.	3.5 h.	4.75 h.
Pt_3O_4	82	.23	2.3 h.	2.6 h.	1.41 h.	1.33 h.
$Pt(OH)_2$	14	.24	No red.	No red.	8.41 h.	32 h.

It is noticeable that the yields of these other oxides were not nearly so satisfactory as that obtained by the fusion method. The oxides, moreover, were not nearly such active catalysts and the same oxide varied in activity from sample to sample even though prepared by the same directions. One of the distinct advantages in the fusion oxide is that a catalyst of standard activity is obtained.

The oxide Pt_3O_4 was made by the fusion of chloroplatinic acid with sodium carbonate. The oxide was formed in satisfactory yields distinctly greater than those of the oxides prepared by any of the other methods except that by fusion with sodium nitrate. The activity as a catalyst, however, was not as great as with PtO_2 or $PtO_2.2H_2O$.

In Table V the times recorded include both the time of reduction of the oxide to platinum black and the time of reduction of the compound. Since the last 3 oxides in the table were black at the beginning, it was very difficult to determine the exact point at which a platinum black was formed and consequently in order to have uniform results for comparison the total time was recorded.

Summary

- 1. The fusion of sodium nitrate and chloroplatinic acid has been carried out at various temperatures between 310° and 700°. The various samples of oxide of platinum produced were tested as catalysts in the reduction of maleic acid and benzaldehyde. It was shown that the oxide prepared at about 500° gave the best results in the reduction experiments.
- 2. A quantitative analysis of the oxide has shown it to have the composition $PtO_2.H_2O.$
- 3. This oxide is insoluble in aqua regia, concd. nitric or concd. hydrochloric acid. It is readily soluble in hydrobromic acid or hydrochloric

Identification of the Di-2,4-xylyl-dibromo-ethane.—One g. of the bromine addition compound was fused with 2 g. of potassium hydroxide for 10 minutes at 135° . The product on acidification gave 2,4-dimethyl-benzoic acid. This also identifies the dixylyl-ethylene as di-2,4-xylyl-ethylene.

Di-2,4-xylyl-ethylene (cis).—Two g. of the trans compound was dissolved in methyl alcohol and allowed to stand in sunlight for a week. A great deal of the original material was unchanged, but on evaporation of the alcohol the last precipitate was an oil which on recrystallization from ligroin gave colorless, needle-shaped crystals; m. p., 65–65.5°. These crystals are soluble in acetone, ether, benzene or chloroform. The bromine addition compound was made in acetic acid solution and was identical with that made from the trans form. A mixed melting point was not lower.

Di-p-phenyl-benzoyl-ethylene (trans).—A mixture of 8 g. of fumaryl chloride, 12 g. of diphenyl, 60 cc. of benzene, and 20 g. of aluminum chloride was kept at room temperature for 1 day. After decomposition of the intermediate compound and removal of the benzene and diphenyl by distillation with steam, the product was washed with hot benzene and a yellow powder was left; m. p., 247.5-248°. It is slightly soluble in benzene, and acetic acid and somewhat more soluble in chloroform. The solution in chloroform was exposed to 36 hours' sunlight but no product other than the original trans compound was obtained.

Di-p-phenyl-benzoyl-dibromo-ethane.—One g. of the di-p-phenyl-benzoyl-ethylene was dissolved in chloroform and bromine added. The color disappeared gradually and on evaporation of the solution a white solid, m. p., 218–218.5°, was obtained. This compound is slightly soluble in acetone or ether. Both this substance and the original ethylene derivative are assumed to contain the p-phenyl-benzoyl group.

Analysis. Calc. for C28H20O2Br2: Br, 30.3. Found: 29.85.

This work was done under the direction of Professor F. B. Allan and was made possible through assistance in the form of a Studentship received from the Research Council of Canada.

Summary

- 1. Rubidge and Qua's method for the preparation of diphenyl-phthalide was found not to be applicable to the preparation of diphenyl-croton lactone from maleic anhydride. An attempt to prepare this lactone from the anhydride of β -benzoyl-acrylic acid and acetic acid was also unsuccessful.
- 2. Several unsaturated keto acids have been prepared from maleic anhydride, and some of their addition compounds have been obtained. Some of these unsaturated keto acids readily formed addition compounds with bromine; others did not.
- 3. Using fumaryl chloride, several unsaturated diketones have been prepared as well as their bromine addition compounds. In two of these the yellow *trans* form has been changed to the colorless *cis* form by exposure to sunlight. The behavior of ditoloyl-ethylene seems to be peculiar; further work will be done on this.

TORONTO, CANADA

form and slightly soluble in benzene, toluene or acetic acid. It did not react with bromine in either cold or hot acetic acid solution, and fusion with potassium hydroxide at 250° gave no decomposition. It is assumed to be the *meso*-anthroyl derivative. The sodium salt and the ammonium salt are only slightly soluble in water.

Analysis of ammonium salt. Calc. for C18H15O3N: N, 4.77. Found: 4.82.

Methyl β -meso-Anthroyl-acrylate.—Three g. of β -meso-anthroyl-acrylic acid was dissolved in 100 cc. of methyl alcohol and hydrogen chloride added. After the solution had stood for 2 days, colorless plates crystallized and these after recrystallization from acetic acid gave needles 2 cm. long; m. p., 149.5–150°. The ester is soluble in acctone, chloroform or benzene and less soluble in acetic acid.

Di-p-toluyl-ethylene (trans).—To 7 g. of fumaryl chloride and 50 cc. of toluene 20 g. of aluminum chloride was added slowly. The reacting substances were kept at room temperature overnight. After decomposition of the intermediate compound the product was light yellow and after 3 recrystallizations from methyl alcohol melted at 134.5°; yield of crude material, 52%. The substance is soluble in benzene, acetone, ether, chloroform or acetic acid but only slightly soluble in methyl or ethyl alcohol. The product obtained by Conant and Lutz melted at 148°.

Di-p-toluyl-dibromo-ethane.—Two g. of the ditoluyl-ethylene was dissolved in 100 cc. of acetic acid and bromine slowly added. The bromine was immediately absorbed and colorless, needle-shaped crystals appeared; m. p., 200–200.5°. These were insoluble in benzene, toluene, ether or acetone, slightly soluble in acetic acid and more soluble in chloroform.

Analysis. Calc. for C₁₈H₁₆O₂Br₂: Br, 37.7. Found: 37 25.

Identification of Di-p-toluyl-dibromo-ethane.—One g. of the bromine addition compound was fused with 2 g. of potassium hydroxide for 10 minutes at 130°. The product on acidification gave p-toluic acid. This also identifies the di-toluyl-ethylene as di-p-toluyl-ethylene.

Di-p-toluyl-ethylene (cis).—Two g. of the trans compound was dissolved in acetic acid and allowed to remain in the sunlight for 3 days. At the end of this time some colorless crystals had appeared in the solution and more were obtained by evaporation of the solution; m. p., 148.5°. When the substance was recrystallized from ethyl alcohol the melting point became 152°. In acetic acid solution this product absorbed bromine and gave colorless needles identical with the bromine addition compound of the original compound. When the substance, m. p. 134.5°, was dissolved in acetone and exposed to sunlight for 2 days the product after one recrystallization melted at 147°. Further exposure to brighter sunlight for 2 days gave a small quantity of a substance melting at 120°. Conant and Lutz obtained the cis compound, m. p. 123°, and this is probably identical with my last product as I had not enough material for recrystallization.

Di-2,4-xylyl-ethylene (trans).—Seven g. of fumaryl chloride, 45 cc. of m-xylene, and 20 g. of aluminum chloride were used and the reaction proceeded at room temperature for several hours. After decomposition of the intermediate compound an oil was obtained, but on solution in methyl alcohol and gradual evaporation of the alcohol a yellow solid separated which on recrystallization from ethyl alcohol melted at 125.5-126°. It is quite soluble in benzene, acetone, ether, chloroform or acetic acid and slightly soluble in methyl or ethyl alcohol; yield, 15%.

Di-2,4-xylyl-dibromo-ethane.—Two g. of the dixylyl-ethylene was dissolved in 150 cc. of hot acetic acid and bromine gradually added. White needles formed; m. p., 145°. This product is insoluble in benzene, acetone or ether and slightly soluble in chloroform.

Analysis. Calc. for C20H20O2Br2: Br, 35.36. Found: 35.38.

acid containing reducing agents such as sulfur dioxide. It decomposes hydrogen peroxide without itself being changed. It oxidizes alcohols to the corresponding aldehydes.

- 4. It has been shown that the nitrates of lithium, potassium, calcium, barium and strontium are not nearly so satisfactory for the fusion with chloroplatinic acid as sodium nitrate.
- 5. A comparison of the catalytic activity of this oxide with the various oxides obtained by methods described in the literature has shown the former to be far superior. Moreover, it is much more readily prepared.

THE CONSTITUTION OF CAPSAICIN, THE PUNGENT PRINCIPLE OF CAPSICUM. III

By E. K. Nelson and L. E. Dawson Received July 2, 1923

In former contributions by one of us² capsaicin was shown to be the vanillyl amide of a decenic (decylenic) acid. Beyond proof that this decenic acid is not a straight-chain acid, its constitution remained undetermined. The primary purpose of the present work was to determine the structure of this acid, thereby establishing the complete structure of capsaicin.

On account of the scarcity of material at the time, it was decided to attack the problem from the synthetic end, which required, of course, the synthesis of a considerable number of 10-carbon acids. In order to simplify the work, the question of the location of the double bond was deferred for the time being, and a saturated acid was sought which, when condensed with vanillyl amine, would give a product identical with that obtained on hydrogenating the side chain of capsaicin.

Such an acid was finally found in 8-methyl-nonoic acid, which has been described by Levene and Allen.³

The location of the double bond in the decenic acid from capsaicin was finally determined by its oxidation with a 5% solution of potassium permanganate, the products being adipic acid and *iso*butyric acid.

This shows that the double bond is located between the sixth and seventh carbon atoms, and that capsaicin is the vanilly amide of Δ^6 , 8-methylnonenic acid,

$$\begin{array}{c} OCH_3 \\ HO \\ \hline \end{array} CH_2NHCO(CH_2)_4CH = CHCH(CH_3)_2 \end{array}$$

³ Levene and Allen, J. Biol. Chem., 27, 433 (1916).

Experimental Part

Hydrogenated Capsaicin.—One g. of capsaicin, dissolved in absolute alcohol, when shaken in the presence of hydrogen with 0.05 g. of colloidal palladium, absorbed 2 atomic proportions of hydrogen within 10 hours. The product, recrystallized from petroleum ether, melted at 65°. Its solution in chloroform did not decolorize a dilute solution of bromine in the same solvent, whereas a solution of capsaicin immediately decolorizes bromine. The appearance and optical properties of hydrogenated capsaicin are very similar to those of capsaicin. The refractive indices, $n_{\rm D}^{20°}$ of the two compounds determined by the immersion method in potassium mercuric iodide solution were as follows.

	α	β	γ
Capsaicin	1.520	1.540	1.580
Hydrogenated capsaicin	1.510	1.520	1.555

In a second experiment, 0.6855 g. of the saturated acid, made by hydrogenating the decenic acid from capsaicin, was converted into the chloride and then condensed with vanillyl amine. The resulting product had the same physical and optical properties as the hydrogenated capsaicin and did not show unsaturation with very dilute solution of bromine.

Synthesis of 8-Methyl-nonoic Acid.—Ethyl isocaproate (110 g.) was reduced to 4-methyl-pentyl alcohol by the method of Levene and Allen.³ The yield of 4-methyl-pentyl alcohol, boiling at 150–152°, amounted to 52.3 g., or 67.3% of the calculated amount. This 4-methyl-pentyl alcohol (52.3 g.) was refluxed for 3 hours with 4 molecular proportions of hydriodic acid (b. p., 127°) and the resulting iodide was separated and rectified. A yield of 97.8 g. (90%) of 4-methyl-pentyl iodide was obtained. The 4-methyl-pentyl iodide was then condensed with aceto-acetic ester according to the method of Locquin,⁵ yielding 83 g. of 4-methyl-pentyl aceto-acetic ester, boiling at 155–160° (20 mm.).

The 4-methyl-pentyl aceto-acetic ester (83 g.) was saponified by the method of Dieckmann, which consisted in boiling it for 4 hours with 10 g. of sodium dissolved in 250 cc. of absolute alcohol. The resulting ethyl 6-methyl-heptylate, boiling at 201–203°, was obtained in a yield of 66.2%. At this point some unchanged material from previous operations was recovered and converted into ethyl 6-methyl-heptylate.

Ethyl 6-methyl-heptylate was reduced by the Levene-Allen method and 33.9 g. of 6-methyl-heptyl alcohol, boiling at 185–190°, was obtained. The corresponding iodide was prepared, with a yield of 56.3 g., boiling at 100–105° (17 mm.). This was condensed with aceto-acetic ester, affording ethyl 8-methyl-nonoate which, on being saponified, gave a yield of 27.4 g. of 8-methyl-nonoic acid, boiling at 150° (15–16 mm.).

Preparation of 8-Methyl-nonoyl Vanillyl Amide, OCH3

HO CH₂.NH.CO(CH₂)₆.CH(CH₃)₂.—The 8-methyl-nonoic acid (1.18 g.) was converted into the acid chloride, and the latter condensed with vanillyl amine. The 8-methyl-nonoyl vanillyl amide formed melted at 65° and a mixture with hydrogenated capsaicin gave no depression in melting point. Its optical properties were also identical with those of hydrogenated capsaicin.

The pungency of the synthetic product, as well as that of hydrogenated capsaicin, was proved by direct quantitative experiment to be as great

⁴ The optical measurements were kindly made by Dr. Edgar T. Wherry of the Bureau of Chemistry.

Locquin, Bull. soc. chim., [3] 31, 757 (1904).
 Dieckmann, Ber., 33, 2670 (1900).

as the pungency of capsaicin. This shows that the double bond exerts little or no influence on pungency, which is contrary to the assumption of Ott and Zimmermann⁷ that unsaturation in the side chain of capsaicin and related compounds is necessary for pungency. The preparation of the vanillyl amides of other synthetic saturated and unsaturated acids, the description of which is reserved for a later communication, has also disproved the assumption that unsaturation in the side chain is a requirement of pungency.

Oxidation of the Decenic Acid from Capsaicin.—The acid isolated from the capsaicin by heating it to 180° with a 25% solution of sodium hydroxide was oxidized in the cold with a 5% solution of potassium permanganate. A partially crystalline product was thus obtained. This was separated by distillation with steam into a non-volatile, crystalline acid and a volatile, liquid acid.

The crystalline acid melted at $147-150^{\circ}$ (adipic acid melts at $149-149.5^{\circ}$). 0.1703 g. of the silver salt yielded 0.1017 g. of silver, or 59.7%; calculated for silver adipate, 59.96%.

The volatile, liquid acid was also converted into the silver salt which was found to contain 54.99% of silver; calculated for silver *iso*butyrate, 55.34%. This was known to be *iso*butyric acid on account of our knowledge of the structure of the corresponding saturated acid. The decenic acid from capsaicin is thus shown to have the double bond between the sixth and seventh carbon atoms and is therefore Δ^6 , 8-methyl-nonenic acid.

Summary

Hydrogenated capsaicin has been prepared and found to be very similar to capsaicin in all its properties, except that it does not decolorize a dil. bromine solution and differs in the refractive indices of its crystals.

A compound identical in all respects with hydrogenated capsaicin was prepared by condensing 8-methyl-nonoic acid with vanillyl amine.

A study of this compound has shown that it is quite as pungent as capsaicin and that the double bond is not necessary for pungency.

The unsaturated acid from capsaicin has been found to have its double bond in the 6 position, thus showing that capsaicin is Δ^6 , 8-methyl-nonenyl vanillyl amide.

SOME DERIVATIVES OF ARSPHENAMINE¹

By Walter G. Christiansen

Received July 9, 1923

The Preparation of Arsphenamine Polyarsenide

In a previous communication from this Laboratory,² the preparation of arsphenamine polyarsenides by reduction of a mixture of 3-amino-4-hydroxyphenylarsenious oxide and sodium arsenite with hypophosphorous acid is described. The arsenic content of the product varies from 47.3 to 53.7% depending upon the ratio of the organic arsenical to the sodium arsenite prior to the reduction. In spite of the fact that these specimens contain $^2/_3$ as much arsenic again as arsphenamine, they are tolerated in doses as large as 140 mg./kg.; many samples of arsphenamine are not tolerated at this dose.

It was shown³ that the toxicity of aromatic amino arseno compounds in general, when prepared from nitro aryl arsonic acids by reduction with sodium hydrosulfite, can be made to vary considerably depending upon the conditions under which the nitro group is reduced, and two sets of conditions for reduction of the nitro group have been developed so that, while using the same quantities of all reagents in both cases, the arsphenamine will be tolerated (a) in fairly large doses and (b) in only rather small doses.4 An investigation of the sulfur compounds in arsphenamine evinced that the more toxic samples prepared by improper reduction of the nitro group contain approximately 2% of sulfur, whereas when the most favorable conditions are employed the sulfur content is only 0.8%.5 A more recent study⁶ proved that when a certain amount of acetic acid is present while 3-nitro-4-hydroxyphenylarsonic acid is being reduced under the most favorable conditions by commercial hydrosulfite to arsphenamine base, the yield is increased without any alteration in the toxicity, but that when too much acid is employed the toxicity of the product suddenly increases.

A study of the production of arsphenamine polyarsenide by reduction of 3-nitro-4-hydroxyphenylarsonic acid and sodium arsenite with sodium

¹ This is the 13th of a series of studies on the properties contributing to the toxicity of arsphenamine being made under a grant from the United States Interdepartmental Social Hygiene Board to the Harvard Medical School; the work is under the general direction of Doctor Reid Hunt.

hydrosulfite shows clearly that the relations found between the mode of synthesis and the toxicity of arsphenamine as summarized above hold true in this case also. Tabulation of the results brings out the differences very distinctly.

Table I
The Relation between the Mode of Synthesis and the Toxicity of Arsphenamine
Polyarsenide

Substances reduced	Reducing agent	Expt.	Tol. dose Mg./kg.	As content %	S conte nt %

acid and sodium arsenite	$Na_2S_2O_4$ (a)	2	∫ 120	44.76	
			120	43.76	1.78.
	(b)	1	80	41.87	2.38
	(c)	1	<80	45.55	

- (a) The nitro group was reduced under the most favorable conditions.
- (b) The nitro group was reduced under the least favorable conditions.
- (c) An excess of acetic acid was present during the reduction.

The arsenic determinations show that the composition of arsphenamine polyarsenide is very variable, and the substance may be best represented

by the formula
$$\begin{pmatrix} -As = As - \\ NH_2 \cdot HC1 \end{pmatrix} As_n$$
. When $n = 2$ the $\begin{pmatrix} NH_2 \cdot HC1 \\ OH \end{pmatrix}$

calculated arsenic content is 50.9%. One of the factors controlling n is the ratio between the quantities of arsonic acid and the sodium arsenite used.

Experimental Part

A. To a vigorously stirred, cold (8°) solution of 10.6 g. of magnesium chloride hexahydrate in 260 cc. of water, 50 g. of sodium hydrosulfite is added, and after about 30 seconds a cold (8°) solution of 2 g. of 3-nitro-4-hydroxyphenylarsonic acid in 46 cc. of water containing 0.66 g. of sodium hydroxide is added gradually during 1 to 1.5 minutes. Two g. of decolorizing carbon is added, and the material, after being heated rapidly to 30°, is filtered. A solution of 0.9 g. of arsenious oxide in 45 cc. of water containing 0.37 g. of sodium hydroxide is added to the clear filtrate, and the solution is heated rapidly with stirring to 55° and maintained at 55–60° for 90 minutes. The arseno compound separates as a finely divided, brownish-yellow solid. The base is removed by filtration and, after it is washed and dried in a vacuum over sodium hydroxide, is converted into the dihydrochloride by dissolving it in 10.5 cc. of absolute methyl alcohol containing a slight excess over 2 moles of dry hydrogen chloride. Filtration will not remove some of the very finely divided insoluble matter, but centrifuging for 5 or 10 minutes produces a clear, bright red alcoholic solution which is poured into 110 cc. of ether previously cooled to 0–5°. After this is filtered, washed with ether and dried in a vacuum over sodium

hydroxide, 1.4 g. of a reddish-orange arsphenamine polyarsenide is obtained which dissolves very readily in water forming a clear, deep red solution. The product is tolerated in doses of 120 mg./kg. and contains 44.2% of arsenic (the average of 2 experiments) and 1.78% of sulfur.

An aqueous solution of the polyarsenide is slightly acid to litmus, gives an orange-colored precipitate of the sulfate when treated with sodium sulfate, and an orange-colored precipitate of the free base when sodium acetate or carbonate is added; these precipitates redissolve in sodium hydroxide forming clear, red solutions. When the aqueous solution is added to coned. hydrochloric acid or to acetone, the dihydrochloride is reprecipitated. When iodine is added to the red aqueous solution, the material is oxidized and the red color is destroyed. In alkaline solution, the compound is oxidized by hydrogen peroxide and the red color disappears.

- B. All of the reagents are used in the same quantities as in A. The dilute, warm (30°) aqueous magnesium chloride solution is stirred very slowly, and immediately after the hydrosulfite has been added, the warm (30°) nitro solution is added very rapidly (5 seconds). The solution is stirred rapidly for about 1 minute to dissolve the remainder of the hydrosulfite completely and then is filtered. The arsenite solution is added, and after the mixture is heated slowly to 55° and stirred vigorously the experiment is continued as in A; yield, 1.4 g. of reddish-orange polyarsenide which dissolves very readily in water to give a clear, red solution. The product is tolerated in doses of only 80 mg./kg. and contains 41.87% of arsenic and 2.38% of sulfur.
- C. This experiment is conducted as described in A, but after the arsenite solution has been added 4 cc. of glacial acetic acid is added; yield, 1.5 g. of reddish-orange polyarsenide which is very readily soluble in water, forming a clear, red solution and which contains 45.55% of arsenic. It is not tolerated in doses of 80 mg./kg.

The toxicity determinations were made by injecting 2% alkalinized solutions intravenously into albino rats. The solutions were prepared by adding 4 molecular equivalents of N sodium hydroxide solution to an aqueous solution of the dihydrochloride.

Sulfarsphenamine

Recently the production of sulfarsphenamine, a compound similar to neo-arsphenamine, has been described and, owing to its low toxicity, therapeutic efficiency, stability in aqueous solution and the fact that it can be injected subcutaneously, it may become quite important in the treatment of syphilis. Voegtlin and Johnson prepared this substance by condensing arsphenamine with 2 molecular equivalents of formaldehyde and adding 4 equivalents of sodium bisulfite to the condensation product; the following formula has been assigned to it.

molecular equivalents of the aldehyde and bisulfite, respectively, were used. When an attempt was made to prepare this substance by following Voegtlin and Johnson's directions, using 2 moles of formaldehyde and 4 moles of bisulfite per mole of arsphenamine, the precipitate formed by the addition of bisulfite redissolved only partially; consequently, the yield

Voegtlin and Johnson, This Journal, 44, 2573 (1922).

was very low. This was found to be due to incomplete condensation between the arsphenamine and the formaldehyde. However, when 3 moles, that is 50% excess of the aldehyde are used, the initial precipitate redissolves completely when only 2 moles of bisulfite have been added. The reaction product which is isolated when 3 moles of aldehyde and 2 moles of bisulfite are employed is not tolerated in doses above 250 mg./kg. and contains less than 1 sulfur atom per atom of arsenic; in this case complete reaction has not been obtained between the bisulfite and the formaldehyde condensation product. By adding another mole of bisulfite after the initial precipitate has redissolved complete reaction is obtained, and the product is tolerated in doses of 350-400 mg./kg. It seems that 3 moles of formaldehyde and 3 moles of bisulfite are much more favorable than 2 and 4 moles, respectively, and the use of bisulfite in excess of the necessary amount, namely, 3 moles, increases the opportunity for contamination of the product with bisulfite and does not improve the product in any noticeable way.

Voegtlin and Johnson lay great stress upon the quality of the bisulfite and state that it must be pure and freshly prepared from sodium carbonate and sulfur dioxide. This is entirely unnecessary and the sulfarsphenamine made from the purified sodium bisulfite which is on the market is the equal in every respect of that secured by the use of freshly prepared, pure bisulfite.

Moreover, it is unnecessary to prepare arsphenamine, that is, the dihydrochloride, to start with. When the dried base obtained by the reduction of 3-nitro-4-hydroxyphenylarsonic acid with sodium hydrosulfite is dissolved in water by the addition of a small amount of hydrochloric acid, this solution serves just as well as one prepared from the dihydrochloride itself.

These two changes, namely, the use of commercial bisulfite and of arsphenamine base instead of the purified dihydrochloride, simplify the production of sulfarsphenamine and lower the cost of its preparation considerably.

Also, sulfarsphenamine that will be tolerated in doses of 350–400 mg./kg. can be prepared from toxic arsphenamine, that is, arsphenamine that is not tolerated at 70 mg./kg., and which was prepared by improper reduction³ of the nitrohydroxy acid.

In Table II, the results of a series of experiments are recorded on which the above conclusions are based. Three molecular equivalents of formaldehyde were used in each experiment.

When the comparatively toxic arsphenamine that has been secured by improper reduction of the nitro acid with hydrosulfite is converted into sulfarsphenamine, the initial precipitate formed by the addition of the bisulfite after the condensation with formaldehyde redissolves in less than 40 seconds, which is very much more rapidly than when relatively non-toxic arsphenamine is used. Since the arsphenamine in this case contains about 2% of sulfur, most of which is present as a sulfonic acid derivative of arsphenamine, it is to be expected that the resulting sulf-

Table II
THE PREPARATION OF SULFARSPHENAMINE

^a Freshly prepared, pure bisulfite.

arsphenamine would have a larger ratio of sulfur to arsenic than when the original material contains little sulfur.

Since sulfarsphenamine should contain 25.1% of arsenic, the material obtained by these reactions is only about 87% pure. To determine the effect, if any, that the impurities have on the toxicity, some of the crude sulfarsphenamine which was tolerated at 350 mg./kg. was converted into the free acid by treatment with acetic acid. The dry, purified acid was reconverted into the sodium salt by solution in the calculated quantity of sodium carbonate and precipitation with alcohol. The sodium salt then contained 25.9% of arsenic and was tolerated in doses of 300-350 mg./kg. Therefore, the impurities in crude sulfarsphenamine are comparatively inert and have little bearing on the toxicity of the substance.

Experimental Part⁸

A. Two and one-half g. of arsphenamine is moistened with 4 cc. of alcohol, dissolved in 32 cc. of water with the aid of mechanical stirring, and 1.25 cc. of formalin (about 37% formaldehyde) is added. After 1 minute, 3.3 cc. of a solution of commercial sodium bisulfite (3.7 g. of bisulfite in 10 cc. of solution) is added; the precipitate that forms gradually redissolves, and after 10 minutes 1.6 cc. more of the bisulfite solution is added. The stirring is continued for 20 minutes, and then, after filtration, the clear, orange-yellow solution is poured into 5 volumes of alcohol. The sulfarsphenamine is separated,

^b Commercial, pure bisulfite.

^c The arsphenamine was prepared by improper reduction of the nitro acid with hydrosulfite.

^d This base is the same as that from which e was prepared.

^e Compare d, above.

⁸ The experimental procedure is, in general, that reported by Voegtlin and Johnson⁷ but owing to the changes in quantities and time, which seem advisable as a result of experiments in this Laboratory, the entire process is outlined again for the sake of clarity.

washed with 95% alcohol and absolute alcohol, and dried in a vacuum over sodium hydroxide; yield, 3 g. of sulfarsphenamine that is very readily soluble in water, forming a clear, orange-yellow solution; it contains arsenic and sulfur in the ratio of 1:1.19. The product is tolerated in doses of 400 mg./kg.

B. A suspension of 2.1 g. of arsphenamine base in 32 cc. of water is stirred mechanically and treated with 0.9 cc. of concd. hydrochloric acid (approximately 2 moles). As soon as the base has dissolved completely, the experiment is continued as in A. In this case the solution commences to become viscous about 30 seconds after the aldehyde has been added, whereas in A this never occurs in less than 1 minute. The bisulfite is added as soon as marked signs of viscousness appear. Three g. of cream-colored sulfarsphenamine is obtained, which dissolves readily in water forming a clear, deep yellow solution and which contains arsenic and sulfur in the ratio of 1:1.21. The product is tolerated in doses of 400 mg./kg.

The toxicity of these preparations was determined by intravenous injection of 6% solutions into albino rats.

During large scale work in the Arsphenamine Laboratory of the Massachusetts State Health Department, the same trouble was encountered as in this Laboratory in obtaining satisfactory results with the quantities recommended by Voegtlin and Johnson. Since the adoption of the changes in quantities herein recommended, these difficulties have been avoided. Also, comparatively large quantities of sulfarsphenamine have been prepared from toxic and non-toxic arsphenamine using commercial bisulfite and the product was tolerated in doses of 400 mg./kg.

A Polyarsenide of Sulfarsphenamine

When arsphenamine polyarsenide is subjected to the procedure used in preparing sulfarsphenamine, a very soluble sodium salt is obtained which may be called sulfarsphenamine polyarsenide. When the bisulfite is added, after the arsphenamine polyarsenide has been condensed with formaldehyde, an orange-colored precipitate forms that redissolves very quickly. The dried sodium salt is an orange-colored powder that dissolves in water forming a deep red solution. Although the toxicity of arsphenamine polyarsenide differs very little from that of arsphenamine, the polyarsenide of sulfarsphenamine is not tolerated in doses even as low as 200 mg./kg., whereas sulfarsphenamine itself is tolerated at 400 mg./kg.

Summary

Arsphenamine polyarsenide may be obtained by reduction of 3-nitro-4-hydroxyphenylarsonic acid and sodium arsenite with sodium hydrosulfite, and the toxicity of the product depends on the mode of reduction just as does that of arsphenamine. In spite of its high arsenic content as compared with arsphenamine, its toxicity differs but little from that of the latter substance.

By modifying the quantities of reagents certain difficulties encountered while preparing sulfarsphenamine by the original method have been overcome. It is unnecessary to use freshly prepared, pure sodium bisulfite in this reaction; commercial bisulfite suffices. Also, it is unnecessary to start with arsphenamine, that is, the dihydrochloride; equally good results can be secured by starting with dry arsphenamine base.

As the impurities present in the crude sulfarsphenamine have little bearing on the toxicity, it is unnecessary to purify the material.

Arsphenamine polyarsenide can be converted into a polyarsenide of sulfarsphenamine, but this substance is comparatively toxic.

THE ARSONATION OF PHENOL¹

By Walter G. Christiansen and Arthur J. Norton Received July 9, 1923

In synthesizing arsphenamine from aniline or phenol by any of the common methods,² all of the reactions except that in which the arsenical group is introduced into the benzene nucleus progress smoothly, and excellent yields (75% or over) are easily obtained. Owing to the low yields obtained when aniline or phenol is arsonated with arsenic acid, the cost of production of the final product is greatly influenced by this reaction. Cheetham and Schmidt,³ by modifying the conditions for arsonating aniline, secured recrystallized arsanilic acid in 26% yields, whereas the yields obtained by previous methods averaged approximately 15%. The arsonation of phenol with arsenic acid has been discussed in two papers; one by Conant⁴ and the other by Jacobs and Heidelberger,⁵ and in both cases the yield of hydrated sodium p-hydroxyphenylarsonate is given as approximately 20%. Conant suggests that by proper adjustment of the experimental conditions, it should be possible to raise the yield to about 30%.

For the production of sodium p-hydroxyphenylarsonate in this Laboratory, the method of Jacobs and Heidelberger was adopted but the yield averaged only 18% instead of 20. The main reaction is expressed by the equation

¹ This investigation was undertaken in connection with a study of arsphenamine which was made under a grant from the United States Interdepartmental Social Hygiene Board to the Harvard Medical School; the work was under the general direction of Dr. Reid Hunt.

² For a brief outline of these methods see Lythgoe, Chem. Age, 28, 390 (1920).

³ Cheetham and Schmidt, This Journal, 42, 828 (1920).

⁴ Conant, ibid., 41, 431 (1919).

⁵ Jacobs and Heidelberger, ibid., 41, 1440 (1919).

By systematic modification of the reaction conditions the yield has gradually been raised until it is now possible to secure the product in 33% yields; although this is not a high yield, it is a very distinct improvement over an 18--20% yield.

Jacobs and Heidelberger mix sirupy arsenic acid (from which the excess of water has been removed by boiling to 150°) with phenol in a flask and heat the mixture under a reflux air condenser in an oil bath maintained at 155-160° for 7 hours. At first the substances remain as 2 distinct layers and the temperature inside the flask is approximately 145°, but as the reaction progresses the contents of the flask become homogeneous and the temperature falls steadily to about 130° due to the retention of the water eliminated by the reaction. Inasmuch as the reaction takes place, for some time at least, between 2 distinct phases, it seems advisable to stir the reacting materials as efficiently as possible. Also, the temperature of the reaction mixture should not be permitted to decrease to any great extent as it is accompanied by a marked decrease in the speed of reaction. This can be avoided by letting the water which is formed distil during the first part of the reaction. Since p-hydroxyphenylarsonic acid is hydrolyzed in water to a marked degree even at 130°6 there is a tendency for the reverse of Reaction 1 to take place and it should probably be written as a reversible reaction. Owing, however, to the excess of arsenic acid and comparatively small amount of water the equilibrium would be far to the right. If the water is allowed to escape, the tendency toward reversal of the reaction will be diminished and the yield should be increased. Thus, to show clearly the extent to which water affects the reaction, when 200 g. of boiled arsenic acid, 100 g. of phenol and 20 cc. of water are heated and stirred under sufficient pressure to maintain the mixture at 140-150°, no reaction takes place.

All the detailed experiments that were made while the individual experimental conditions were being examined will be omitted in this report and only the method finally adopted will be carefully described.

Experimental Part

Three hundred and sixty g. of sirupy arsenic acid (75–80%) is boiled in a beaker until the temperature of the acid is 150°; about 60 g. of water is driven off leaving a sirup containing approximately 95% of orthoarsenic acid which is then added to 150 g. of phenol in a 500cc. round-bottom short-neck flask. By means of a 3-hole stopper, an efficient, jacketed stirrer and a thermometer are introduced into the flask and a connection is established with a downward condenser. The flask is set in an oil-bath which is heated at once to 155–160°, and the stirrer is run at a rate high enough to insure thorough mixing of the contents of the flask. When the inside temperature reaches 140° boiling commences, and water plus a very little phenol begins to distil. The distillation is allowed to continue until 30 cc. (1 molecular equivalent) of water has been collected; this usually requires 1 to 1.5 hours, and the inside temperature rises to 146°. The downward

⁶ Schmitz, Ber., 47, 370 (1914).

condenser is then replaced by a return air condenser, and the reaction is allowed to continue until a total of 7 hours has elapsed from the time the contents of the flask first reached 140°. After the return condenser has been attached, the inside temperature declines slowly to 141° or 142°, and the reaction mixture becomes thicker and somewhat tarry. After the contents of the flask have been partially cooled, they are poured into 2 liters of water and mechanically stirred; the agitation is continued for a short time in order to break up the tarry material and enable the water to dissolve the hydroxyphenyl arsonic acids completely.

The reaction mixture is worked up by the method employed by Jacobs and Heidelberger, with a few modifications. Finely ground, fresh barium hydroxide is added gradually to the well-stirred water solution until the material is slightly alkaline to litmus, in order to remove the excess of arsenic acid; when this point is reached the solution becomes pink. If the procedure is carried out properly, 350-400 g. of Ba(OH)₂.8H₂O should suffice. The time required by this method is greater than when a hot solution of barium hydroxide is used, but the method is more convenient and does not cause such a great increase in volume. After removal of the barium arsenate, by filtration, the mother liquor and washings are treated with sulfuric acid until the solution contains neither barium nor sulfate ions. When the barium sulfate has been separated and thoroughly washed, the filtrate is concentrated on a steam-bath to about 1.5 liters, neutralized to litmus with sodium hydroxide, filtered, evaporated until the solution becomes well coated with crystals and then treated with 2.5 volumes of alcohol. After the mixture has cooled in an ice box the sodium p-hydroxyphenylarsonate is separated, washed with alcohol and dried in an oven at 80°. A second crop may be secured from the filtrate by concentrating it further and precipitating with alcohol. The total yield of anhydrous sodium p-hydroxyphenylarsonate is 126 g. (33%). By proper manipulation it is possible to obtain as much as 122 g. in the first crop and to have it free from sulfate, arsenate and sodium o-hydroxyphenylarsonate, which is one of the by-products formed in this reaction.⁵

When the downward condenser is not replaced by a return condenser, the total volume of water that distils is 55-60 cc., whereas the arsonation of phenol should liberate only 1 molecular equivalent (30 cc.) of water. Moreover, when all of the water is removed from the reaction chamber in this way, the mass becomes very tarry; the tar formation was so extensive in one experiment that the reaction had to be discontinued after 5.5 hours. The oxidation of organic matter to tarry material by the arsenic acid is the source of the excess of water that distils. To determine whether the reaction product is destructively oxidized, 20 g. of anhydrous sodium p-hydroxyphenylarsonate and 57 g. of boiled arsenic acid were heated and stirred so that the inside temperature was 145-150° for 3.5 hours. During this time, no water distilled, there was not the slightest trace of tar formation, and 15 g. of pure, anhydrous sodium p-hydroxyphenylarsonate was recovered from the material by working as described above. As there are slight, unavoidable mechanical losses incident to the use of the long process required to isolate the product, and as the original material was not exceptionally pure, the recovery of 15 g. is very good. This experiment proves conclusively that the reaction product is not destroyed when subjected to the action of hot arsenic acid and that the tar must be formed either from phenol that has not been acted on or from an intermediate substance formed in the reaction.

⁷ Carefully washed barium arsenate proved just as efficient as lead arsenate as an insecticide when sprayed on potato plants and, when suspended in water, could be used in a spraying machine without difficulty.

⁸ The filtration of large quantities of barium sulfate is usually tedious, but if filtering carbon is added to the suspension to be filtered and if a mat of this carbon is prepared on the filter by filtering an aqueous suspension of carbon, the barium sulfate may be removed rapidly and completely even when it is precipitated from cold solutions.

possible that the first step in the reaction is the formation of a phenyl ester of arsenic acid analogous to the known phenyl esters of sulfuric and phosphoric acids^{9,10,11} and that this then rearranges to the p- and o-hydroxyphenylarsonic acids.

It has been frequently noted that the second crops of sodium p-hydroxy-phenylarsonate contain some material insoluble in water and that the amount of this material varies directly with the degree of tar formation during the reaction. Examination of the insoluble matter showed that it is chiefly arsenious oxide which must be formed when the arsenic acid acts as an oxidizing agent. A few catalysts, such as copper arsenate, iodine or a dehydrated clay, were introduced but in each case the yield decreased instead of increased. It was hoped that the finely divided, dehydrated clay would provide a surface on which the two liquids might react and would facilitate the removal of water.

As Jacobs and Heidelberger⁵ state that, after the removal of the barium sulfate, it is preferable to concentrate the solution in a vacuum, it seemed advisable to determine the extent to which the product is hydrolyzed in boiling water.

This was done by distilling 100 cc. of a 5% aqueous solution with steam so that 20 cc. of distillate collected every 5 minutes and analyzing the distillate for phenol by the bromine method, that is, by addition of an excess of bromine water of known strength, the determination of the excess of bromine by the addition of potassium iodide and titration of the liberated iodine with thiosulfate solution. When solutions of pure phydroxyphenylarsonic acid prepared either from the acid itself or by addition of hydrochloric acid to a solution of the purified sodium salt are examined in this way, the distillate is found to contain only 0.1 to 0.5 mg, of phenol in each 20 cc. After a slight excess of sodium carbonate has been added to the solution being distilled, the phenol content of the distillate is found to be approximately 1.0 mg. in 20 cc. The steam-distilled solution gives a very slight reaction for arsenic acid when tested with hydrogen sulfide. When 250 cc. of a 0.5% solution of phenol in water is distilled with steam, the distillate at first contains 156 mg, in each 20 cc, and it is only after prolonged distillation, namely, when the concentration of the phenol solution has become very low that the distillate contains only 1 mg. of phenol in 20 cc. Consequently, the hydrolysis of p-hydroxyphenylarsonic acid and its sodium salt is practically nil at 100°. This agrees with Schmitz'12 conclusion which was arrived at by another method. These results indicate clearly the absence of any necessity for concentrating the solutions in a vacuum.

The modifications of Jacobs and Heidelberger's method of arsonating phenol outlined in this paper have been applied to large-scale production in the Arsphenamine Laboratory of the Massachusetts State Department

- ⁹ Baumann, Ber., 11, 1907 (1878), isolated the phenyl ester of sulfuric acid as its potassium salt which, when heated, rearranged mainly to potassium p-phenolsulfonate. Similar results were obtained with other phenols.
- ¹⁰ Heymann and Koenigs, *ibid.*, **19**, 3304 (1886), obtained the potassium salt of phenylphosphoric acid.
- ¹¹ A phenyl ester of arsenious acid is known. Lang, Mackey, and Gortner, J. Chem. Soc., 93, 1364 (1908).

of Health, and the yields have increased very greatly over those that were obtained prior to the institution of these changes.

Summary

By vigorous agitation of the reacting substances and partial removal of the water produced during the arsonation of phenol by arsenic acid, it is possible to secure a 33% yield of anhydrous sodium p-hydroxyphenylarsonate instead of the 20% yield obtained by previous methods.

It is suggested that a phenyl ester of arsenic acid may be an intermediate in the formation of hydroxyphenylarsonic acids by this reaction.

By distillation of aqueous solutions of p-hydroxyphenylarsonic acid, with steam, it is shown that at 100° this substance hydrolyzes scarcely at all into phenol and arsenic acid. This confirms Schmitz' results obtained by another method.

N-METHYL-PARA-AMINO-ORTHO-CHLOROPHENOL SULFATE, A NEW PHOTOGRAPHIC DEVELOPER

By Walter G. Christiansen Received July 9, 1923

For a number of years N-methyl-p-aminophenol sulfate (Metol) has been the outstanding member of the aminophenol class of photographic developing agents, but analogous substances with additional groups attached to the benzene ring have not been investigated to determine the effect of these groups on the photographic developing properties of Metol. In this Laboratory the hydrochloride of p-amino-o-chlorophenol and the sulfate of its N-monomethyl derivative have been prepared. These compounds possess excellent developing properties when tested on both plates and paper but the methyl derivative is the superior; the finished plates and prints obtained by use of the latter substance are indistinguishable from those secured when Metol is used, but this material shows no marked advantages over Metol. Consequently, it may be concluded that the presence of a nuclear chlorine atom has little influence on the ability of Metol to function as a photographic developer. The amine is methylated by a well-known method, namely, condensation with formaldehyde and reduction of the condensation product.

Experimental Part

p-Nitro-o-chlorophenol. —A mixture of 10 g. of c. p. p-nitrophenol with 200 cc. of concd. hydrochloric acid is heated in a tall, narrow beaker until solution is complete.

¹ The method herein described is a modification of that used by Kollrepp, Ann., 234, 3 (1886).

The solution is cooled to room temperature while it is stirred mechanically, and the nitrophenol partly separates again in very fine crystals. A special type of stirrer is used, because during the last part of the reaction, that is, after chlorination, the mass in the beaker is a thick paste. The stirrer is constructed from an ordinary T stirrer with long arms by bending the ends of the arms into vertical positions so that they are close to the walls of the beaker. Through a long-stem dropping funnel, the end of which is in the acid and just above the horizontal section of the stirrer, a solution of 3 g. of potassium chlorate in 60 cc. of water is run in slowly while the mixture is vigorously stirred with this device. The nitrophenol dissolves and then the chloro compound starts to separate. As the reaction proceeds, the paste becomes very thick, but the vigorous stirring prevents the end of the dropping funnel from becoming plugged and permits the chlorate solution to run into the mixture. The agitation is continued for 1/2 hour and the mixture is allowed to stand overnight. After filtration, washing with water and air drying, 11 g. of nearly white p-nitro-o-chlorophenol melting at 106-8° is obtained: the pure compound melts at 110°.1

The product can be purified by suspending it in hot water and adding glacial acetic acid gradually until the material dissolves completely. As the solution cools, pure p-nitro-o-chlorophenol separates.

p-Amino-o-chlorophenol.—Sodium hydrosulfite (about 40 g.) is added gradually to a boiling solution of 10 g. of p-nitro-o-chlorophenol in 60 cc. of water containing 0.27 g. of sodium hydroxide, until the red color disappears. As the solution cools p-amino-o-chlorophenol precipitates. After this is separated, washed with water and air-dried, 5 g. of compound, m. p., 2 150–151°, is obtained as a white powder. By recrystallization from water, the substance can be secured in white needles.

Three g. of the amine is suspended in 25 cc. of water and treated with hydrochloric acid until it dissolves, and decolorizing carbon is added. The colorless solution obtained by filtering out the carbon is added to 35 cc. of coned. hydrochloric acid. After the liquid has been thoroughly cooled, the precipitated hydrochloride of p-amino-o-chlorophenol is separated, washed with hydrochloric acid and dried in a vacuum over sodium hydroxide. The white solid dissolves very readily in water to give a colorless solution that is acid to litmus but not to congo red. Ferric chloride oxidizes the material with the development of a deep blue color. When a solution of p-dimethylamino-benzaldehyde in dil. hydrochloric acid is added to an aqueous solution of the above hydrochloride, the solution becomes orange colored and an orange precipitate separates. In sodium hydroxide solution this amino chlorophenol oxidizes and becomes dark brown.

N-methyl-p-amino-o-chlorophenol.—A solution of 8.5 g. of p-nitro-o-chlorophenol in 200 cc. of water and 62.5 cc. of aqueous sodium hydroxide (d., 1.324) in a 500cc. round-bottom flask is heated to boiling. While it is being stirred mechanically, 20 g. of zinc dust is added during 10-15 minutes; this is sufficient to reduce the nitro group and produce a colorless solution. An additional 10 g. of zinc dust is added at once. A 3-hole stopper is inserted into the neck of the flask. Through 1 hole is a glass tube that dips below the liquid in the flask and serves as a sleeve for the stirrer, the second hole permits a reflux condenser to be attached and through the third hole a long-stem dropping funnel is introduced so that the end of the stem is below the surface of the liquid. The liquid is refluxed for 15 minutes and stirred vigorously, and then 5 cc. of formalin (37% formaldehyde) is added during 15 minutes. The refluxing is continued for 15 minutes longer and the solution is filtered through a hot funnel into a flask containing 10 g. of sodium bisulfite.³ Coned. hydrochloric acid (about 70 cc.) is added until the precipitate that

² Kollrepp obtained this compound by another method of reduction and found the melting point of the pure substance to be 153°. Ref. 1, p. 6.

³ The bisulfite prevents the hot alkaline solution from oxidizing and becoming black.

forms is redissolved, and then sodium carbonate is added until the solution no longer effervesces; this requires about 13 g. of sodium carbonate monohydrate. After the mixture has cooled it is extracted with three 50cc. portions of amyl acetate, and the extracts are filtered. By adding sulfuric acid dropwise to the amyl acetate, the amino compounds are precipitated as sulfates which are filtered out and extracted very thoroughly several times with alcohol to remove impurities. After it has dried, 7 g. of crude N-methyl-p-amino-o-chlorophenol sulfate is obtained.

By recrystallization from water, using decolorizing carbon, this substance separates as fine white needles that dissolve in water forming a colorless solution that is acid to litmus. The aqueous solution when treated (a) with ferric chloride becomes red and then very deep purple, (b) with sodium nitrite gives a white precipitate, (c) with sodium carbonate becomes brown.

Analyses. Calc. for $(C_7H_8ONCl)_2H_2SO_4.H_2O$: Cl, 16.45; S, 7.45. Found: Cl, 16.55, 16.25; S, 7.49, 7.45.

I wish to acknowledge the assistance of Mr. Arthur J. Norton in some of the experimental work.

Summary

The preparation of p-amino-o-chlorophenol hydrochloride and N-methyl-p-amino-o-chlorophenol sulfate is described. Both of these substances are good photographic developing agents but the methylated compound is the better. The latter compound appears to be equal to but no better than Metol, from which it differs only in having a chlorine atom attached to the benzene ring.

REDUCTION POTENTIALS OF QUINONES. I. THE EFFECT OF THE SOLVENT ON THE POTENTIALS OF CERTAIN BENZOQUINONES

By James B. Conant and Louis F. Fieser Received July 11, 1923

The measurement of reduction potentials affords a new method of studying quantitatively the free energy of an addition reaction which can be brought about with a series of related substances. By such quantitative studies the differences caused by substitution and by structural changes can be discovered and when sufficient data have been obtained it should be possible to make many interesting and important generalizations in regard to the driving force of a given organic reaction and the structure of the organic compound concerned.

The normal reduction potential of a quinone is a measure of the free energy of the reduction of that quinone in the solvent employed. It has been found that the normal potential for certain benzoquinones in aqueous solution is affected by the presence of salt¹ and that the potentials of a

¹ S. P. L. Sörensen, M. Sörensen and Linderström-Lang, Ann. chim., 16, 283 (1921).

number of quinones in mixtures of alcohol and aqueous acid are somewhat different from the values obtained in aqueous solution.² This effect of the change of solvent on the potential is related to the ratio of the solubility of the quinone and hydroquinone as Sörensen has carefully proved. In the light of these results it is necessary to consider the following questions: to what extent are the reduction potentials of a series of organic compounds influenced by these solubility ratios and, further, in comparing the effects of substitution in quinones what solvent or solvents should be employed in measuring the potentials? To answer these questions we have determined the potentials of a series of benzoquinone derivatives (1) in alcoholic solution, (2) in aqueous solution and (3) under conditions in which the nature of the solvent does not influence the potential.

When we consider a cell composed of a hydrogen electrode immersed in a certain solvent connected with a half-cell containing an inert electrode immersed in the same solvent saturated with both the hydroquinone and quinone in question and containing both solid substances, it is obvious that on the passage of 2 faradays of electricity the following transformations would be realized: quinone (solid) $+ H_2 \longrightarrow$ hydroquinone (solid). The potential of this combination thus enables us to calculate directly the free energy of reduction referred to the 2 solid states. This free energy change and the corresponding reduction potential are independent of the solvent employed. In the case of tetrachloro-benzoquinone such a cell can actually be constructed and the potential determined. If the quinone, however, forms a quinhydrone with the corresponding hydroquinone, a saturated solution of the two substances cannot usually be formed without the separation of solid quinhydrone. In this case it is experimentally necessary to measure two separate combinations: one, a half-cell containing a solution saturated with the quinone and quinhydrone, and another containing a saturated solution of the hydroquinone and quinhydrone. One-half the sum of these two potentials $(\pi_q$ and $\pi_h)$ is the reduction potential referred to the change from solid quinone to solid hydroquinone (π_s) .

2 Quinone (solid) +
$$H_2 \longrightarrow$$
 Quinhydrone (solid) + 2 $F_{\pi q}$ (1)

Quinhydrone (solid) +
$$H_2 \longrightarrow 2$$
 Hydroquinone (solid) + $2 F\pi_h$ (2)

Adding (1) and (2),

Quinone (solid) + H₂
$$\longrightarrow$$
 Hydroquinone (solid) + $\frac{2F(\pi_q + \pi_h)}{2} = 2 F\pi_s$
or $\pi_s = \frac{\pi_q + \pi_h}{2}$ (3)

In two cases in which the quinhydrone formed only slowly in aqueous solution it was possible to measure π_s directly and also to calculate it from the quinhydrone cells; the agreement was very satisfactory.

² Conant and Fieser, This Journal, 44, 2480 (1922).

A subtraction of (2) from (1), on the other hand, gives,
2 Quinone (solid) + 2 Hydroquinone (solid)
$$\longrightarrow$$

2 Quinhydrone (solid) + 2F ($\pi_q - \pi_h$) (4)

Thus, the difference between the potentials of the two combinations is a measure of the free energy of the formation of the solid quinhydrone from its solid components.

Such measurements are novel, in the case of benzoquinone itself, only in their application to the determination of the free energy of the reduction referred to the solid state. Granger and Nelson³ saturated acid with hydroquinone and quinone in order to establish a definite ratio of quinone to hydroquinone in their verification of the logarithmic shape of the reduction curve. Sörensen¹ showed that solutions of sodium chloride saturated with quinhydrone and quinone, or quinhydrone and hydroquinone, gave constant potentials independent of the amount of salt present; these potentials were in close agreement with the values calculated from the solubility data which he experimentally determined. Biilmann and Lund4 gave further evidence of this constancy and proposed the terms "quino-quinhydrone" and "hydro-quinhydrone" to describe the two electrodes that were free from the "salt error." They calculated the free energy of formation of quinhydrone at 18° but did not calculate the free energy of formation of solid hydroquinone from solid quinone.

Experimental Procedure

The normal potential in solution (π_0) was measured for all the quinones in alcoholic solution, and in aqueous solution when the solubility was sufficient, by electrometric titration with titanous chloride. This method has been thoroughly investigated⁵ and has been recently applied to the determination of reduction potentials in mixtures of alcohol and aqueous acid.² The normal potential was found by interpolation of the titration curve to 50% reduction. As an indication of the slopes of these curves the difference between this potential and that at 20% and 80% reduction is given, in millivolts, under the headings $\Delta \pi_1$ and $\Delta \pi_2$. The theoretical value is 18 mv. All of these measurements were made at 25°.

We have previously shown that the normal potential is the same whether 50% or 95% alcohol is the solvent. Consequently, the one or the other concentration was used, according to the solubility of the quinone in question, the lower one being employed when possible in order to obtain better conductivity. Since π_0 often varies with the concentration of hydrochloric

² Granger and Nelson, This Journal, 43, 1401 (1921).

⁴ Biilmann and Lund, Ann. chim., 16, 321 (1921).

⁵ (a) Mansfield Clark, J. Washington Acad. Sci., 10, 255 (1920). (b) Conant, Kahn, Fieser and Kurtz, This Journal, 44, 1382 (1922). (c) LaMer and Baker, ibid., 44, 1954 (1922).

acid, it was desirable to investigate this variation at least to the extent of using 2 different acid concentrations for the measurements. In aqueous solution the acid was 0.1~N and 1.0~N, but the presence of a large amount of alcohol so decreases the conductivity that the more dilute solution was replaced by 0.5~N hydrochloric acid. This variation in π_0 with relatively small changes in acid concentration gives an indication of the susceptibility to such changes of the quinone-hydroquinone solubility ratio.

A weighing bottle of 25cc. capacity, fitted with a bright and a platinized platinum electrode, formed a convenient half-cell for carrying out the measurements which involved the use of saturated solutions. It was connected by a siphon plugged with filter paper to a Hildebrand hydrogen electrode vessel containing the same solvent as that used for making the saturated solution. The solids to be investigated were mixed with the solvent in this bottle which was then rotated in a thermostat at 25°. Potential measurements were made after the mixture had been shaken for different lengths of time; the constancy of repeated measurements was an indication that the solution was saturated with respect to both components.

Another method of insuring saturation was first to prepare a solution at $40-50^{\circ}$ and after cooling it to the temperature of the bath, measure the potential. The latter was the more convenient method and always gave consistent results. All solutions measured at 0° were first saturated at 25° .

The choice of the solvent to be used in these cells containing solid substances depended on many factors. Aqueous solutions were employed when possible owing to the greater conductivity thus obtained. Even $0.1\ N$ hydrochloric acid adds to quinone slowly, and the reaction might occur with a velocity sufficient to vitiate the results if stronger acid were employed.

In solutions less concentrated than $0.1\ N$ the hydrogen-ion concentration is perceptibly changed when the acid is saturated with hydroquinone. Therefore, $0.1\ N$ hydrochloric acid was used when possible. In the case of compounds that were too insoluble in water, aqueous alcoholic solutions were employed. It was found necessary to do this only with the tetra-substituted quinones; these substances do not add hydrogen chloride and, consequently, stronger hydrochloric acid could be used to insure better conductivity with no injurious effects.

In most cases, the potential was constant a few minutes after the cell was connected; a bright platinum, a gold plated and a platinized electrode gave identical readings. Several measurements were made with each cell after the potential had become constant. Each potential reported in the experimental portion of this paper represents the average value for each cell independently prepared. The reduction potential referred to the solid state (π_s) was calculated from the average of all the cells measured in the manner explained above.

The potential for each cell is reported to 0.1 mv. when the constancy of the electrodes permitted such a degree of accuracy. The final averages

⁶ Granger, Dissertation, Columbia University, March, 1920.

are reported to the nearest millivolt, as for most of the compounds the results are not significant beyond this figure and the potentiometer employed could not be relied on to more than 0.5 mv. The value of the hydrogen electrode was not corrected for dry hydrogen under standard conditions, as this correction is beyond the limit of accuracy of the present work. The accuracy of the measurements varies greatly with the substances investigated as can be seen by examining the concordance of the different determinations. The exact details of the experiments depended to such a great extent on the nature of the quinone in question that the results for each compound will be given separately.

Experimental Results

Benzoquinone.—The quinone and hydroquinone employed melted at $112-113^{\circ}$ and 169° , respectively. Quinhydrone was prepared according to the method of Biilmann and Lund⁴ by the partial oxidation of hydroquinone. Quino- and hydro-quinhydrone half-cells were prepared by saturating the 0.1~N acid with both components simultaneously.

BENZOQUINONE 0.1 N HCl Saturated with quinhydrone and Ouinone Hydroquinone Quinone Hydroquinone -At 25°v. 0.74900.61290.76980.6270.6275.7483.6118 .7698.7490.6132.7700 .6126. 7488 .6126.7699.6272Av.

The potentials of the individual cells interpolated to 18° agree very well with the determinations of Sörensen and of Biilmann in the papers previously referred to. Thus the value of π_s at 18° is found to be 0.6867, while Sörensen's results give 0.6869, Biilmann's 0.6870. Granger and Nelson's measurements,³ calculated to a suitable basis, give an average value for the hydro-quinhydrone electrode at 25°, of 0.6123, as compared with our number of 0.6126.

 $\pi_s = 0.699$

Toluquinone.—The quinone was prepared by steam distillation of a mixture of o-toluidine, manganese dioxide and sulfuric acid (1:4); it was recrystallized from alcohol; m. p., 67–68°; yield 15%. Eastman's toluhydroquinone, (m. p., 124–125°) was employed. The quinhydrone was prepared either by shaking the components with water or by mixing their alcoholic solutions, adding a little water, and allowing the green crystals to form. When washed with water and dried it melted at 99–100° with decomposition. Siegmund reports the melting point as 96–97°,

 $\pi_s = 0.681$

⁷ Clark, Am. Chem. J., 14, 565 (1892).

⁸ Siegmund, J. prakt. Chem., [2] 92, 359 (1915).

while Nietzki⁹ gives 52°. There are many such discrepancies in the literature, so that it appears likely that these melting points or points of decomposition are not characteristic of purity of quinhydrones.

p-Xyloquinone.—Siegmund⁸ states that p-xyloquinhydrone was not formed on applying the general method used in the preparation of other alkyl quinhydrones. Consequently, an electrode saturated with both quinone and hydroquinone was employed, and no evidence of the formation of a quinhydrone was observed in the potential measurements.

The p-xyloquinone used was Kahlbaum material and melted at 123.5°. For the preparation of the hydroquinone it was moistened with alcohol and a solution of stannous chloride containing hydrochloric acid was added. After the mixture had been thoroughly stirred, it was warmed on the steam-bath to complete the reduction. This caused the separation of a hard, black substance which, however, soon changed to the white hydroquinone and dissolved. The solution was boiled with animal charcoal and filtered, when p-xylohydroquinone separated in long, white needles; yield, 65%. It was completely pure, melting at 111.5°. This method of reduction is very convenient and is of general applicability.

Half-cells were prepared both by saturating the acid with a mixture of the solids and by mixing their saturated solutions and reading the potential immediately. Both methods gave the same result. In some cases the bright platinum and platinized electrodes were as much as 1 or 2 mv. apart, probably because of the slight solubility of the compounds. In these cases average values are reported.

Duroquinone (Tetramethylbenzoquinone).—The authors are greatly indebted to Dr. Lee I. Smith, of the University of Minnesota, for the sample of duroquinone (m. p., 110–111°) used in this work. It was reduced with stannous chloride in the manner previously described, except that a large volume of water (2 to 3 liters per g.) was required to dissolve the hydroquinone. Durohydroquinone crystallized from water in pure white, lustrous plates melting at 226–227°. This compound, prepared by reducing the quinone with zinc and sodium hydroxide, sodium amalgam and alcohol, zinc and glacial acetic acid, and aniline, is reported as melting at 210°, 10° 220°11° and 210–224°, 12° and is said to be reoxidized by the air. No such oxidation was observed. The low reduction potential of the quinone (comparable with that of phenanthraquinone) would lead one to expect that the hydroquinone would be oxidized by the air but, since the reduction of the quinone is probably slow, the reverse process is probably also slow, presumably because of steric hindrance of the methyl groups.

The potential of this compound, which forms no quinhydrone, could not be measured in aqueous solution, apparently because of the very slight solubilities of the components. Consequently, measurements were carried out in aqueous alcohol containing 1.0 mole of hydrogen chloride per liter. The electrodes came rapidly to a definite equilibrium.

Duroquinone 50% Alcohol saturated with the quinone and the hydroquinone Volts at 25° 0.4800 0.4796 0.4801; π_s = 0.480 Volts at 0° 0.4990 0.4988 0.4996; π_s = 0.499

Duroquinone is too insoluble to permit titrations in aqueous solution. Titrations in alcohol were rendered somewhat tedious by the tardiness with which equilibrium was established. After each increment of reducing agent was added the potential fell 100 or 200 mv. (towards the titanous-titanic potential level) and then rose slowly to a constant value. It should be noted that the results of this slow titration are entirely consistent with the potential of a saturated solution of the quinone and hydroquinone; there can be no doubt that the titration is valid even with such refractory substances as duroquinone.

Thymoquinone.—Kahlbaum's thymoquinone, m. p., 45.5°, was reduced with stannous chloride in the usual way, giving long, white needles; m. p., 141.5°; yield, 88%. The usual procedure, using sulfur dioxide, 13 takes from 3 to 4 days and yields a dirty white product which, when purified, melts at 139.5°. Thymoquinhydrone was prepared by allowing a mixture of the ethereal solutions of equivalent weights of the components to evaporate very slowly. The lustrous, dark green crystals melted at 78° with decomposition.8

Electrode equilibrium was at times erratic in both cells, and both the bright and platinized types of electrodes often gave inconsistent, inconstant values. On the other hand, both types often became perfectly constant at the same point, so that there was no doubt when true equilibrium had been reached.

Monochloroquinone.—Monochlorohydroquinone was prepared¹⁴ in a 74% yield by passing dry hydrogen chloride into a chloroformic solution of benzoquinone. When recrystallized from chloroform it melted at 101–102°. Oxidation by Clark's method proved convenient for small quantities and gave a 56% yield. By oxidation with potassium dichromate and extraction with benzene as in the method that has been developed for quinone, ¹⁵ an 84% yield was obtained, but the method was not as rapid. The compound was recrystallized from alcohol and melted at 57°. The quinhydrone was best prepared by the partial oxidation of the hydroquinone with ferric ammonium sulfate in aqueous solution. The bronzegreen needles melted at 67° ¹⁶ with decomposition.

¹⁴ Levy and Schultz, Ann., 210, 138 (1881).

¹⁵ "Organic Syntheses," John Wiley and Sons, 1922, Vol. II, p. 85.

¹⁶ Ling and Baker [J. Chem. Soc., 63, 1314 (1893)] obtained a hydrate melting at $70-72^{\circ}$.

Difficulty was experienced in the measurement of the potentials of both this compound and 2,3-dichloroquinone because of the unusually great solubility of their hydroquinones. In $0.1\ N$ hydrochloric acid at 25° the solubility of hydroquinone is $0.0696\ g$. per cc.³ while that of monochlorohydroquinone is about $0.7\ g$. per cc. Even at 0° both the monochloro- and 2,3-dichlorohydroquinones are so soluble that they form deep red, sirupy solutions in which potential measurements would be very unreliable. This difficulty was to a large extent obviated by using $0.1\ N$ hydrochloric acid saturated with sodium chloride as the solvent, thus depressing the solubilities of the organic compounds to a very considerable extent. In this way results were obtained which, though perfectly reliable, are not of the highest degree of accuracy since the bright and platinized electrodes gave measurements sometimes as much as $2\ mv$. apart. Averages are reported in the following tables.

2,6-Dichloroquinone.—This compound, prepared ¹⁷ by oxidizing trichlorophenol with chromic acid (69% yield), was crystallized from alcohol and from glacial acetic acid. Both samples melted at 120.5° . It was reduced, with 80% yield, to the hydroquinone which was crystallized from benzene and melted at 161° .

All of the dichloroquinones form quinhydrones, but not as readily as does benzoquinone. The 2,5 and 2,6 derivatives, described by Ling and Baker, 16 are of such an ill-defined character that they are scarcely suited to potential measurements. The 2,5 derivative forms a violet hydrate which, on drying, changes into a pale yellow, anhydrous quinhydrone. The quinhydrone of the 2,6 isomer is variously described as brown powder, dark needles, and brown prisms with a reddish shimmer.

An anhydrous quinhydrone cannot be used in our half-cell if not in ¹⁷ Kehrmann, J. prakt. Chem., [2] 40, 481 (1889).

equilibrium with the solvent used. The best way to insure that such equilibrium is maintained is to prepare the quinhydrone in the solvent concerned, add an excess of the quinone or hydroquinone, and measure the potential when the solution is completely saturated. This method was used with 2,6-dichloroquinone, and the results are indicated below.

2,6-Dichloroquinone

Av.	.726	. 669	.743	.690
	$\pi_s = 0.6$	98	π_{i}	=0.717

These results are decidedly irregular but π_s , being an average value, is probably correct within a few millivolts, and it is certainly accurate enough for purposes of comparison. That the results obtained in saturated solution for all of the dichloroquinones are thus less accurate than those for the other compounds studied seems to be due wholly to the character of the quinhydrones which they form. It soon appeared that even the method employed above could not be used for the other isomers, since the quino- and hydro-quinhydrone electrodes gave quite varying potentials, indicating that the quinhydrone or its hydrate was not of constant composition. But since these quinhydrones do not form as readily as does the 2,6-derivative, it was found possible to mix saturated solutions of the quinone and hydroquinone and obtain reproducible readings before any quinhydrone separated. This method was proved valid in the measurements of trichloroguinone, when both this procedure and the one using the quinhydrone gave the same value for π_s . For further confirmation and for purposes of verifying the above results obtained with

2,6-dichloroquinone, measurements were made on half-cells prepared by mixing saturated solutions of the two components. The values found for π_s were, at 25°, 0.697, 0.699, 0.692 (compare 0.698), and at 0°, 0.715, 0.714 (0.717). Because of the rapidity of precipitation of quinhydrone, the first values reported are considered to be more nearly correct.

These results are in good agreement with determinations made by Baker¹⁸ which gave the value 0.7210 for 0.2~N hydrochloric acid. Her sample was prepared from 2,6-dichloro-p-aminophenol.

2,3-Dichloroquinone.—2,3-Dichloro-hydroquinone was obtained by Peratoner and Genco by the action of sulfuryl chloride on hydroquinone ^{19a} and by the reduction of quinone dichloride with sulfur dioxide. ^{19b} They also observed that this compound was a by-product in the preparation of 2,5-dichloro-hydroquinone from monochloroquinone and hydrochloric acid. Oliveri-Tortorici²⁰ obtained a 12% yield by the last-named method and pointed out that the other two processes are not only troublesome but give rise to a variety of by-products. Den Hollander²¹ recently repeated the experiments of the Italians but was unable to obtain any of the desired compound. On saturating a cooled ethereal solution of monochloroquinone with dry hydrogen chloride he obtained a mixture that he could not separate by fractional crystallization from benzene but which he identified by oxidation and separation of the quinones as a mixture of the 2,5 and the 2,6 isomers.

Under apparently identical conditions we obtained, after fractional crystallization from benzene, 2,3-dichloro-hydroquinone (melting at 137°) and monochlorohydroquinone. The products of the reaction are thus difficult to control.

A satisfactory method, however, has recently developed in the work of Eckert and Endler²² on the chlorination of hydroquinone in glacial acetic acid. Since their interest lay in finding a suitable method for the preparation of the 2,5-isomer, their directions were examined and modified as follows.

Forty g. of hydroquinone was suspended in 200 cc. of glacial acetic acid and treated with chlorine at $40-50^{\circ}$ until the solution had gained 33 g. of chlorine (30% excess). Only a small amount of crystals formed on cooling and the liquid was concentrated in a vacuum. The crystalline paste was dissolved in water and filtered hot to remove a small amount of insoluble tetrachloro-hydroquinone. The filtrate was boiled with animal charcoal and filtered hot. As the solution cooled, 28 g. of rose-colored

crystals separated which lost water at 100° and melted at 138–139°. When these were dried in benzene and crystallized, 19.5 g. of white crystals was obtained that melted at 143°; 9 g. was recovered from the various filtrates but was not purified; total yield, 43%; yield of pure product, 30%.

Oxidation to the quinone was accomplished by Clark's method with an 88% yield. The product crystallized from alcohol in long needles melting at 100-101° (the melting point given is 96-98°).

Measurements with this compound were made in 0.1 N hydrochloric acid saturated with sodium chloride as in the case of monochloroquinone, because of the extreme solubility of the hydroquinone. Cells containing the red quinhydrone (probably a hydrate), which is formed on shaking the components with the solvent, were variable and inconstant, but a mixture of the saturated solutions of the components was sufficiently stable to permit measurements to be made. The length of time during which the potential remains constant (before the quinhydrone starts to separate) is, of course, dependent on the many factors that initiate the crystallization of a supersaturated solution. Inoculation by minute crystals adhering to the apparatus used in a previous experiment invariably caused the potential to drop and the red quinhydrone hydrate to separate in 1 to 2 minutes. But even when all precautions in regard to cleaning the apparatus were taken, crystallization often began before a large number of readings could be made, especially at 0°, and especially when the halfcell had to be shaken to obtain true equilibrium at the platinum surfaces.

2,5-Dichloroquinone.—The crude hydroquinone (m. p., $156-159^{\circ}$) was obtained from hydroquinone and potassium chlorate in 68% yield by the directions of Ling.²³ Monochlorohydroquinone (m. p., $100-105^{\circ}$) was

²³ Ling, J. Chem. Soc., 61, 558 (1892).

obtained from the filtrate as a by-product. The dichloro-hydroquinone was recrystallized from benzene and melted at 166°.

It was oxidized in the cold with dichromate and sulfuric acid, and the quinone, recrystallized from alcohol and washed with ether, melted at 158.5°. It is necessary to wash with ether and dry rapidly, for otherwise the surfaces of the crystals become darkened with the formation of the quinhydrone.

Potential measurements were carried out on mixtures of the saturated solutions of the quinone and hydroquinone. Quinhydrone formation was so slow that concordant results were also obtained by stirring the acid with the two solids at 25°.

Trichloroquinone.—Kahlbaum's trichloroquinone (m. p., 162–163°) was reduced with stannous chloride and the hydroquinone crystallized from glacial acetic acid. After removal of the acetic acid of crystallization in a vacuum desiccator the compound melted at 136°. By the spontaneous evaporation of a chloroformic solution of the components, trichloroquinhydrone was obtained in well-formed clusters of green-black crystals melting²⁴ at 114–115°.

Half-cells were prepared by stirring a suspension of the quinone and hydroquinone in $0.1\ N$ hydrochloric acid at 25° for as long as 15 hours and by cooling from a higher temperature; no quinhydrone formation was observed. On cooling to 0° , however, small amounts of this compound separated, so that when working at this temperature the solids were dissolved separately and the solutions mixed. Such a half-cell was stable for 1 to 2 hours. Though the quinhydrone is formed with difficulty in

²⁴ Ling and Baker (Ref. 16) obtained by this method a compound melting at 103°. Of their other preparations, the highest-melting compound (115-117°) analyzed for ¹/₂ H₂O but did not lose water over coned. sulfuric acid.

the presence of water, electrodes containing previously prepared quinhydrone were stable at 25°. The potentials of a quino- and a hydroquinhydrone half-cell were 0.6811 and 0.6612, from which $\pi_s = 0.671$, in good agreement with the following results.

Tetrachloro-benzoquinone.—Tetrachloroquinone (m. p., 283-284°) was reduced with stannous chloride in the usual way. The hydroquinone was repeatedly crystallized from glacial acetic acid, dissolved in this solvent, and precipitated with alcohol. It melted constantly at 230-231°.

Half-cells saturated with the quinone and the hydroquinone were employed. Though both components are almost insoluble in water, measurements in $0.1\ N$ acid could be carried out, although equilibrium was established with some difficulty, especially at 0° .

Thus, at 0° one cell, on long standing, reached a potential about 4 mv. above the recorded value, while the other cell under similar conditions was 4 mv. below this value. When the cell was shaken, the potential of each came to about the same (the recorded) value. Slight polarization apparently causes appreciable concentration changes in these dilute solu-

tions. It was more convenient to use aqueous alcohol as the solvent, although even in this case, electrode equilibrium was not of the best and both types of electrode were occasionally erratic. The agreement of the results in aqueous and in aqueous-alcoholic solution constitutes a good proof of the constancy of this quinone-hydroquinone electrode.

The Potentials Referred to the Solid and Dissolved States

A summary of the results obtained is given in Table I. A few values, the details of which do not appear above, are taken from a previous paper.² The potentials of benzoquinone, toluquinone, monochloroquinone and 2,6-dichloroquinone in dil. acid have also been determined by other investigators and our results agree with theirs within 1 mv. except in the case of toluquinone; for this compound the more accurate value of Biilmann²⁵ is given preference to our number of 0.6435. The two starred figures are taken from the results of LaMer and Baker^{5c} who used 0.2 N hydrochloric acid as solvent. In the two columns under the normal potential for each of the solvents two values are given when π_0 varied with the acid concentration beyond the limits of experimental error. When but one figure is given under the heading "1.0 N HCl," it indicates that such variation was not observed.

It will be observed from the table that the potentials for the three conditions exhibit a certain parallelism. This is shown more clearly in Fig. 1 in which the potentials are plotted against the number of substituents. For the dichloroquinone the *para* isomer was arbitrarily selected for plotting since its potential is always intermediate between those of the other two. In those cases in which π_0 varied with the acid concentration an average value was used for the purpose of characterizing each compound as completely as possible.

²⁵ Biilmann, Ann. chim., 15, 109 (1921).

The three lines for both the chlorine and methyl series are roughly parallel. In every case but one, the order of the potentials is: alcoholic solution > aqueous solution > solid state. With the tetramethyl com-

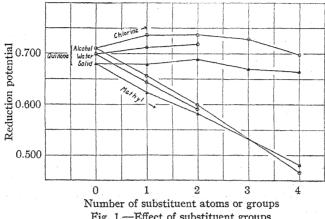

Fig. 1.—Effect of substituent groups

pound this order is reversed for the alcoholic solution and the solid state (the substance was not soluble in aqueous solution). It is evident from Fig. 1 that from the results obtained either in solution or referred to the

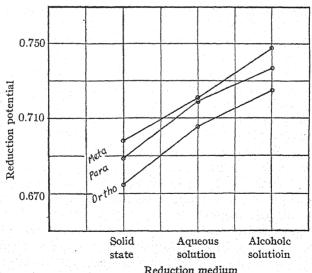

Fig. 2.—Dichloroquinones

solid state one would conclude: (a) that the introduction of methyl groups progressively and regularly decreases the potential, and (b) that the introduction of chlorine atoms first raises the potential and then lowers it even

below that of the parent substance. In Fig. 2, in which the potentials are plotted on an arbitrary scale, it is seen that even the subtle differences between the positional isomers are reflected in a nearly parallel manner by the potentials referred to the solid state, an aqueous solution or an alcoholic solution.

It will be further observed from Table I that all of the temperature coefficients of the potentials referred to the solid state have the same sign and are very nearly identical. It was shown in a previous paper² that this is also true of the temperature coefficients in aqueous and alcoholic solution. Therefore, relations based upon either π_3 or π_0 can reasonably be expected to hold at any temperature at which the comparisons may be made.

Thus, a definite answer has been obtained to the questions raised at the beginning of this article. The lines in Fig. 1 are so nearly parallel that one may safely say that the *relation between the potentials of a series of compounds* is very nearly the same whether the experiments are performed in aqueous solution, alcoholic solution or in saturated solutions.

We have been particularly anxious to settle this point in connection with our studies on the potentials of many naphthoquinone and anthraquinone derivatives which are too insoluble to be measured in aqueous solution either by the titration method or in saturated solutions. If the relationship in a series of quinones is essentially independent of the nature of the solvent we can safely proceed with our measurements of these insoluble substances in alcoholic solution. There is every reason to believe that the divergences from this simple generalization are greatest in the case of such benzoquinone derivatives as we have examine. The introduction of a substituent into the naphthoquinone or anthraq sinone nucleus would certainly change the ratio of the solubility of the quinone to the hydroquinone much less than the introduction of the same substituent into benzoquinone. In fact, evidence in regard to this point is already at hand; we have measured some 20 naphthoguinone and anthraguinone derivatives in alcoholic solutions containing 1.0 N and 0.5 N hydrochloric acid and the potential (π_0) was found to be the same in both solvents; this is in contrast to such benzoquinone derivatives as xyloquinone and the dichloroquinones. Another example of the relatively great susceptibility of the potential of benzoquinone derivatives to changes in the solvent is found by comparing the varying potential of benzoquinone in salt solutions1 with the consistency of the potentials of certain anthraquinone sulfonic acids in buffer solutions.5b

In considering those cases in which the relationship of the potentials of a series of compounds varies somewhat with the nature of the solvent, the problem arises as to which set of measurements is most significant. For example, in developing a general theory of the relation between con-

stitution and reduction potential, are the potentials of the chloroquinones in alcoholic solution (top line, Fig. 1) to be considered, or the potentials referred to the solid compounds (lowest line, Fig. 1)? In discussing the potentials of the isomeric dichloroquinones (Fig. 2), should one employ the results in alcoholic solutions or aqueous solution or those referred to the solid state? The potentials that are referred to the solid state (π_s) represent the algebraic sum of the free energy of three distinct processes, thus: $nF\pi_s = \Delta F$ (formation of dilute solution of quinone) + $nF\pi_0$ + ΔF (precipitation of the hydroquinone from dilute solution).

The introduction of a substituent into a quinone affects the value of all three terms on the right-hand side of this equation. We are concerned with the effects of substitution on the affinity of the quinone for hydrogen; since π_s includes not only this term but also the energy changes involved in passing from the two solid states into dilute solution, it is not an accurate measure of the relationship we are investigating. The ideal potential would be measured in a solvent in which both the quinone and the hydroquinone molecules are completely free from association or solvation of any sort; in other words, in a solvent in which the conditions of a perfect gas are realized. Under such conditions where the absolute activity26 was equal to the concentration, the potentials of a series of quinones would give a true measure of the effect of substitution on the affinity of the quinone for hydrogen. The values of π_0 obtained in aqueous or alcoholic solution are at present our best approximation to this ideal potential and probably give relationships which are only slightly in error. As the results in both solutions are almost parallel, one cannot go far wrong in deducing generalizations from either of them. For the present purpose it would be misleading to assign arbitrarily an activity coefficient of unity to the compounds in pure aqueous solution and refer our results to this standard; for all that we know at present, the absolute activity coefficient may be more nearly unity in alcoholic than in aqueous solution.

An examination of the experimental results obtained with the chloro-quinones shows the general consistency of the series of potentials in alcoholic solution (π_0) whereas the potentials referred to the solid state form an irregular series and they are related to the irregular solubility relationships of certain of the chlorohydroquinones. The potentials of the first 4-chloro compounds, both in alcohol and in water, are all higher than that of quinone itself; the relation is not additive, however, and the potential gradually falls with the presence of 3, then 4, chlorine atoms. In the experimental portion of this paper attention was called to the abnormal solubility of mono- and of 2,3-dichloro-hydroquinone. The potential of the latter compound in alcohol changes greatly with the acid concentration, an indication of a susceptible solubility ratio. But, al-

²⁶ Lewis, Proc. Am. Acad. Arts Sci., 43, 259 (1907).

though the ratios for these two compounds are anomalous, the relative positions of their potentials in solution fall in line with those of the other chloroquinones. This is not the case with π_s . Again the potential is low with 3 or 4 chlorine atoms present, and again the 2,5- and 2,6-dichloroquinones occupy a position above that of quinone. But mono- and 2,3-dichloroquinone, whose solubility ratios are abnormal, fall below the position of the parent compound. Thus, from the above data it appears that π_0 is more significant for the purposes of studying structure than π_s .

The main points of interest in connection with the problem of the relation between reduction potential and chemical constitution have already been pointed out in this discussion. It should be further noted that thymoquinone (Table I) has the same potential as p-xyloquinone and is very different from its structural isomer duroquinone. This disposes of the idea that the lowering of the reduction potential is a simple function of the molecular weight.27 The data at present available are not sufficient for any wide generalizations in regard to even benzoquinone derivatives; nevertheless the striking difference between the effects of methyl groups and chlorine atoms deserves special comment. Whereas the effect of the methyl group is progressively accumulative in lowering the potential, the introduction of chlorine atoms first raises then lowers the potential. The usual distinction between a "positive" methyl group and a "negative" chlorine atom harmonizes well with the decreasing potential of the methyl homologs and the increased potential of monochloroquinone. However, some other factor must be considered in explaining the potentials of the other chloroquinones. It will be very interesting to determine whether or not other "negative" groups or atoms behave in the same manner as the chlorine atom.

Comparison with Thermochemical Data

In 1900 Valeur²⁸ made an extensive study of the thermochemistry of quinones in which he measured the heats of combustion of the quinones and their hydroquinones and thus calculated the heats of reduction. Comparison of his values with the total energy of reduction in solution as found electrometrically has already been shown by Biilmann²⁵ and by the authors² to yield fairly concordant results in a few cases. From the above data $(\pi^{25^{\circ}}_{s})$ and $d\pi_{s}/dt$ it is now possible to compare Valeur's figures for the solid state (ΔH_{s}) with the same quantities calculated from potentials. Such a comparison is given in Table II. Two values are inclosed in brackets to indicate that they are of a lower degree of accuracy than the others, because of the difficulties referred to in the experimental portion of this paper.

²⁷ First advanced by Kehrmann, Ber., 31, 979 (1898).

²⁸ Valeur, Ann. chim., 21, 470 (1900).

Table II

Comparison of Thermochemical and Electrochemical Data

referred to the solid state (ΔH_s) Thermochem. (Valeur) Electrochemically Kj. Benzoquinone 175.1 172.8 Toluguinone 156.3 166.2 Thymoguinone 146.3155.4 Monochloroquinone (172.3)165.52,6-Dichloroquinone 140.9 (178.4)Trichloroquinone 93.2 175.3 Tetrachloroguinone 99.1 171.9

Since potential measurements are so likely to be free from large accidental or systematic errors, we are convinced that the great discrepancy which is evident from the table is due to both the great experimental difficulties in thermochemical work and the errors inherent in the calculations of the total energy change from the heats of combustion of the quinone and the hydroquinone. The heat of reduction is the small difference between the large heats of formation of quinone and of hydroquinone. Furthermore, an error in the heats of combustion of each substance is multiplied by the molecular weight and the two errors are additive. The accuracy of the thermochemical measurements is in most cases not very great. Thus for benzoquinone, which has been investigated by others29 besides Valeur, the mean of all the determinations shows a probable error of 8.7%. With other quinones, for each of which Valeur made 2 or 3 determinations, the error is always greater owing to the increased molecular weight. Valeur's two values for benzoquinone agree within less than 2%; and for the alkyl derivatives within 7%. Now, while these compounds were easily burned, great difficulties were experienced with the polychloro compounds; a correction for unoxidized chlorine had to be made and auxiliary combustible material evolving as much as 76% of the total heat had to be employed. Valeur's value for tetrachloroquinone is 42% lower than ours; while the difference is 47% for trichloroguinone, for which potential measurements show a high degree of accuracy. other chloro derivatives show similar, though smaller, deviations. thermochemical data must be considered to be greatly in error for these quinones.

Unfortunately, while Valeur was fully aware of the errors of his method and expressly stated that his results were but approximations, he made them the basis of conclusions as to the oxidizing power of quinones, which also involved the tacit assumptions of equal solubility ratios and of the truth of the Berthelot principle. Needless to say, these conclusions are

²⁹ Berthelot and Recoura, Ann. chim., [6] 13, 311 (1888). Berthelot and Longuinine, ibid., [6] 13, 333 (1888). Stohmann, J. prakt. Chem., [2] 45, 335 (1892).

at variance with the results of potential measurements and must be discarded.

Energy of Quinhydrone Formation

The total energy of formation of solid benzoquinhydrone from solid quinone and hydroquinone was calculated by Berthelot³⁰ from the heat of formation in solution and the heats of solution of the factors and the product. This same value may be calculated from the potentials and temperature coefficients of the quino- and hydro-quinhydrone electrodes. The potential (π_{qh}) corresponding to the free energy of the reaction, Quinone (solid) + Hydroquinone (solid) \longrightarrow Quinhydrone (solid), is calculated, as explained above, (Eq. 4) from the simpler relation, $\pi_{qh} = \pi_q - \pi_h$. From the data on p. 2198, the total energy change at 13° is found as follows.

$$\frac{\mathrm{d}\pi_{7h}}{\mathrm{d}t} = \frac{(0.749 - 0.613) - (0.770 - 0.627)}{25} = -0.00028 \text{ v.}$$

$$\Delta H = 96.5 \times 0.139 + 96.5 \times 286 \times 0.00028 = 21.1 \text{ kj.}$$

This is quite different from Berthelot's value of 37.1 kj. for the same temperature. In view of the general concordance of our electrochemical results with those of Sörensen and of Bilmann, it is not unlikely that the discrepancy is due to an error in the thermochemical measurements.

It has been pointed out ³¹ that the free energy of the reaction, Quinone (solid) + $H_2 \longrightarrow$ Hydroquinone (solid), is given by the expression,

$$\Delta F_s = 2F\pi_0 + RT \ln \frac{a}{b},\tag{5}$$

in which π_0 is the reduction potential referred to the dissolved state; a and b are the solubilities of quinone and hydroquinone, respectively, in a solution saturated with them both. This stipulation, that the solubilities employed be those of each compound in the presence of the other and not in solution by itself, was shown by Smits³² to be necessary in the application³³ of the van't Hoff equation for the shift in equilibrium constant with a change in solvent. Equation 5 simply states that to obtain the free energy of reduction in the solid state one must add to the free energy of reduction in solution $(2F\pi_0=RT\ln K)$ the free energy of bringing quinone from a saturated to a dilute solution $(RT\ln a)$ and of concentrating the dilute solution of hydroquinone $(-RT\ln b)$. The free energy of passing from the solid phase to a saturated solution is, of course, zero.

We may now expand this equation to include those cases in which simultaneous saturation of a solution with quinone and hydroquinone is not realizable. If k is the dissociation constant of quinhydrone and c its solubility, it is seen that, in any solution saturated with quinhydrone and

³⁰ Berthelot, Ann. chim., [6] 7, 203 (1886).

³¹ Ref. 2, p. 2490.

³² Smits, Z. physik. Chem., 92, 35 (1918).

³³ Dimroth, Ann., 377, 127 (1910).

(all solids). Thus:

one of its components, $k = \frac{a \times b}{c}$; $a = \frac{kc}{b}$; $b = \frac{kc}{a}$. These values for a and b may now be substituted in Equation 5 for a solution saturated with quinone in the first case and with hydroquinone in the second. An electrode dipping in the first solution records the potential corresponding to the free energy of reduction of quinone to quinhydrone (ΔF_q) ; in the second, the free energy of reduction of quinhydrone to hydroquinone (ΔF_p)

Quinone +
$$H \longrightarrow 1/2$$
 Quinhydrone: $\Delta F_q = \frac{1}{2} RT \ln K + \frac{1}{2} RT \ln \frac{a^2}{k_1 c}$ (6)

$$^{1}/_{2}$$
 Quinhydrone + $H \longrightarrow$ Hydroquinone: $\Delta F_{h} = \frac{1}{2} RT \ln K + \frac{1}{2} RT \ln \frac{k_{2}c}{h^{2}}$ (7)

Subtracting (quinone + hydroquinone → quinhydrone)

$$\Delta F_{qh} = \Delta F_q - \Delta F_h = RT \ln \frac{a \times b}{c} - \frac{1}{2} RT \ln k_1 k_2 \qquad (8)$$

In Equations 6 and 7 the dissociation constants used are the actual constants $(k_1 \text{ and } k_2)$ for quinhydrone when in the presence of a saturated solution of quinone and of hydroquinone, respectively. Granger and Nelson³ have shown that k_2 differs from k, the normal dissociation constant. Using their solubility data and their value for k_2 at 25° for 0.1 N hydrochloric acid and assuming at first that $k_1 = k$, ΔF_{qh} is found to have a value of 13.37 kj. This is higher than the value of 13.14 kj., found from the potential measurements and recorded in Table III. But, using the normal potential of quinone and the solubilities, in 0.1 N hydrochloric acid, with the same assumption concerning k_1 , ΔF_q and ΔF_h are found to be equal to 72.54 kj. and 59.16 kj. From our potential measurements these quantities are found to be 72.28 kj. and 59.16 kj., respectively. The lack of exact agreement in the values for ΔF_q indicates that the dissociation constant of quinhydrone is inconstant not only in the presence of an excess of hydroquinone but also in the presence of an excess of quinone.

Table III
Free Energy of Formation of Solid Quinhydrone from Solid Components

2,6-Dichloroquinone	.057	5.5	.053	5.1	+0.4	
Trichloroquinone	.020	1.9				

Before examining Table III it should be pointed out that any conclusions based on the values given are rendered somewhat doubtful by the fact that the chloroquinhydrones undoubtedly exist in contact with aqueous solution in the form of hydrates. Consequently ΔF_{gh} represents the free

energy of formation and of hydration of the compounds in these cases. However, in relation to the above comparison of the affinity of reactions occurring in solution and in the solid state, it is perhaps significant that temperature coefficients indicated in the table vary so greatly as even to be of opposite sign. For benzoquinhydrone ΔF_{qh} decreases slightly with temperature while for thymoquinhydrone it is doubled in the same temperature interval and there is no indication of hydrate formation in either case.

Whether or not this is true of the free energy of formation of quinhydrones in solution cannot, at present, be decided. The latter quantity, calculated from the dissociation constants in water, is 3.3 kj. (25°) for benzoquinhydrone^{3,25} and 5.8 kj. for toluquinhydrone. The affinity of formation of the complex in solution is increased by the substitution of a methyl group while, when the total process involving the solids is considered, this group lowers the affinity. The first term in Eq. 8, $RT \ln \frac{a \times b}{c}$, is found by subtraction to be 10.1 kj. for benzoquinhydrone and 1.6 kj. for toluquinhydrone. The small value of this term indicates that the solubilities of its components. This rather surprising relationship is easily demonstrated by the fact that no toluquinhydrone precipitates when saturated solutions of its components are mixed. Benzoquinhydrone precipitates at once under these conditions, as the relatively large value of the "solubility term" indicates.

Since ΔF_{ab} , the free energy of formation of solid quinhydrone, is subject to wide variations in its temperature coefficient and because of the different solubility relations of a series of closely related compounds, it cannot be considered to be of much significance in the study of the structures of these complexes. It does give an indication of the "ease" with which the various quinhydrones are obtained. In order that a quinhydrone be obtained from a given solution of the components it is necessary that (1) they associate and that (2) the quinhydrone, being less soluble than its factors, precipitate. The total free energy, ΔF_{ab} , will be the same regardless of the solvent, so that if a solvent is chosen in which relatively great association takes place, the quinhydrone will not be so insoluble relative to its components in that solvent as in one in which association is less. Thus, one may prepare a quinhydrone by precipitation, by mixing the components in a solvent which favors precipitation, or by evaporation, if the solvent chosen favors association but not precipitation. Of course the quinhydrone may be made more insoluble by adding an excess of one of the components, according to the law of mass action, unless the quinhydrone is of the toluquinone type, when addition of a component precipitates the quinhydrone contaminated with that component.

It is interesting to notice that other investigators have observed the effect of these two factors, solubility and dissociation, in determining the course of the reaction, though the precise relationship was not seen. Torrey and Hunter³⁴ believed that the stability of the halogenated quinhydrones depends "on the number of halogens present only as this affects the solubility of the factors and of the quinhydrone itself." Jackson and Bolton,³⁵ finding that the quinhydrone of iodanil but not of chloranil could be prepared, and believing the solubility relations to be about identical in the two cases, held that the solubility relations play no part in the formation or non-formation of quinhydrones, but that the determining factor is the negativity of the substituent groups. Since this factor, the negativity, must determine dissociation, the two opposing views are now fused into one which maintains that both solubility and dissociation constants are important.

It will be observed that the figures in the table agree well with the known behavior of these quinhydrones. The free energy of formation of benzo-quinhydrone is the greatest of all and is decreased by the introduction of substituents, whether these are positive or negative. Tendency of formation vanishes with the introduction of 2 methyl groups or 4 chlorine atoms. It is well known that the stability of quinhydrones decreases with the number of halogen substituents, and that neither chloranil nor p-xyloquinone forms a quinhydrone with its hydroquinone.³⁶

We wish to acknowledge our indebtedness to the Cyrus M. Warren Fund of the American Academy of Arts and Sciences for two grants which have greatly assisted this work.

Summary

- 1. The question has been raised as to the relationship of the reduction potentials of a series of quinones in different solvents and referred to the solid state.
- 2. The reduction potentials of 4 alkyl derivatives and 6 chloro derivatives of benzoquinone have been measured in alcoholic solution, in aqueous solution (with three exceptions) and referred to the solid state.
- 3. Essentially the same relationships have been found whether the potentials measured in aqueous or alcoholic solutions were compared. The potentials referred to the solid state are not entirely parallel to those measured in solution. From these facts and general considerations it has been shown that in comparing the reduction potentials of a series of quinones the substances should ideally be measured in a solvent in which the absolute activity coefficient of the organic substances is unity; alcoholic

³⁴ Torrey and Hunter, This Journal, 34, 702 (1912).

³⁵ Jackson and Bolton, Ber., 45, 871 (1912); This Journal, 36, 304 (1914).

³⁶ Ref. 16. Schlenk, Ann., 368, 287 (1909).

or aqueous solutions seem to be sufficiently close to this ideal condition to make the measurements in these solvents significant.

- 4. The introduction of alkyl groups progressively lowers the reduction potential in the case of the 4 alkyl compounds investigated. The introduction of chlorine, on the other hand, first raises and then lowers the potential.
- 5. In order to measure the reduction potential referred to the solid state of those quinones that form quinhydrones, it was necessary to measure the potential of cells containing quinone-quinhydrone and hydroquinone-quinhydrone. The validity of this procedure has been demonstrated. Data concerning the energy of quinhydrone formation have been thus obtained.
- 6. The temperature coefficient of the reduction potential referred to the solid state has been measured for all of the quinones investigated and the total energy of reduction thus calculated. A comparison with previous thermochemical measurements shows great discrepancies in the case of the polychloroquinones; the cause for this discrepancy seems to lie in the errors inherent in the thermochemical measurements.

Cambridge 38, Massachusetts

NEW BOOKS

A Course of Laboratory Experiments on Physico-chemical Principles. By Miles S. Sherrill, Associate Professor of Theoretical Chemistry in the Massachusetts Institute of Technology. The Macmillan Co., New York, 1923. x+125 pp. Illustrated. 22.5×14.5 cm. Price \$2.00.

The 27 experiments contained in this book are divided into 12 groups of from 1 to 5 experiments, under the following headings: Molecular Weight from Vapor Density; Vapor Pressure and its Lowering by Solutes; Distillation in Relation to Vapor Pressure; Distribution of Solutes between Phases; Freezing-Point Lowering and Molal Composition; Electrolysis, Transference and Conductance; Rate of Chemical Change; The Equilibrium of Chemical Changes at Constant Temperature; Equilibrium of Chemical Systems in Relation to the Phases Present; Heat Effects Attending Chemical Change; Electromotive Force of Cells; Effect of Temperature on Chemical Equilibrium. Each experiment is carefully organized according to a uniform plan, in which the Principles Involved are first listed, followed in order by an Outline, a description of Apparatus, the detailed Procedure, the required Treatment of Results, and a Discussion of the broader aspects of the experiment and the sources of error.

The individual experiments are, in general, good. This is particularly true, for example, of the study of the equilibrium of hydrogen and iodine at high temperatures, and of several of the experiments on electromotive force. The use of conductivity measurements in following the rate of a

reaction illustrates the advantageous combination of the study of method and principle. It is no doubt the intention that a number of the experiments be used as alternates. The performance of both experiments on vapor density, for example, would disproportionately emphasize this portion of the work. Similarly, it is a question whether experiments on distribution are sufficiently representative or important to justify their utilization in three different assignments. In one case, the endeavor to keep experiments simple and apparatus robust has been carried too far. The experiment on electrolytic conductance, in which the effect is measured of varying the length, concentration, etc., of copper sulfate solution between copper plates in a wooden trough, seems of doubtful value for a student of average intelligence.

In criticizing the book from a more general standpoint it is necessary to bear in mind the author's single intention of emphasizing principles (to large classes with little time). The reviewer is one of those who believe that arrangements as to time and facilities should be made to permit some emphasis of two other important features: (1) the stimulation of the initiative and resourcefulness of the better students in their experimental work, and (2) the study of standard methods, per se, with apparatus good enough to give the feeling that real tools are being used. The work of the present manual consists mainly of set exercises, rather than experiments in the planning or adaptation of which the student takes increasing part as the work progresses. By its sustained carefulness and completeness in this regard, it may fail to assist the instructor in achieving the first of the above objects, and the second of them has been deliberately subordinated. Having made his choice, however, Professor Sherrill has accomplished his purpose with undoubted success.

E. D. EASTMAN

Principles of Chemical Engineering. By WILLIAM H. WALKER, WARREN K. LEWIS and WILLIAM H. McAdams, Professors of Chemical Engineering at the Massachusetts Institute of Technology. McGraw-Hill Book Co., Inc., 370 Seventh Ave., New York; London, 6 and 8 Bouverie Street, E. C. 4; 1923. ix + 637 pp. 156 figs. 23.5 × 15 cm. Price \$5.00.

This book follows the general scheme of dividing industrial chemical processes into a number of basic or "unit" processes, such as flow of heat, distillation, combustion, drying, flow of fluids, etc., and then treating each one of these fundamental operations from a general standpoint without reference to any complete manufacturing process. The underlying, scientific principles are first discussed, then these principles are utilized to explain the phenomena involved and, wherever possible, to develop equations that enable one to predict the result of a change in conditions or to design a piece of equipment for a specified duty. In nearly all cases the use of the equations is well illustrated by the solution of typical prob-

lems founded, for the most part, upon data obtained from actual tests on operating equipment or from undergraduate theses.

The foundation for the quantitative treatment which is accorded to nearly all of the subjects discussed, is well laid in the first chapter, which is devoted to a general exposition of the methods of making industrial calculations. This chapter contains nothing essentially new, but condenses into small space an excellent review of many fundamental laws and clearly shows how they can be pressed into the engineer's service. The quantitative treatment of each subject is usually accompanied by a brief description of the most important standard types of equipment available for commercial use. The limitations and advantages of each are discussed in the light of the general principles previously considered. Notable exceptions to this occur in the cases of "Flow of Heat" and "Flow of Fluids," especially the latter, where one expects some description of fans, pumps, air lifts, etc.

Many of the subjects, such as the flow of heat, combustion, gas, producers, etc., have for some years been included in many of the standard textbooks on mechanical engineering and hydraulics, but from a wholly different viewpoint. For example, in the case of "Flow of Fluids," the quantitative treatment has been generalized. In this book it applies not merely to steam, air and water under the special conditions usually encountered in engineering practice, but to the much greater variety of fluids under many different conditions of pressure and temperature with which the chemical engineer has to deal. Likewise, such subjects as combustion and gas producers are treated from a much more chemical point of view. It is obvious to chemists that the use of molar quantities would introduce considerable simplification.

From the amount of space devoted to filter calculations one is led to believe that commercial filtration has been largely reduced to a mathe-Careful study of the development of the formulas matical basis. reveals that the general equations are, to a large extent, based on assumptions for the validity of which no experimental evidence is adduced. Furthermore, there are so many variables involved in filtration that the constants in the equations are really functions of a number of complex variables and as a result their usefulness is greatly limited. The same criticism applies to the chapter on "Drying," more than 2/3 of which fairly bristles with equations for the design of all kinds of driers under every possible condition. These equations are developed from a few fundamental differential equations involving assumptions as to the mechanism of drying which are not supported by any direct experimental evidence. A few of the final equations are tested on the data obtained from undergraduate theses with satisfactory agreement, but such a test merely serves to show that the equations are satisfactory for the purpose of interpolation under the given conditions.

There is no question as to the desirability of eventually placing all the subject matter of chemical engineering on a mathematical basis, but if this is to be stable it must rest on well-tested principles. This is possible in many cases at the present time, but in others it seems to the reviewer to be decidedly premature.

Chemical engineering covers a rather broad field and naturally the authors have been obliged to limit themselves to a few of the most important subjects. Many chemists and chemical engineers will probably disapprove of the prominence given some subjects, of the scant attention received by others (notably fuels and power) and of the complete omission of many important subjects, such as corrosion, plant control methods, mixing, etc. However, these are points on which no two persons could agree and, on the whole, it may be said that the authors have made a wise selection.

Since it is practically the pioneer in its field this book should receive an enthusiastic welcome from all those who are interested in the application of chemistry (one almost feels constrained to say physics, because the majority of the underlying principles belong more properly in the domain of physics than in that of chemistry) to industry and particularly from those who are concerned with instruction in industrial chemistry and chemical engineering. This is the purpose for which it is primarily intended and it has already proved its worth through having served an extensive apprenticeship as a text, in the form of notes, not only at the Massachusetts Institute of Technology but at several other institutions as well.

One may not agree with all the mathematics, with the arrangement or relative importance given to the various subjects, but one is certainly impressed with the vast amount of quantitative information presented and particularly with the ingenious ways in which well-known scientific principles are applied to the solution of industrial problems.

BARNETT F. DODGE

Lehrbuch der Cellulosechemie (Textbook of Cellulose Chemistry). By Dr. Emil Heuser, Professor of Cellulose Chemistry at the Technical School, Darmstadt. Second edition. Gebrüder Borntraeger, Berlin, 1923. vii + 211 pp. 3 figs. 24.5 × 16 cm. Price \$1.55.

The second edition of this very suggestive and useful monograph, while it includes references to articles on cellulose that have appeared since 1920, shows no great change or development in the author's point of view. The book has been written and rewritten primarily from the standpoint of the organic chemist to whom cellulose is a special type of polyacid alcohol—a specific polysaccharide which is always the same chemical compound no matter what its botanical source. Thus we find the cellulose alcoholates, esters, ethers, as well as oxidation and hydrolysis products of cellulose

discussed from the standpoint of the research chemist as well as that of the technologist with a consistent clarity of expression that merits the highest praise. The circumlocution, which for the past 30 years has haunted monographs on cellulose, and those hopeless labyrinths of detail that demoralized investigators, have disappeared. On the other hand, the interests of the physical chemist and the needs of the technologist who is daily brought into contact with the colloid chemistry of cellulose have been subordinated and at times completely neglected. While the author has done this quite deliberately, realizing the many loose ends that he would encounter in this field, the reviewer regrets that this important phase of cellulose chemistry plays such a minor role in his useful book. Nor does the author always give both sides of a mooted question. As a single example, the work of the physical chemist, Leighton, which argues against compound formation when cellulose is brought into contact with alkali, has received no mention in Heuser's first chapter, whereas the recent (though perhaps less critical) work of the organic chemist, Karrer, which favors the hypothesis of compound formation is duly cited. Hibbert's important critical review of the literature on cellulose, and his subsequent formulation of the constitution of cellulose have not been adequately mentioned and the classical quantitative researches of Irvine and his colleagues at St. Andrews have not been given the place they deserve in Heuser's chapter on "Constitution of Cellulose." In spite of these obvious errors of omission. Heuser's little volume is invaluable to the chemist interested in carbohydrates and to technologists in the many industries in which cellulose serves as a raw material.

Louis E. Wise

An Introduction to the Chemistry of Plant Products. Vol. II. Metabolic Processes. By Paul Haas, D. Sc., Ph.D., University of London, and T. G. Hill, University of London. Longmans, Green and Company, 55 Fifth Avenue, New York; 39 Paternoster Row, London, E. C. 4; Toronto; Bombay, Calcutta and Madras; 1922. viii + 140 pp. 11 figs. 14.5 × 22.5 cm. Price \$2.50 net.

In the third edition of the work under notice the material previously included in one volume has been divided into two parts in order, as has been stated by the authors, to give the more purely physiological aspect of the subject fuller treatment. While, therefore, the first volume is now chiefly restricted to a description of some of the principal chemical constituents of plants, the second one deals more specifically with metabolic processes. The subject matter of the present volume is divided into 6 chapters, which are given the following titles: I. Introduction: The Living Plant; II. The Synthesis of Fats; III. The Synthesis of Carbohydrates; IV. The Synthesis of Proteins; V. Respiration; VI. Growth (including a brief consideration of auximones, hormones and vitamins). Although the changes which take place in living plants were formerly

considered to lie chiefly within the domain of vegetable physiology, and therefore to be more especially of interest to the botanist, it is evident that these metabolic processes are now also actively engaging the attention of the chemist, for it is only by the application of chemical and physical methods that further knowledge can be obtained respecting vital phenomena and their biological significance. It is well known, as the authors have noted, that more than 50 years ago Baeyer formulated the hypothesis that carbon dioxide is split up by the plant into carbon monoxide and oxygen, and that the water is concurrently resolved into its constituent elements. It was further assumed that the carbon monoxide and hydrogen thus produced then combine to yield formaldehyde, which undergoes polymerization and so forms a hexose. These chemical changes which were thus presumed to be comparatively simple have, however, in the meantime been the subject of considerable discussion, with some attending modification of the original views, and for the elucidation of photosynthesis in its fundamental as well as in its broader aspects the most refined methods of chemical investigation have now been brought into requisition. It is to be expected that problems so recondite in character should be attended with many statements which as yet must be regarded as more or less hypothetical or speculative, and also that errors of observation may occur. As an example of the divergence of views respecting the chemical changes effected in biological processes it may be sufficient to call attention to the results obtained by an American investigator1 who has been unable to confirm the statements concerning the reduction of aqueous carbon dioxide to formaldehyde by the action of ultraviolet light and the subsequent polymerization of the aldehyde to hexose sugars.

The work under present consideration is one which will be perused with interest by both chemists and botanists and, although aiming only to present such an account of the various processes and products of plant life as to form a basis for further study, it contains much information of immediate usefulness respecting the existing state of knowledge. The book is well printed and is provided with a very complete index.

F. B. POWER

Clinical Laboratory Methods. By Russell Landram Haden, M.D., Associate Professor of Medicine, University of Kansas, School of Medicine, Kansas City, Kansas. C. V. Mosby Company, St. Louis, Missouri, 1923. 294 pp. 69 figs. and 5 plates. 23.5 × 15.5 cm. Price \$3.75.

Modern diagnostic laboratories are constantly called upon to carry out a considerable variety of procedures. Some of them are in the nature of chemical analyses, both qualitative and quantitative, some are bacteriological, some cytological, and some serological.

¹ Spoehr, This Journal, 45, 1184 (1923).

This book is the equivalent of such note books as are compiled in many laboratories for the benefit of the different workers. No attempt has been made to discuss the procedures or to give alternate methods, beyond indicating the value for each determination found on the average normal subject, or to discuss the interpretation of the results; as the author states in the preface, the book is not a textbook. The reviewer would like to point out that such a book will not enable a chemist to undertake clinical pathological tests, nor will it enable the worker trained in bacteriology and the technique of blood counting to carry out successfully quantitative analyses on blood and urine. The first group of workers would, for instance find difficulty in identifying intestinal protozoa from the charts and tables given, and the clinical pathological worker would almost certainly get into difficulties through ignorance of some of the precautions necessary for insuring purity of reagents, standard solutions, etc., in spite of the precautions described in the twelfth chapter, should he try to carry through chemical analyses.

In the province which the book is intended to cover it is successful. The examinations chosen for presentation are such as are at present of most use in studying patients. None is described that does not have a rather wide application, and few have been omitted that have been proved to have any extensive clinical application. The book, therefore, should be useful for any laboratory as a help in measuring the value of the service which it is prepared to render to the clinician. Whether the methods—particularly the chemical methods described—are those best adapted to each procedure, is a question on which different workers will markedly differ. As was stated in a review of Dr. Haden's book in the British Medical Journal, chemical methods in use are changing so rapidly that probably none of the procedures in use today will continue to be followed 10 years from now; criticism of individual methods is, therefore, of comparatively little value.

It seems to the reviewer that this book will serve very well as the basis for a useful handbook for any clinical pathological laboratory. The successful laboratory will almost inevitably change some of the procedures, omit some and add others; nevertheless, the publication of such a work, if the limitations implied by the statements in the preface are kept in mind, will prove of great value to hospital and commercial clinical pathological laboratories.

[Contribution from the Chemical Laboratory of the University of California]

FREE ENERGY OF THE THIOSULFATE ION

By F. Russell Bichowsky¹ Received May 24, 1923

In order to determine the free energy of formation of the thiosulfate ion from its elements, three reactions are suggested as suitable for study.

The first, $S_5^{--} + H_2O = S_2O_3^{--} + 3H_2S$, is known to go, at moderate temperatures, largely in the direction written, and though the reverse reaction has not been described, preliminary experiments show that it takes place to a measurable extent even at 100° . If equilibrium can be reached and can be measured, this reaction gives a new and important means of obtaining not only the free energy of formation of thiosulfate ion but also of sulfur dioxide.²

The second reaction, which appears suitable, is the familiar reaction, $S_2O_3^{--} + H^+ = S + HSO_3^-$. This reaction is known to be reversible, the reverse reaction being one of the usual methods of preparing thiosulfates. However, at acid concentration where the equilibrium is measurable the reaction is very slow at room temperatures, while at higher temperatures difficulties of analysis and the uncertainties of the degree of ionization of the substances involved render this method unsuitable.

The third reaction, $S_2O_3^{--} = S + SO_3^{--}$, is really the same as the second, except that instead of using hydrogen ion to keep the concentration of the sulfite ion low, other means are used to control the concentration of the sulfur or sulfite ion. Biltz³ found that copper reacts with the fused **

² By means of the chain of reactions: $4S + HS^- = S_5^- + H^+; H_2S = HS^- + H^+; H_2S = S_7 + H_2; S_5^- + 3H_2O = S_2O_8^- + 3H_2S; SO_2 + H_2O = SO_8^- + 2H^+; S_2O_3^- = S + SO_8^-$, the last of these being the reaction actually measured in this investigation.

³ Biltz, "Laboratory Methods in Inorganic Chemistry," Wiley and Sons, 1909, p. 131.

hydrate of sodium thiosulfate to give cuprous sulfide and sodium sulfite. This reaction is apparently irreversible. It suggests, however, that at high temperatures sodium thiosulfate dissociates into sulfite and sulfur. If this is so, the vapor pressure of sulfur in the equilibrium mixture must be very low, as prolonged heating of either the anhydrous or hydrated sodium thiosulfate in a high vacuum failed to show any distillation of sulfur into the cold parts of the tube, and the reaction mixture, when cooled, failed to give any test for sulfite. At very high temperatures (red heat and above) the reaction, $4\text{Na}_2\text{S}_2\text{O}_3 = 3\text{Na}_2\text{SO}_4 + \text{Na}_2\text{S}_5$, takes place in preference. It is possible that some metal besides copper might be used, but if the reaction is to be studied in solution, the number of such metals is rather limited.

Moreover, the other alternative, namely, lowering the sulfite concentration by using the thiosulfate of some element whose sulfite is very slightly soluble, would be more satisfactory theoretically, as it would avoid the difficulty of analyzing mixtures of thiosulfates and sulfites, as well as the difficulties of the thermodynamic treatment of such solutions. A number of elements form soluble thiosulfates and insoluble sulfites. The thiosulfates of calcium and barium were chosen for experimental investigation because these elements are divalent, thus eliminating the formation of intermediate ions, they do not readily form thiosulfate complexes, they are not easily hydrolyzed, they exist in only one oxidation stage, and their sulfides are soluble.

Preliminary experiments showed that up to 200° saturated solutions of barium thiosulfate dihydrate which is only slightly soluble, do not dissociate. 2.0 Molar solutions of calcium thiosulfate were partly decomposed into sulfur and calcium sulfite dihydrate, when heated for 4 days at 150°, leaving the solution about 0.4 M. Some hydrogen sulfide and sulfate were formed but no gypsum or anhydrite could be detected in the solid material. The reverse reaction was then tried, that is, calcium thiosulfate dehydrate and sulfur were heated with water for 4 days at 140°. The unaltered sulfur and sulfite were removed and the solution was analyzed: 100 cc. contained 0.01958 mole of calcium ion, 0.01945 mole of thiosulfate ion, 0.0001 mole of sulfide ion, approximately 0.0001 mole of hydrogen ion, and approximately 0.0001 mole of sulfate ion; no sulfite and no polythionate could be detected. It is therefore evident that equilibrium is established at 140° between the separate phases, liquid sulfur, solid calcium thiosulfate dihydrate, and a solution containing only calcium ion and thiosulfate ion at some concentration between 0.4 and 0.19 molar. More careful determinations were, therefore, undertaken.

Preparation of Calcium Thiosulfate Hexahydrate.—Calcium thiosulfate

⁴ Determined microscopically by Mr. Merwin of the Geophysical Laboratory, Washington, D. C.

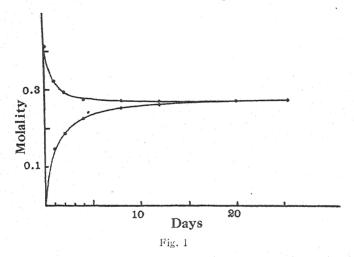

is an extremely soluble salt, a saturated solution at 25° containing 2.28 moles of CaS₂O₃.6H₂O per 1000 g. of solution (new determination). It can readily be prepared in solution by adding a concd. solution of calcium chloride to a cold concd. solution of sodium thiosulfate, when sodium chloride separates. The crystals of calcium thiosulfate can then be fractionally crystallized by adding alcohol, redissolving the precipitate in water and reprecipitating with alcohol. This method works well with small quantities if a trace of alcohol is no objection. For large quantities, the best method is to dissolve 510 g. of crystallized sodium thiosulfate in 465 g. of water, then add, with constant stirring, 350 g. of finely crystallized calcium chloride dihydrate. The temperature of the solution should not rise above 60° during this process. The solution is allowed to stand overnight, the clear solution is decanted through a large filter, and cooled to 0° or -10° and allowed to crystallize. Prepared in this way, the crystals contain only a small amount of sodium chloride as an impurity, from which they can be freed by recrystallization. The solid salt dehydrates rapidly at room temperature, also decomposing into sulfur and sulfite at the same time. In contact with its saturated solution it is stable for several weeks at 25°. At 0° it is apparently indefinitely stable. The 2 M solution is stable up to about 35° and is the most convenient form in which to keep the salt. The solutions used in this investigation were free from excess of calcium and contained less than 0.1% of sodium chloride.

Calcium Sulfite.—The dihydrate was prepared (1) by precipitation of fresh sodium bisulfite with calcium chloride, (2) by recrystallization of commercial calcium sulfite from a solution of sulfurous acid, (3) by partial oxidation of calcium thiosulfate with hydrogen peroxide in alkaline solution (a new reaction), (4) by thermal decomposition of solutions of calcium thiosulfate. These samples varied strikingly in crystalline habit, but had nearly the same refractive index, and no difference in behavior was noted among them. The material used in the final experiments was all prepared by Method 1. Above temperatures somewhere near 160° the dihydrate is unstable in contact with water, presumably forming the semi-hydrate, CaSO₃.1/2H₂O, analogous to CaSO₄.1/2H₂O.

The sulfur used was the common purified substance.

Equilibrium Measurements.—Two sets of sealed Pyrex tubes were made up, each of the first containing about 15 cc. of M calcium thiosulfate solution to which a little powdered sulfur and calcium sulfite dihydrate were added; each of the second, 15 cc. of water and an excess of sulfur and calcium sulfite dihydrate. These were heated side by side in an air thermostat, constant to 0.5° of the temperature desired. From time to time one from each set was withdrawn, cooled, filtered through a dry filter into a weighed flask containing a few drops of a solution of cadmium

acetate to precipitate any hydrogen sulfide present. The flask was then weighed again, and its contents filtered through a dry filter to remove cadmium sulfide. The precipitate was washed until the washings did not affect the titer and the filtrate was titrated with 0.1 N iodine solution; weighed burets were used. If equilibrium were reached the concentration of both tubes should be the same. In the case where special care was taken, as in the experiment at 141°, the values from above and below did not differ by 0.1%, and there is apparently no reason why this accuracy should not be reached, if needed, at any temperature. At 174° equilibrium was not reached, the titer of the tubes starting with the thiosulfate side remaining constant at 0.118 M per 1000 g. of solution, and those from the water side slowly changing at a concentration of about 0.158 M per 1000 g. solutions, even after 2 weeks' heating. Microscopic examination showed that in the first case the solid phase was not calcium sulfite

dihydrate, but presumably the semihydrate. In the tubes containing water the solid material was largely the dihydrate with some semihydrate present. An accident prevented the completion of the run at 120° and the results are not accurate. The results of a typical run are presented in Fig. 1.

At temperatures below 110° the reaction was too slow to allow this method to be used. So, instead of starting with pure water or a concentrated solution of thiosulfate, solutions of known strength, say 1.2, 1.00, 0.80, 0.60 M were prepared and heated in the presence of calcium sulfite dihydrate and sulfur in sealed Pyrex bulbs in a vapor bath. Samples were withdrawn after a week and analyzed, and it was noted whether the strength of the calcium thiosulfate had decreased or increased. Thus it could be determined that the equilibrium concentration lay between, say,

1.00 and 0.80. By making up a new set of tubes with concentrations of 1.00, 0.95, 0.90, 0.85, 0.80, M the process could be repeated and the equilibrium limits narrowed still more. Table I gives the results of one such run.⁵ Final values for the equilibrium concentrations are given in Table II, where Line I gives the temperature, Line 2, the concentration in moles per 1000 g. of water, and Line 3, the form of sulfur stable at the temperature in question.

TABLE I

	Sample Eq	UILIBRIUM DET	TERMINATION

Form of sulfur	$S_{\lambda\mu}$	$S_{\lambda\mu}$	$S_{\mathbf{m}}$	$S_{\mathbf{m}}$	$S_{\mathbf{r}}$

In order to use these equilibrium data to calculate the free-energy change at the standard temperature and concentration it is necessary to know the heat of the reaction, the heat of dilution of these concentrated solutions, the heat capacity of all substances involved and the free energy of dilution of the thiosulfate solution.

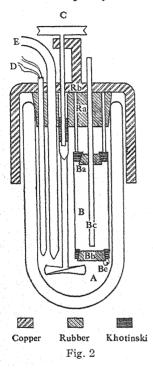

The Heat of Reaction.—No direct determination of this quantity was available, and though it may be calculated from the equilibrium measurements themselves, the calculation is so involved in this case that it was thought advisable to determine this factor calorimetrically. In theory this may readily be done by treating in a calorimeter a solution of calcium thiosulfate with an excess of acid and then, under identical conditions, an equivalent amount of calcium sulfite dehydrate with the same amount of the same acid. The chief chemical difficulty lies in the fact that the sulfur formed by the action of acids on thiosulfate solutions is not rhombic sulfur but a mixture of S_{λ} and S_{μ} . Under the conditions of these experiments the change of these substances into rhombic sulfur is slow and the heat involved in that process must be allowed for. A rough approximation

⁵ It will be noted that the rate of the reactions by which thiosulfate is formed is quite different (being between two different phases) from the rate at which it decomposes, though, of course, the slope of the two curves in Fig. 1 must be equal at equilibrium. At any given time short of equilibrium the one reaction is thrice as far from equilibrium as the other.

⁶ Brownlee, This Journal, 29, 1032 (1907).

of the heat involved may be made from existing data. Under the conditions of the experiments the value estimated was 110 cal. per mole. Fortunately, in one case, the sulfur could be isolated, washed, and treated with ammonium hydroxide in the calorimeter and this value determined directly. The value found was 200 calories per mole.

The apparatus used in our calorimetric experiments, except those in the heat capacity of calcium sulfite dihydrate, is shown in Fig. 2. The

calorimeter was submerged up to the stopper in a large, stirred water-bath, the heavy copper parts serving to keep the top at approximately the temperature of the bath. At the beginning of the experiment, the stopper Ba and appurtenances were inverted, the stopper Ba adjusted, and the vessel B filled with a known weight of 1:1 hydrochloric acid. Stopper Bb was then adjusted, the Dewar flask A filled with a known weight of water and of calcium sulfite or of calcium thiosulfate solution of equivalent strength. The stopper Ba and appurtenances were then put in place. The thermel, E (in most cases a 15 junction thermel belonging to Dr. White) was inserted, the calorimeter placed in the bath, and the run begun,8 using all the usual precautions of the fore period and stirring described in Dr. White's paper.9 At the moment of mixing, stirring was stopped and the stoppers Ba and Bb were pushed out by means of rod Bc, the stopper Bb swinging back against the wall of the Dewar flask on the platinum wire hinge Be. Stirring was then started and the run com-

pleted in the usual manner. The heat capacity was determined electrically, using the heater D. The current and the voltage were read on a White double potentiometer, the time being controlled by a very accurate interval switch belonging to Dr. White. The final values for the two reactions are: for Reaction (1), 0.0638 mole of CaS_2O_3 in 302 g. of soln. +64.02 g. of 1:1 HCl solution = 205.51 calories of heat absorbed. The sulfur formed

⁷ Lewis and Randall, "The Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Co., 1923, p. 532. The nomenclature of these authors is adopted throughout this paper.

⁸ All of the calorimetric determinations except those starred were carried out in Dr. White's laboratory in the Geophysical Laboratory in Washington, D. C., often with Dr. White's personal assistance. I wish here to express my gratitude to Dr. White for these many courtesies.

⁹ White, This Journal, 40, 1872 (1918).

contained 10.1% S_u. (2)* 0.06374 mole of CaS₂O₃ in 302 g, of solution + 63.99 g. of 1:1 HCl = 206.60 calories of heat absorbed. In this run the calorimeter was washed, 0.5 M ammonium hydroxide added to the vessel B and water added to the vessel A. When these were mixed there was a quick evolution of heat, followed by a slow evolution of heat amounting to about 10 calories, or 200 calories per mole of sulfur present. Calculation gives 110 calories per mole for the reaction $S_{\lambda\mu} = S_r$, on the assumption that the sulfur is "hardened" before the run began, and 365 calories on the assumption that it is not. (3) 0.06382 mole of CaSO₃.2H₂O (10.381 g.) and 290.1 g. of H₂O + 64.00 g. of 1:1 HCl solution = 212.5 calories of heat evolved. (4) 0.0639 mole of CaSO₃.2H₂O and 290.3 g. of water + 64.05 g. of 1:1 HCl solution = 212.2 calories of heat evolved. (5)* Another sample of calcium sulfite dihydrate calculated to the same weight gave 215.0 cal. We shall take for the reaction CaS2O3 (0.2127 mole per 1000 g. of soln.) = $CaSO_3.2H_2O + S_r$, $\Delta H = -6300$. believed that the total error due to heat losses, etc., does not amount to over 10 calories per mole, but due to the slowness of the reaction involving thiosulfate and sulfur the error in the total heat of reaction may be many times this, say, 1000 calories per mole.

Heat of Dilution.—Using the same apparatus, the heats of the following reactions were determined. (1) (1 mole of CaS₂O₃ in 33.50 moles of H₂O) + (197.4 moles of H_2O) = (1 mole of CaS_2O_3 in 230.4 moles of H_2O); $\Delta H = 408.5 \text{ cal.}$ (2)* (1 mole of CaS₂O₃ in 33.4 moles of H₂O) + 197 moles of $H_2O = (1 \text{ mole of } CaS_2O_3 \text{ in } 230.4 \text{ moles of } H_2O)$; $\Delta H = 407.9$ (3) (1 mole of CaS_2O_3 in 33.5 moles of H_2O) + (0.734 moles of CaS_2O_3 in 164.8 moles of H_2O) = (1.724 moles of CaS_2O_3 in 198.3 moles of H_2O); $\Delta H = 177.5 \text{ cal.}$ (4)* (1 mole of CaS₂O₃ in 33.5 moles H₂O) + (320 moles of H_2O) = (1 mole CaS_2O_3 in 353.5 moles of H_2O); $\Delta H = 353$ cal. It would have been better to carry out measurements in even more dilute solutions but the advantage of this was not realized until the apparatus was no longer available. Reaction 3 can be combined with Reaction 1 giving Reaction 3a, that is, (1 mole of CaS₂O₃ in 33.5 moles of water) + (83 moles of H_2O) = (1 mole of CaS_2O_3 in 116 moles of H_2O); $\Delta H = 274$ cal. It will be noted that of Equations 1, 3a and 4, each gives the heat effect of adding x moles of water to a thiosulfate solution of the same strength. It happens that the data for these experiments fall on an hyperbola whose equation is $\Delta H = \frac{N'_1}{0.163 + 0.00168 N'_1}$ where N'_1 is the number of moles of water added to 1 mole of calcium thiosulfate dissolved in 33.5 moles of H₂O. Changing units we obtain $^6\Delta H = \frac{N_1 - c}{E_1 + BN_1}$ where N_1 is the number of moles of water in the final solution to 1 mole of calcium thiosulfate. E = 0.107; c = 33.5 and b = 0.00168. Now $\frac{\partial H}{\partial N_1}$ = $\overline{L_1}$ the partial molal heat content of the water of the solution and $N_1 \frac{\partial \overline{L_1}}{\partial N_1} = \partial \overline{L_2}$. Or, carrying out the indicated transformation, $\overline{L_1} = \frac{E + bc}{(E + bN_1)^2}$ and $\overline{L_2} = \frac{E + bc}{b} \left\{ \frac{E + 2bN_1}{(E + bN_1)^2} \right\}$. Values of $\overline{L_1}$ and $\overline{L_2}$ for the mol ratio N_1 given in Col. 1 are tabulated in Table III.

Specific Heat of Solutions of Calcium Thiosulfate.—Incidental to determining the heat of dilution, the specific heats of the various concentrations of calcium thiosulfate were determined. The values found were 0.704, 0.769, 0.840, 0.918, 0.954 for solutions whose concentrations were 1.750, 1.3234, 0.888, 0.447 and 0.213 M, respectively. Using the method of intercepts, the values of \overline{c}_{p_1} and \overline{c}_{p_2} were determined. These values for the concentrations used in the equilibrium experiments are given in Table IV, Lines 2 and 3, respectively. Line 1 gives the concentration in moles per 1000 g. of water.

TABLE IV

Partial Molal Heat Capacity 0.1625 0.2665 0.393 0.618

Concil	0.1020	0.2000	0.585	0.019	0.713	1.120
\overline{c}_{p1}	18.00	17.99	17.98	1795	17.90	17.70

Heat Capacity of Calcium Sulfite Dihydrate.—A preliminary estimate of the change of heat capacity of the equilibrium reaction based on known data and a value for $c_p/\text{CaSO}_3.2\text{H}_2\text{O}$ based on Kopp's law showed that the Δc_p term in the free-energy equation would have quite exceptional importance. No value of the specific heat of calcium sulfite dihydrate, $\text{CaSO}_3.2\text{H}_2\text{O}$, being available in the literature, determinations were undertaken, using a simple calorimeter, and the drop method. Quartz was used as a comparison substance. Using two different samples of calcium sulfite, almost identical values were obtained, namely 0.274 and 0.273 calories per g. or 42.7 calories per mole. Kopp's law gives 41.1 calories per mole.

Free Energy of Dilution of Solutions of Calcium Thiosulfate.—In order to obtain the free energy of dilution of solutions of calcium thiosulfate, several series of freezing-point curves were made. The set in which most confidence can be placed was made with an apparatus similar to that described by Rodebush, 10 and Rodebush's original 4-junction thermel.

¹⁰ Rodebush, This Journal, 40, 1204 (1918).

Values of the concentration in moles per 1000 g. of solution and Δt are: m = 1.260, $\Delta t = -3.96$; m = 0.810, $\Delta t = -2.106$; m = 0.578, $\Delta t =$ -1.414; m = 0.264, $\Delta t = -0.623$; m = 0.0674, $\Delta t = -0.160$. Besides these, the following values at lower concentrations appear to possess some meaning: m = 0.02045, $\Delta t = -0.0482$; m = 0.0106, $\Delta t = -0.0282$; m = 0.00553, $\Delta t = 0.0156$. As far as these determinations go, the activity coefficient seems to be about that found by Lewis and Randall for bivalent sulfates. The best estimate appears to make the activity coefficient 0.40 at 0.01 M. Using this value as a basis, and following the methods of calculation used by Lewis and Randall, the values for γ , the activity coefficient at 25° of solutions of calcium thiosulfate for the equilibrium concentrations, were obtained. The heat capacity and the heat of dilution and its change with concentration were not neglected in this calculation. $m = 0.01, \gamma = 0.40; m = 0.20, \gamma = 0.165; m = 0.163,$ $\gamma = 0.149$; m = 0.2665, $\gamma = 0.127$; m = 0.393, $\gamma = 0.113$; m = 0.618, $\gamma = 0.0995$; m = 0.713, $\gamma = 0.0972$; m = 1.117, $\gamma = 0.0964$.

With these data at hand, it is now possible to calculate ΔF_{298} for the reaction CaSO₃.2H₂O + S_r = CaS₂O₃ aq. + 2H₂O, directly from the equilibrium measurements. It is convenient, however, instead, to modify the usual procedure somewhat, and calculate the activity of each of the solutions employed at the temperature of equilibrium. This is the true equilibrium constant of the actual reaction at that temperature.

The results for the logarithm of the equilibrium constant are: T $= 414, \log K = -2.971; T = 393, \log K = -2.630; T = 383, \log K =$ -2.334; T = 373, $\log K = -2.221$; T = 352, $\log K = -1.881$. This is the equilibrium constant for the reaction in which the sulfur is in the form stable at the temperature of the measurement, that is, the form given in Table I, Col. 4. The equilibrium constant for the reaction CaSO3.- $2H_2O + S_r = CaS_2O_3$ aq. $+ 2H_2O$ is slightly different from this. This correction may be calculated from the free energies of the various reactions: $S_r = S_{\lambda u}$, $\Delta F_{447} = -90$, $\Delta F_{414} = -35$, $\Delta F_{398} = -20$; $S_r = S_m$, $\Delta F_{383} = -2$, $\Delta F_{373} = -1$, as given by Lewis and Randall. Using the data on the heat capacity of H₂O and S_r given by Lewis and Randall, 12 together with the data obtained in this paper, the change of heat content for this reaction is: $\Delta H = -1945 - 14.02T - 0.00235T^2$ or $-RI \ln K$ $= -1945 + 14.02T \ln T + 0.00235T^2 + IT$. From this equation it may be calculated for T = 414, I = -67.1, T = 393, I = -67.8; T = -67.8383, I = -69.7; T = 373, I = -69.7; T = 353, I = -69.9. There appears to be a trend in the values of I, due presumably to a faulty value of the heat of reaction and also in part to the unsatisfactory freezing-point data. The best value appears to be I = -68.6. For the reaction S.

¹¹ Ref. 7, p. 532.

¹² Ref. 7, pp. 102, 531.

+ CaSO_{3.2}H₂O = CaS₂O₃ (M) + 2H₂O, therefore, ΔF° = 1310 calories. The error here is probably not over 300 calories and might easily be decreased, given better thermal and activity data.

Solubility of Calcium Sulfite Dihydrate.—The solubility of this substance has been determined by Weisberg¹³ and by van der Linden.¹⁴ Their results are 0.057 g. per liter at 18° and 0.065 g. per liter at 25°, respectively. However, it is difficult to prepare calcium sulfite dihydrate free from gypsum, the presence of which would affect the solubility very greatly. Van der Linden notes that his sulfite was not free from sulfate and hence presumably contained gypsum. At any event, the solubilities determined above are not consistent with the solubility of calcium sulfite dihydrate in a solution saturated with gypsum as determined by van der Linden, namely, 0.032 g. per liter. A series of determinations was therefore undertaken with various samples of calcium sulfite, in which the solution was saturated at 25° and titrated with 0.001 N iodine solution. Contrary to the common opinion, even more dilute solutions of iodine can be used without an abnormal blank correction, provided the solution is kept 0.1 N in iodide ion. The sulfite used was prepared, (1) by precipitating the salt from solutions of calcium chloride by the addition of sulfur dioxide and sodium hydroxide simultaneously, (2) by dissolving calcium sulfite dihydrate in a pure solution of sulfurous acid and precipitating the salt by boiling off the sulfur dioxide in a vacuum, (3) by washing the commercial salt with air-free distilled water. None of these samples was quite free from sulfate. The values for the solubility obtained were, respectively. 0.000202, 0.000107, 0.000087 mole per liter. The solubility of Samples 1, 3, and the commercial salt in the presence of solid gypsum were 0.0000371, 0.0000367, 0.0000372 mole per liter or 0.029 g. per liter, agreeing closely with the value of van der Linden. Taking 0.000037 as the final value and applying the principle of ionic strength,7 the mean activity of the sulfite and calcium ions in a saturated solution of calcium sulfite dihydrate at 25° is 0.000261; that is, for the reaction $Ca^{++} + SO_3^{--} + 2H_2O =$ CaSO₃.2H₂O, $\Delta F_{238}^{\circ} = -9740$ or, adding $\Delta F_{238}^{\circ} = -8430$ for the reaction $SO_3^{--} + S_r = S_2O_3^{--}$. Now, Lewis and Randall give for the free energy of formation of the sulfite ion, $\Delta F_{298}^{\circ} = -116,680$. Therefore, the free energy of formation of the thiosulfate ion in solution of unit activity is -125110 calories.

Summary

A complete thermodynamic study has been made of the reaction, $S + CaSO_3.2H_2O = CaS_2O_3$ aq. $+ 2H_2O$. This reaction has been proved to be reversible and the equilibrium constant has been measured at various temperatures. The heat of the reaction has been determined experi

¹³ Weisberg, Bull. soc. chim., [3] 15, 1097.

¹⁴ Van der Linden, Arch. Sukerind., 24, 1113 (1916).

mentally as have the specific heat, freezing point and heat of dilution of solutions of calcium thiosulfate of various strengths. The solubility of calcium sulfite dihydrate and its specific heat have also been measured. Using these and other data, the free energy of formation, ΔF_{208} ° of the thiosulfate ion has been calculated to be —125,110 calories.

THE CATALYTIC COMBINATION OF ETHYLENE AND HYDROGEN IN THE PRESENCE OF METALLIC COPPER II. MEASUREMENTS OF REACTION VELOCITY AT 150°, 200° AND 250°

By Robert N. Pease Received May 31, 1923

In a recent paper¹ the author has recorded results which indicate that the combination of ethylene and hydrogen in the presence of copper at 0° and 20° is, in its first stages, approximately monomolecular with respect to hydrogen, while ethylene in excess acts as an inhibitor. Grassi² has studied this reaction to some extent at temperatures between 150° and 275° and reports that in this region the reaction is bimolecular, as would be expected from the chemical equation. Grassi also found that the temperature coefficient between 150° and 275° was very small and decreased with rising temperature whereas between 0° and 20°, the author found the temperature coefficient to be in the neighborhood of 1.6 per 10°, which is of the same order as that for many uncatalyzed reactions. These marked differences in the characteristics of the reaction in the two temperature regions made it important to repeat a part of Grassi's work, especially as this investigator carried his determinations over only a small fraction of the total reaction.

The apparatus and method were the same as those used in the previous determinations at 0° and 20°, except that the temperature was maintained by means of an electrically heated air-bath. The copper catalyst in the state in which it was used for the runs at the lower temperature was much too active for use in the neighborhood of 200°. Partial de-activation was accomplished by heating it to 500-550° in a vacuum. During this treatment, the catalyst shrank about 15% of its original apparent volume and turned from a dirty red-brown to a salmon pink.

Reaction Velocity at 200°

The catalyst in the latter stage of activity was used for a series of runs at 200°. The results of this series, which are shown graphically in Figs. 1 and 2, indicate that the reaction is not exactly bimolecular as Grassi

¹ Pease, This Journal, 45, 1196 (1923).

² Grassi, Nuovo cimento, [6] 11, 147 (1916).

states, though it approximates to this. For a bimolecular reaction, Curve I for the 50% mixture should lie to the left of the other two, as it does, in accordance with the principle that for a bimolecular reaction the velocity is a maximum with such a mixture. The other two curves, corresponding to 2:1 mixtures, should coincide. Actually, the velocity appears to be somewhat greater when hydrogen is in excess.

The decrease in pressure when hydrogen is in excess, is probably due in part to the solution of hydrogen in the copper. It is certain that the copper was able to take up some hydrogen, as was shown by measurements at 200°

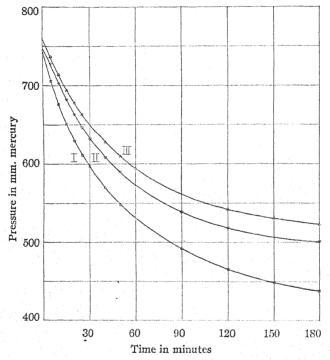

Fig. 1.—Reaction velocity at 200°, with initial pressure of 1 atmosphere. Curve I, 50% mixture, Run 105,[\bigcirc]; Curve II, $2H_2-1C_2H_4$, Run 110,[\triangledown]; Curve III, $1H_2-2C_2H_4$, Run 108,[\triangle]

of pressure against volume with pure hydrogen. After each addition of gas there was a slow "drift" in the pressure, lasting sometimes for hours, and the total hydrogen in the bulb at any pressure was distinctly greater than that of either helium or ethylene. (These two gases gave the same results within experimental error, indicating that only minimal amounts of ethylene are adsorbed.) While it is impossible to state with certainty that this hydrogen was dissolved and not adsorbed, everything points to this. Previous heat treatments had caused marked decreases in the ad-

sorption at 0° so that even at this temperature only a small adsorption was to be expected, and at 200° this must have been reduced to negligible proportions, if adsorption decreases with increasing temperature as is usually assumed. Nevertheless at 0.5 atmosphere and 200° , 1.0 cc. of hydrogen was taken up. This is as much as the same catalyst in a tremendously more active state took up at 0° . Furthermore, if this hydrogen is all adsorbed, it is adsorbed in many times greater quantity than ethylene.

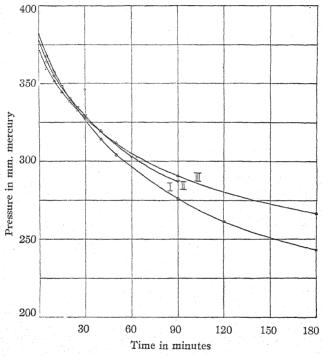

Fig. 2.—Reaction velocity at 200°, with initial pressure of 0.5 atmosphere. Curve I, 50% mixture, Run 106,[\odot]; Curve II, $2H_2 - 1C_2H_4$, Run 111,[∇]; Curve III, $1H_2 - 2C_2H_4$, Run 109,[\triangle]

This would lead one to expect a marked influence on the reaction velocity, when none is found.

Reaction-velocity measurements were carried out with 50% mixtures and mixtures containing 2 volumes of one gas to 1 volume of the other, each at initial pressures of 0.5 and 1 atmospheres. To determine how the reaction velocity varies with the hydrogen and ethylene concentrations, the decreases in pressure in millimeters of mercury from the 5th to the 15th minute (ΔP) have been compared with the initial volumes of each of the gases in the bulb. Thus, in one experiment there were 4.14 cc. of hydrogen and 8.10 cc. of ethylene, while ΔP was 15.0 mm. In another

there were 8.33 cc. of hydrogen and 4.17 cc. of ethylene, while ΔP was 16.5 mm. Again, in one experiment there were 8.52 cc. of hydrogen and 16.65 cc. of ethylene, while ΔP was 42.0 mm. In another, there were 16.65 cc. of hydrogen and 8.33 cc. of ethylene, while ΔP was 46.0 mm. It is seen that for the same amounts of 2:1 mixtures, the velocity is nearly the same whether hydrogen or ethylene is in excess, although an excess of hydrogen seems to correspond to a slightly greater velocity, as already mentioned. A comparison of reaction velocities when the amount of one gas is the same and the other is varied indicates, however, that a simple proportionality does not exist between gas concentration and reaction velocity. Thus, in two of the experiments, there were 8.10 cc. and 8.33 cc. of ethylene, respectively, while the volumes of hydrogen were 4.14 cc. and 16.65 cc. The corresponding reaction velocities were 15.5 mm. and 46.0 mm. The volumes of hydrogen stand in the ratio of 1:4.0. while the reaction velocities stand in the ratio of 1:3.0. In two other experiments the volumes of hydrogen were 8.33 cc. and 8.52 cc., respectively, while the volumes of ethylene were 4.17 cc. and 16.65 cc. The corresponding reaction velocities were 16.5 mm, and 42.0 mm. The volumes of ethylene stand in the ratio of 1:4.0 while the ratio of reaction velocities is 1:2.5. If it is assumed that the relation between reaction velocity and concentration can be expressed by $(dp/dt) = k \cdot V_{Ha}^{a} \cdot V_{Collar}^{b}$ these relationships would give a = 0.80 and b = 0.66. The reaction velocity seems to vary not as the first power of the concentrations but as the 0.8 power of the hydrogen concentration and the 0.66 power of the ethylene concentration. If it is assumed that reaction velocity is directly proportional to the product of the amounts of the two gases adsorbed, the adsorptions of the gases should vary with these same fractional exponents of the pressure.

The results of calculations of the velocity constant, k in the equation $(\mathrm{d}p/\mathrm{d}t) = k \cdot V_{\mathrm{H}_2}^{0.80} \cdot V_{\mathrm{C};\mathrm{H}_2}^{0.86}$, are given in Table I. The values of ΔP , the decrease in pressure from the 5th to the 15th minute, were substituted for $\mathrm{d}p/\mathrm{d}t$ and the initial volumes of hydrogen and ethylene for V_{H_2} and $V_{\mathrm{C};\mathrm{H}_2}$. Values of K were then calculated. $k = \Delta P/(V_{\mathrm{H}_2}^{0.8} \cdot V_{\mathrm{C};\mathrm{H}_2}^{0.66})$. It is seen that the constants agree reasonably well.

TABLE I

	THE VELOCI	TY CONST	ant at 20	0°		
Run No. 1	05 106	108	109	110 1:	11 11	2
$V_{\mathrm{H_2}}$	2.31 6.38	8.52	4.14 16	6.65 8	.33 12	.48
$V_{C_2H_4}$	2.31 6.37	16.65	8.10	3.33 4	.17 12	.57
$\Delta P \dots 5$	4.5 20.0	42.0 1	5.0 46			.0
<i>K</i>	1.4 1.3	1.2	1.2 1	1.2 1	.2 1	.3

It has already been mentioned that no measurable amount of ethylene is adsorbed at 200° and that it is very doubtful if hydrogen is, either.

Under these circumstances, it is not surprising to find that the reaction approximates more nearly to what one would expect, namely, a bimolecular reaction. The reaction at 0° was found to be approximately monomolecular with respect to hydrogen and to be partially inhibited by ethylene. This latter could be traced to the marked adsorption of ethylene by the catalyst. In the absence of such marked adsorption at 200°, no such effect would be expected and none is found.

Temperature Coefficient

Grassi² found that for equal initial concentrations (not pressures) of 50% mixtures, the initial decreases in pressure in each 10-minute interval

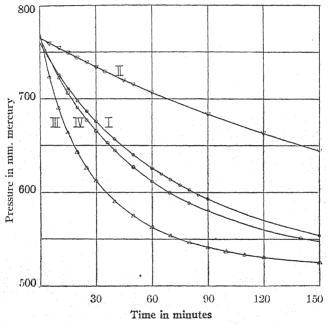

Fig. 3.—Reaction velocity at 150°, 200° and 250°, initial pressure of 1 atmosphere.—Mixture of $2C_2H_4-1H_2$. Curve I, velocity at 200°, Run 116,[\bigcirc]; Curve II, velocity at 150°, Run 117,[\bigcirc]; Curve III, velocity at 250°, Run 118,[\triangle]; Curve IV, velocity at 200°, Run 119,[\bigcirc]

at 150°, 200°, 250°, and 275° were 2.2, 10.7, 12.8, and 14.0 mm., respectively. When these are corrected for temperature, and 200° is taken as the standard, they become 2.4, 10.7, 11.6, 12.1 mm. Since the concentrations are the same, the velocity constants are directly proportional to the above corrected pressure decreases. These correspond to a very small and continuously decreasing temperature coefficient.

For comparison with Grassi's results, the author measured the reaction velocity at 150°, 200° and 250°. In these experiments a mixture of 1

volume of hydrogen to 2 volumes of ethylene was used, as it was thought that there would be less interference due to solution of hydrogen with such a mixture. The results of these measurements are shown graphically in Fig. 3. In Table II are given values of k calculated by the same relation as before, namely, $k = \Delta P/(V_{\rm H_2}^{0.8}, V_{\rm C_2H_4}^{0.66})$. The values of ΔP have been corrected for temperature. The volumes are those at 0° and 760 mm.

 $\label{table II}$ Reaction Velocity at 150°, 200° and 250°

	Temp.				•			
Run No.	۰c.	$V_{ m H2}$	V_{G2H4}	ΔP	k	$\Delta k/_{10}$ °	$\Delta P(\text{Grassi})$	$\Delta k/_{10}$ °
116	200	8.40	16.79	36.5	1.05 $)$	1.31	10.7	1.35
117	150	9.30	18.60	11.2	$0.27 \int$	1.91	$2.4\int$	1.00
118	250	7.67	15.35	53.8	1.74	1.15	11.6	1.02
119	200	8.32	16.63	30.0	0.85∫	1,10	(10.7)	1.02

Unfortunately, there was a noticeable decrease in activity during these runs. This has been taken into account in calculating temperature coefficients.

For comparison, the values of ΔP from Grassi's results are given. These correspond directly to velocity constants, since the gas concentrations were made the same at the different temperatures. It will be seen that between 150° and 200°, the temperature coefficients of reaction velocity calculated from the two sets of results are in good agreement (1.31 and 1.35). Between 200° and 250°, the author's results give a distinctly higher coefficient than do those of Grassi, (1.15 and 1.02). Both sets agree, however, in assigning a very small and continuously decreasing coefficient to the reaction. The decrease in temperature coefficient between the 150–200° regions and the 200–250° regions is abnormally large even with the authors'

values. On the basis of the Arrhenius equation, $\log \frac{k_2}{k_1} = \frac{A}{4.57} \cdot \frac{T_2 - T_1}{T_1 \cdot T_2}$, there is a normal decrease with increasing temperature if A, the so-called "heat of activation," is regarded as constant. The observed values of k are not in agreement with this assumption, however, the calculated values of A being 10800 cal. between 150° and 200° and 7000 cal. between 200° and 250°. As an explanation of the anomalous result just mentioned, the decrease in the adsorptive power of the contact mass with increasing temperature suggests itself. The active masses in a contact catalytic action are functions of the amounts of reactants adsorbed. In comparing reaction rates at two temperatures, the comparison should therefore be made at such gaseous concentrations that equal amounts of reactants are adsorbed at the two temperatures. Actually, comparisons are made at equal gaseous concentrations, corresponding to continuously decreasing adsorptions, or surface concentrations, with increasing temperature. This leads to temperature coefficients (and heats of activation) smaller

than the true ones corresponding to the reaction on the surface and continuously decreasing, unless the adsorption is a linear function of the temperature. The observed temperature coefficient is composite of two effects, namely, the true positive coefficient of the surface action and the negative coefficient of adsorption. In the present case the adsorptions at the temperatures in question were not measurable in the case of ethylene and are of doubtful significance in the case of hydrogen, so that no such correction can be made. That the adsorption of ethylene by copper does decrease markedly through a part of the temperature region is shown by the results of Taylor and Burns,³ who found that the adsorption at 1 atmosphere on a particular sample of copper was 0.65 cc. at 110° and not measurable at 218°. Experiments are at present in progress to determine the temperature coefficients of adsorption of ethylene and hydrogen on active copper between 0° and 200°.

Although the absolute reaction velocities in the experiments at 0° and 20° already reported are not directly comparable with those just given because of the enormous difference in catalytic activity, it might be expected that the temperature coefficients of reaction velocity (and the heats of activation) might be compared. The velocity constants at 0° and 20° were 0.50 and 1.32 in the particular units chosen, leading to a temperature coefficient of 1.62 per 10° and a heat of activation of 7700 cal., a value which lies between the two obtained at the higher temperatures (10,800 cal. and 7000 cal.). Since the adsorption of hydrogen at 0° and 20°, upon which the reaction appears to depend in this region, was the same, one would have expected that the temperature coefficient and heat of activation in this temperature region would have been the true one for the surface action on the basis of the argument already given. In this case a value for the heat of activation considerably larger than that at the higher temperature was to have been expected instead of an intermediate value. Perhaps further discussion may best be postponed until more results have been accumulated. It is of interest, however, to find that the heats of activation for the reaction in the presence of the copper catalyst in two such different states of activity are of the same order.

This investigation was carried out with the aid of a National Research Fellowship in the Laboratory of Physical Chemistry, Princeton University.

Summary

Measurements of the velocity of combination of hydrogen and ethylene in the presence of copper at 150°, 200° and 250° have shown that in this temperature region the reaction is more nearly bimolecular, in contrast to the combination at 0°, at which temperature the reaction is approximately monomolecular with respect to hydrogen and inhibited partially by excess

^{*} Taylor and Burns, This Journal, 43, 1273 (1921).

of ethylene. The more nearly normal character of the reaction at the higher temperatures is believed to be due to the fact that under these circumstances the reacting gases are not measurably adsorbed by the catalyst. The temperature coefficient is much smaller at the higher temperature and is decreasing. By taking into account the decrease of adsorption with rise in temperature as well as the normal increase in velocity of the surface reaction, these facts have been accounted for qualitatively.

THE KINETICS OF THE CONVERSION OF CREATINE INTO CREATININE IN HYDROCHLORIC ACID SOLUTIONS

By Graham Edgar and R. A. Wakefield Received June 4, 1923

Introduction

The literature contains numerous references to the conversion of creatine into creatinine in the presence of acid catalysts. Practically all of these investigations have either been purely qualitative in nature, or have been concerned with determining the conditions under which the reaction goes to completion, in order to permit the quantitative estimation of creatine (as creatinine) by the colorimetric method of Folin.¹

The reversible reaction

$$H-N = C \begin{cases} NH_2 \\ N-CH_2COOH \end{cases} \longrightarrow H-N = C \begin{cases} NH-C = O \\ N-CH_2 \\ CH_3 \end{cases}$$

$$Creatine \qquad Creatinine$$

$$CT = O \\ CH_3 \\ CT = O \\ CH_3 \\ CT = O$$

$$CT = O \\ CT = O$$

is of great interest in biochemistry, as it occurs in the normal and abnormal processes of the metabolism; it is also of interest from the theoretical standpoint, as it represents a type of reaction catalyzed by acids to which less attention has been paid than those of ester hydrolysis and similar reactions. The present paper represents a brief study of the kinetics of the reaction in the presence of hydrochloric acid as a catalyst.

Experimental Methods

Materials.—Commercial creatine of very good quality was purified by two crystallizations from water, and was allowed to dry in the air. The product was pure white, odorless, and finely crystalline. Other reagents used were commercial c. p. products.

As analytical standards pure creatinine picrate² and creatinine zinc chloride were employed.

¹ Folin, Am. J. Physiol., 13, 48 (1905).

² Edgar, J. Biol. Chem., 56, 1 (1923).

Apparatus.—The reaction-velocity experiments were carried out in test-tubes fitted with rubber stoppers. These were kept at constant temperature by immersion in boiling water, alcohol or acetone, the mean temperatures being taken as 100°, 78° and 57°, respectively; a temperature of 25° was obtained by use of an electrically controlled thermostat.

For the analysis (colorimetric) a Duboscq type of colorimeter was employed, illuminated by a special colorimeter lamp.

Experimental Technique.—The pure creatine was dissolved in water and a measuredquantity of the solution was put into a test-tube and brought to the desired temperature. A definite quantity of standard hydrochloric acid (previously heated to the same temperature as the creatine) was then added, and the mixture placed in the constant temperature bath. A series of similar tubes was used in each run, in order to avoid loss of time in removing and measuring samples for analysis. At the end of given time intervals, separate tubes were removed from the bath and the reaction was stopped by adding immediately a quantity of sodium hydroxide solution equivalent to the acid, and cooling rapidly. The solution was then analyzed for creatinine formed, by the wellknown Folin¹ method, making use of the red color developed when creatinine is treated with picric acid and sodium hydroxide. A standard solution of creatinine (as picrate or as creatinine zinc chloride) was treated with picric acid and alkali in exactly the same way as the unknown solution, and the color was compared as usual. Repeated colorimeter readings were taken and all precautions necessary to obtain precise results with this method were observed. The accuracy is believed to be about 1% of the total creatinine present.

Results.—The results of a characteristic experiment are given in Table I, together with reaction-velocity constants calculated for a first order reaction. Table II gives the average values of the constants calculated from experiments under other conditions; the agreement of individual constants was in all cases similar to those in Table I. Table II also contains values calculated from an equation derived below.

Discussion

General.—Reaction 1 proceeds in pure water to a condition of equilibrium³ in which the ratio of creatine to creatinine is of the order of unity. Creatinine is, however, much more basic than creatine, and in the presence of acid the reaction goes "to completion" with the formation of a salt of creatinine.⁴ It is obvious from the data in Table I, (confirmed by the actual data from which Table II is constructed) that under these conditions of experiment the reaction is essentially unimolecular. Whether or not an actual bimolecular reaction with the hydrogen-ion catalyst is involved⁵ cannot be determined from the data, although it seems probable from the data given in the following paragraph. It may be noted that combination of the creatinine with the acid presumably reduces the concentration of catalyst somewhat as the reaction proceeds; it is therefore necessary to keep the concentration of creatine small as compared with that of the acid; this has been done in all experiments, as is shown by the data in Table II.

The Effect of Acid Concentration.—The velocity constants obviously increase with the concentration of acid, increasing from the values in 0.19 N hydrochloric acid to those in 0.76 N acid (Expts. 3, 5 and 7, Table II), somewhat more rapidly than the increase of the acid concentration, although the slope of the velocity-constant—acid-concentration curve passes through an apparent minimum around 0.4 N hydrochloric acid. This is in accordance with data of other investigators on other reactions catalyzed by hydrochloric acid, and it seems probable that the velocity constants are proportional to the hydrogen-ion activity, although the data do not enable an exact comparison to be made.

The Temperature Coefficient.—The data in Table II show that at any given concentration of hydrochloric acid the effect of temperature may be expressed by the Arrhenius⁶ equation

$$\frac{\mathrm{d}\ln K}{\mathrm{d}T} = \frac{E}{RT^2} \tag{2}$$

where E is the "critical increment" or "heat of activation." For a concentration of hydrochloric acid equal to 0.38 N the values calculated for the temperature intervals 25–57°; 57–78°; 78–100° are 19050, 20400, 20500 calories, respectively, indicating that for this temperature range E may be regarded as practically independent of the temperature. A similar calculation of the value of E for an acid concentration of 0.19 N and a temperature range of 78–100° gives a value of 19790 calories, indicating that for this range of concentrations E is independent of the acid con-

⁶ Arrhenius, Z. physik. Chem., 4 (1889).

centration. We can therefore express the velocity constants under the whole range of conditions approximately by the integrated equation

$$\ln K = -\frac{E}{RT} + C \tag{3}$$

where E has the mean value of 20,000 calories, and the value of the constant C depends upon the concentration of acid. Changing to ordinary logarithms, Equation 3 becomes

$$\log K = -\frac{4368}{T} + C' \tag{4}$$

the average values for the constants for the three acid concentrations being as follows: $0.19\ N$ HCl, C'=9.8496; $0.38\ N$ HCl, C'=10.1538; $0.76\ N$ HCl, C'=10.5400. If these values are substituted in Equation 4 and the values of K calculated for the different experiments we obtain the results given in the last column of Table II, which agree reasonably well with the experimental values. If the values of C are plotted against the acid concentration we may obtain by interpolation, values of the constant for any acid concentration within the range studied, which will enable the calculation of an approximate velocity constant at any temperature. This may be of use in determining the time necessary for practically complete conversion under various conditions, as in the analysis of creatine solutions.

It may be noted that the value for the critical increment is of the same order as that observed by various investigators for many other cases of acid catalysis in different types of reaction.

Summary

- 1. Measurements have been made of the rate of conversion of creatine into creatinine in hydrochloric acid solution at various temperatures and concentrations of acid.
- 2. The general nature of the reaction, and the influence of temperature and acid concentration are discussed.

A STUDY OF THE MOVING BOUNDARY METHOD FOR DETERMINING TRANSFERENCE NUMBERS

By Duncan A. MacInnes and Edgar Reynolds Smith Received June 27, 1923

In our study of solutions of strong electrolytes it became desirable to obtain accurate transference numbers of a number of salts throughout a range of concentrations. From its apparent precision and the rapidity with which the measurements can be made, the moving boundary method

for obtaining these numbers seemed attractive, and a careful study of the method was accordingly undertaken.

As usually described, the moving boundary method for determining transference numbers is as follows. The transference number of one of the two ions of a salt is equal to the distance moved by the boundary of one of the ion constituents divided by the distances moved in the same time and under the same potential gradient by the boundaries of both ion constituents. These distances can be measured in an apparatus shown diagrammatically in Fig. 1. A solution of the salt CA under investigation is placed between one of CA' and another of C'A, having, respectively, the same cation and anion as the salt CA. The boundary at a and that at b are visible because of the different refractive indices of the solutions. On passing current through the apparatus the boundary a moves up to a' and the boundary b moves down to b'. The ratio: aa'/(aa' + bb') is equal to the transference number T_a . The solution of C'A must be lighter, and that of CA' heavier, than the solution of CA, and the ions C' and A' have smaller mobilities than the ions C and A, respectively, in order that the boundaries shall persist during the passage of current. The apparatus can also be constructed in the form of a U-tube, in which case both of the following or indicator solutions must be lighter than the solution whose transference number is being measured.

Fig. 1 Aside from the purely qualitative early work by Lodge¹ and others, the only workers who have published measurements made by this method are Denison and Steele,² and later Denison.³ These workers obtained a large amount of transference data including measurements on most of the more common strong electrolytes at various concentrations.

The authors of the present article have made an endeavor to extend and amplify Denison and Steele's work. In the first part of the investigation, after obtaining sharp and readily visible boundaries (which proved to be by no means easy), it was found that, although precise measurements could be obtained, the results were not reproducible unless all possible variables, such as impressed e.m.f. and the kind and the concentrations

of the salts forming the indicator solutions, were kept constant. Also, the results obtained departed widely and erratically from the accepted values of the transference numbers. A single instance of the difficulties encountered will suffice. Measurements were made on a 0.1 N solution of potassium chloride, using 0.1 N lithium chloride and potassium acetate solutions as indicators. The "transference numbers" at 135, 230 and 325 volts were 0.638, 0.550 and 0.531, respectively. These values were reproducible to about 0.1% at each voltage, though they all depart widely from the correct value, 0.508.4 It is interesting to note that the values approach nearer to the correct number for the higher potentials. A change of the nature or concentrations of the indicator solutions leads to quite different results from those given.

From these and many other similar discouraging results it became quite evident that either the method was useless or some additional factor must enter. In correspondence with Professor Denison he suggested that the concentrations of the indicator solutions should be adjusted according to the relation,

$$C/T = C'/T' \tag{1}$$

in which C and T are the concentration and the transference numbers of the solution under observation and C' and T' are the corresponding values for the indicator solution. Kohlrausch, 4 in an early paper, derives this relation as a necessary condition for a stable moving boundary. He states, however, that the condition represented by that equation will automatically be established, if not present at the outset, from which it would be concluded that the initial concentration of the indicator solution is of little importance. Later, it was given a simpler derivation by Denison. 5 Denison and Steele^{2a} also state that the condition represented by Equation 1 establishes itself automatically, and give no limits to this spontaneous adjustment. These authors say, "It has been proved that the concentration of the lithium chloride (indicator solution) becomes automatically adjusted, so that the potential gradient is just sufficiently increased to make the lithium ions keep pace with the potassium ions," the latter being the ions of which the transference number is wanted. Denison⁵ has shown in his derivation that, under the conditions given, Equation 1 holds.

It became of interest to us therefore to determine (a) whether the boundaries move at the theoretical velocities if the condition given in Equation 1 is fulfilled at the boundaries, and (b) whether any of the automatic adjustment, predicted by Kohlrausch, takes place. It is evident that if the concentrations of the solutions must be exactly adjusted according to the ratio given by Equation 1, the moving boundary method is useless for obtaining transference numbers, since these numbers, as well as

⁴ Kohlrausch, Ann. Physik, 62, 209 (1897).

⁵ Denison, Z. physik. Chem., 44, 581 (1903). See also Miller, ibid., 69, 436 (1909).

those of the indicator solutions at a series of concentrations, must be known in advance. On the other hand, if there is even a small amount of the automatic adjustment predicted by Kohlrausch the correct transference numbers can be arrived at as the result of a series of experiments which approximate, more and more closely, to the theoretical conditions. This will be discussed more fully, later.

Because of a reduction of the number of variables and the ease of practical manipulation the apparatus we finally used involved only one moving boundary. If the current through the apparatus is kept constant throughout the experiment the transference number can be computed with as great accuracy as from the movement of two boundaries, provided, of course, that the boundary moves at the rate required by the theory under the conditions of the experiment.

The equations involved in the computation of the ionic mobilities and transference numbers when only one boundary is used are obtained as follows: If V is the velocity with which the ion constituent moves and U_1 its mobility, and ϵ the potential gradient then

$$V = U_1 \epsilon \tag{2}$$

Now the current through the tube, i, is determined by Equation 3, in which C is the concentration, A the area of tube and F the Faraday equivalent;

$$i = (U_1 + U_2) \epsilon CAF \times 10^{-3} = \epsilon \kappa A$$
 (3)

since the specific conductance, $\kappa = (U_1 + U_2)CF \times 10^{-3}$. From (2) and (3) then

$$U_1 = V \kappa A / i = l \kappa A / i t \tag{4}$$

in which l is the distance along the tube moved by the boundary in the time t.

From the mobility U_1 the transference number can, of course, be computed, but the transference number can also be computed from the measurements without a knowledge of the specific conductance, since

$$V = U\epsilon = T\Lambda\epsilon/F$$
now $\epsilon = i/\kappa A$ and $\Lambda = 1000\kappa/C$, therefore, ϵ

$$T = VCFA/1000i = lCFA/1000it$$
 (5)

Apparatus and Procedure

The cell shown in Fig. 2 was used for the study of the individual mobility of an ion constituent and the determination of transference numbers by the single boundary method.

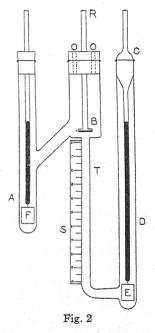

Let us consider the case of the measurement of the mobility of the potassium-ion constituent in a solution of potassium chloride. The electrode vessel D and measuring tube T are filled with the potassium chloride solution, which is kept out of

 $^{^6}$ Since lA is the volume swept through during the time t, and it is the number of coulombs, the transference number can be found by measurement with one boundary and a measurement with a coulometer in series, a principle we may make use of in future work.

B and A, and the combination ground glass stopper and electrode tube C is put firmly in place. In this case the electrode E is a piece of platinum gauze plated electrolytically with silver and then covered with silver chloride by electrolysis. This ground glass stopper C was used instead of rubber because the latter, when pushed strongly into the tube, may undergo a slow expansion which would influence the motion of the boundary. The glass rod R has a flat circular enlargement, B, on the lower end, which is tipped with a circular disk of thin rubber held on by a small central spot of de Khotinsky cement. This rod, which slides easily through the hole in the rubber stopper, is next pressed firmly over the top of T and the entrapping of air bubbles under it is avoided. Any excess of solution squeezed out of T and into B by this action is removed by a capillary pipet

thrust through one of the openings, marked O, in the rubber stopper. The electrode vessel A is then filled with lithium chloride solution and the anode F, which consists of a platinum gauze electroplated with silver, is inserted. The apparatus is next placed in a glass walled thermostat (regulated to $25^{\circ} \pm 0.05^{\circ}$), and the connections to the source of voltage are made. Then lithium chloride solution is pipetted through one of the openings marked O until B is filled. R is then gently loosened, but not yet pulled up, so that several milliamperes pass. The boundary between the lithium and potassium ions at once starts down the tube T. After the boundary has advanced about a centimeter the rod R is carefully pulled up. It was found possible to discard entirely the parchment paper used at the point corresponding to B in Denison and Steele's apparatus. The use of this paper is quite objectionable as it soaks up, from the tube T, solution which is afterward released into the indicator solution.

The boundary was rendered visible by means of an arrangement similar to that used by Denison and Steele. A sheet of white paper was fastened on a frame and placed behind the thermostat. Two electric light bulbs were put behind the paper. By means of a cord and pulley a piece of black cardboard could be raised and lowered between the illuminated paper and the back of the thermostat.

the thermostat. When the cardboard was raised to a position just below the boundary the latter became visible and could be read, on the scale S, readily to 0.1 millimeter.

The current through the tube, which was of the order of a few milliamperes, was maintained constant, within a few tenths of a per cent. by hand regulation of a rheostat in the circuit. Its value was known from the potential drop, measured with a potentiometer, across a standard resistance. The regulation was effected by observation of the scale of the galvanometer connected with the potentiometer. The source of current was a storage battery yielding 90 volts, to which was occasionally added a battery of dry cells. The volumes, corresponding to readings of the scale S in the tube T were obtained by means of a calibration with mercury. The length of T effective for measuring the motion of the boundary was 9 cm. and the scale S was graduated in millimeters. The position of the boundary could be estimated to the nearest 0.1 mm., so the precision of measuring the distance moved by the boundary was 0.2% or better.

The Experimental Results

All the figures obtained in a single experiment, with the apparatus just described, are given in Table. I These results show the constancy of the

velocity of the boundary during its whole passage down the tube, provided a constant current is sent through the apparatus. All the results given later in this article are averages of figures obtained as in this typical experiment and having about the same experimental accuracy. In making the readings times were read on the second that the boundary passed a given line on scale S.

In all the experiments the cathode side of the apparatus was closed in order that there might be no movement of the boundary arising from changes of level of the solution due to the electrolysis. It is necessary, however, as G. N. Lewis⁷ has pointed out, to consider a correction for the volume change at the cathode during the passage of the current. However, at $0.1\ N$ this correction is only one part in 5,000 for both salts.⁸

It will be recalled that the main purpose of this investigation was to determine the effect of the concentration of the indicator solution, and the current density, on the velocities of the boundaries, and the resulting effect on the computed mobilities and transference numbers. In Tables II to V are given the results of measurements on boundaries formed, in each case, with the solution being measured at 0.1 N and varying concentrations of the indicator solutions. Tables II and III are the results obtained on the movement of the boundary between potassium and lithium chlorides with two different potential gradients in the tube, and Tables IV and V are corresponding results for potassium bromide solutions. The figures given in Tables IV and V are averages, in each case, of closely agreeing duplicates, whereas the corresponding figures in Tables II and III represent single experiments.

⁷ Lewis, This Journal, 32, 862 (1910).

⁸ Lewis' formula is: N=N'-vc, in which N is the Hittorf transference number, N' the uncorrected value from the moving boundary measurements, v the volume change at the electrode due to the passage of a Faraday, and c the concentration. The cathode reaction consists of (a) the formation of 1 equivalent of silver, (b) the formation of N equivalents of potassium halide and (c) the disappearance of an equivalent of AgCl. For KCl the resulting volume changes are (a) 10.3 cc., (b) 13.5 cc. and (c) 25.7 cc., the term (b) being the partial molar volume of KCl in 0.1 N solution, computed in the usual way from density measurements, multiplied by 0.49. The net change of volume is therefore 0.002 liter and the correction term 0.0002. The corresponding terms for KBr are (a) 10.5, (b) 17.3 and (c) 29.7.

numbers) varies widely with the concentration of the following, or indicator, solution. However, at $0.065\ N$ for potassium chloride and at about the same concentration for potassium bromide there is a minimum in the curves. Within the experimental error the measured mobility at this

point is unaffected by changing the potential gradient. In addition, at this point, the relation between the concentrations of the measured and indicator solutions corresponds closely to Equation 1

$$C/T = C'/T'$$

For lithium chloride, for instance, the value for T' computed from Equation 1 is 0.320 whereas the results of MacInnes and Beattie⁹ give by inter-

⁹ MacInnes and Beattie, This Journal, 42, 1117 (1920).

polation the value of 0.316 for this concentration. The agreement would be exact if the minimum were taken as $0.064\,N$. In addition it will be seen, from an examination of the tabulated data, that on either side of the minimum there is a range of concentrations of indicator solution (about 5%) in which the measured mobilities and transference numbers are independent of this concentration within the experimental error. Apparently throughout this small range the automatic adjustment of the concentration of the indicator solution, as predicted by Kohlrausch, does take place. Outside this range the adjustment quite as evidently fails to occur. Erroneous values for transference numbers will therefore be obtained if the concentration of the indicator solutions is not adjusted within this range.

Some results have also been obtained which show that if the composition of the indicator solution is adjusted according to Equation 1, the transference number obtained by observation of the moving boundary is, within the experimental error, independent of the potential gradient. The figures are given in Table VI. The boundary becomes invisible, under the conditions of the experiments, with a potential gradient lower than about 2 volts per cm. If too large a potential gradient is used the boundary is distorted by heating effects.

Table VI Results of Moving Boundary Experiments at Different Potential Gradients Concentrations. KCl = $0.1\ N$; LiCl = $0.065\ N$

3.315	2.25	657	.492		
2.951	2	No boundary visible			

In practical use of the moving boundary method for determining transference numbers an estimate of the probable value of the number should be made and the indicator solution concentration should then be computed according to Equation 1, and a measurement made. The indicator concentration should then be varied slightly and the measurement repeated. This should be continued until a portion of a plot similar to Fig. 3, and including the minimum value, can be prepared.

Further, the value obtained should be shown to be independent of the current through the apparatus, that is, to the potential gradients in the solutions. This procedure may sound tedious, but it is far more rapid, and also more accurate, than the determination of the same numbers by the Hittorf method. It also appears desirable that evidence showing that the adjustment of the compositions of the measured solution and the indicator

solution has been obtained, should be given in all future work with the moving boundary method.

It does not, at present, appear to be possible to give a clear picture as to why the boundaries move too fast on both sides of the "adjustment" represented by Equation 1, and why, on the side of a too dilute indicator solution, the apparent mobility passes through a maximum and then again decreases. Some experiments under consideration will, we hope, throw light on the subject. It seems probable, however, that if the adjustment to the conditions of Equation 1 cannot take place by the dilution of the indicator solution, the adjustment may occur in the leading solution.

The Transference Numbers

In this investigation we have obtained accurate transference numbers for potassium chloride and potassium bromide solutions at 0.1~N and at 25° . The value for potassium chloride, $0.492~\pm~0.001$, agrees substantially with the value, 0.493, given, by Denison and Steele. It is, however, somewhat lower than the number given by the Hittorf and e.m.f. methods, which average about 0.496.

Our transference number for potassium in potassium bromide, 0.485, lies between the value, 0.480, obtained by Denison and Steele by the moving boundary method, and the number, 0.495, found by Jahn and Bogdan¹⁰ at 18°, and the same value obtained at 25° by Pierce and Hart¹¹ in an extensive investigation by the electromotive-force method.

This investigation was originally undertaken to obtain data for a further test of the relation

$$T \wedge \eta^n = K \tag{6}$$

in which T is the transference number, Λ the equivalent conductance, η the relative viscosity, and the exponent n an empirical constant. For the series of alkali chlorides and hydrochloric acid K has been found, by one of the authors, 12 to be a constant at any one concentration. Physically, K is the conductance of the ion in a solution whose relative viscosity is unity. Table VII gives the data and the computation for the potassium ion from the two salts at $0.1\ N$ and 25° . The effect of the viscosity is small,

but noticeable, at this low concentration. The exponent, n, has been assumed provisionally to be unity. It appears then, for this limited amount of data at least, that within the limit of error Equation 6 holds for the potassium ion as well as for the chloride ion. It is hoped to extend this investigation to cover a wide range of strong electrolytes.

Summary

A modification of the moving boundary method of Denison and Steele for determining transference numbers, involving a single boundary, has been developed.

The boundaries move with the theoretical velocities only when the two solutions in contact at a boundary are adjusted, within about 5%, to the relation C/T = C'/T' in which C and C' are the concentrations and T and T' are the transference numbers. The correct value for T can therefore be obtained by a series of experiments approaching more and more closely to this condition. Unless this adjustment is obtained results are not independent of the composition of the indicator solution, or of the current through the apparatus, and may vary widely and erratically from the true values.

Transference numbers at 25° , for potassium chloride and potassium bromide in $0.1\,N$ solutions have been obtained. These numbers show that the conductance of the potassium ion is the same in these two solutions if correction is made for viscosity.

THE WETTING OF GLASSES BY MERCURY¹

By Earle E. Schumacher Received June 30, 1923

A number of observers have held that mercury does not wet glass because the latter is always covered by a film of adsorbed gas which prevents the mercury from coming into real contact with the glass. If this view is correct then, as Bancroft² has pointed out, mercury should readily wet glass if the adsorbed gas were completely removed. In order to test the accuracy of this hypothesis, a number of experiments were performed in which mercury was placed in glass containers whose walls had been

¹ The term wetting is used in this paper in the sense that wetting is complete when the angle of contact between liquid and solid is zero and the meniscus concave, and that the liquid does not wet the solid in cases in which the angle of contact is zero and the meniscus is convex. In these experiments wetting was considered to have taken place whenever the meniscus of mercury was less convex at the conclusion of the experiment than it was at the start.

² Bancroft, J. Ind. Eng. Chem., 13, 88 (1921).

freed as far as possible of adsorbed gas. A description of several of these experiments will be given in this paper, together with a discussion of the results obtained and the conclusions reached.

Experimental Part

Fig. 1 illustrates the apparatus used in the first experiment.

The essential parts are the small aspirator, D, the distilling apparatus, B, the liquid air traps, G and F, and the mercury-vapor pump, H. In addition to the apparatus shown in this figure, two motor-driven oil pumps were utilized to maintain a suitably low pressure at the outlet of the mercury-vapor pump, H. All glass parts in the apparatus were made of soda-lime glass and before being used in these experiments, were cleaned with chromic acid and then thoroughly washed with distilled water. Immediately after the last washing the glass apparatus was sealed to the evacuating system and the water that still remained on the glass was pumped off.

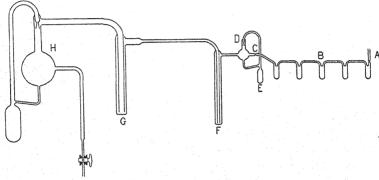

Fig. 1

At the start of the experiment the glass parts B, D and F, were subjected to a temperature of 400° for several hours, the pressure within the apparatus being maintained continuously at approximately 1×10^{-6} mm. of mercury, as measured by the Buckley type of ionization manometer. This treatment undoubtedly reduced the amount of adsorbed gas on these parts to a minimum. After this heat treatment the glass tube leading upward from Bulb A of the distilling train, B, was opened and redistilled mercury, purified according to the method recommended by G. A. Hulett,³ was introduced into Bulb A, after which the tube was immediately closed and the internal pressure again reduced to at least 1×10^{-6} mm. of mercury. The aspirator, D, was then kept at a temperature of 400° for approximately 50 hours and at the same time, 4 of the 5 bulbs in the distilling train were receiving similar treatment.⁴ By distil-

³ Hulett, Phys. Rev., 33, 307 (1911).

⁴ In this connection some consideration was given to the possibility of further reducing the amount of adsorbed gas on the glass by heating to higher temperature in a vacuum oven. On account of the physical limitation that would be imposed under this plan it seemed that the preliminary nature of the experiments did not warrant its adoption.

ling the mercury from one bulb to another it was possible to give the glass in the distilling train a good heat treatment, thereby freeing its surface of the adsorbed gas that was taken up when the mercury was introduced. Gases entrapped by the mercury were, of course, released and pumped out during this distillation of the mercury from one bulb to another. All glass parts in the distilling train received higher heat treatment during this heating than they ever received again during the experiment. After terminating the heat treatment to which the glass parts B and D were subjected, about 12 cc. of mercury was distilled over into D and the distilling train then sealed off at C. This amount of mercury was sufficient to cause the small aspirator, D, to function as such very satisfactorily. The distilling of the mercury in D, was continued for 50 hours and this was believed to have removed any gas that was still entrapped by the mercury.

The experiment described above was repeated five times, using different aspirators in each case, all of which, however, were made of soda-lime glass. In all of the experiments the conditions were maintained as near like those cited above as possible. In two of the aspirators, at the termination of the experiments, the mercury seemed to wet the glass slightly, while in the other three the mercury behaved just as it ordinarily does when placed in a glass container which has not been evacuated. In the two cases where a wetting seemed to occur, the surface of the mercury in Bulb E appeared to be perfectly flat. The mercury surface in one of these aspirators when exposed again to air slowly acquired a convex meniscus; the mercury in the other aspirator was not appreciably affected by air even after exposure for several days. In none of these experiments did the mercury ever assume a concave meniscus.

Additional experiments were conducted in a similar apparatus made of 702-EI Pyrex glass instead of soda-lime glass. The results obtained were about the same as those found when soda-lime glass was used, except that in the cases where there was evidence of wetting it usually took place more quickly. As it seemed possible that a correlation might exist between wetting and the chemical composition of the glass, further work was undertaken to investigate this point. For the small type of aspirator used in the above experiments an apparatus was substituted consisting of 6 bulbs sealed together. The first 4 bulbs, at the entrance of the train were made of soda-lime glass; the fifth bulb was made of Pyrex 702-EJ glass and the sixth bulb was of quartz. In several of these experiments a bulb made of Pyrex 702-P glass was substituted for one of the soda-lime bulbs. The soda-lime glass was sealed to the Pyrex bulb by connecting tubing made of glass varying in composition from that of the soda-lime glass at one end to Pyrex 702-EJ glass at the other. By means of a similar connecting tube, varying in this case from Pyrex at one end to quartz at the other, the Pyrex bulb was sealed to the quartz bulb. The bulbs, after being sealed to the evacuating system, were exhausted and with the pressure⁵ being maintained within them at approximately 1×10^{-6} mm. of mercury they were heated to a high temperature for about 50 hours, the soda-lime glass being kept at 400° while the Pyrex and quartz bulbs, by means of individual heating units, were kept at temperatures of 550° and 800°, respectively. After this heat treatment, which must have reduced the amount of adsorbed gas held by the glass to a minimum, mercury was distilled into the bulbs from a distilling apparatus such as was used in the experiment described above. After sufficient mercury had distilled into the bulbs to fill any one of them, the distilling apparatus was sealed off from the rest of the system. The mercury was then distilled from one bulb to another until the experiment was concluded; during this process whenever any bulb was empty it was always subjected to a heat treatment before mercury was again distilled into it. In each of these five experiments entirely new soda-lime and Pyrex bulbs were used. On account of the difficulty of obtaining satisfactory quartz bulbs, however, and also because of their high cost, it was necessary to use the same quartz bulb in all five cases.

In these experiments, the behavior of the mercury in the quartz bulb was extremely interesting. Before the curvature of the mercury showed any change in the soda-lime or Pyrex containers, it usually became quite flat in the quartz bulb. In only one experiment did the meniscus of the mercury actually become slightly concave, but in four other experiments the surface of the mercury was absolutely flat. In the previous experiments in which the small aspirators were used, if a wetting did occur there was always the possibility that something from the glass or some other source had contaminated the mercury, but here in the case of the wetting of quartz by mercury no such possibility existed. In every experiment during the early stages of the distillation the mercury that wet the quartz, when distilled again into the soda-lime or Pyrex glass bulbs, failed to show any wetting. The same mercury here wet in one bulb and failed to wet when distilled into another.

In these experiments with the bulbs, as in the experiments with the small aspirators, the behavior of the mercury in the Pyrex and soda-lime containers differed considerably from one experiment to another. In two of the experiments the surface of the mercury became quite flat in the Pyrex containers, but in at least four others it did not. In the two cases, the mercury was distilled from bulb to bulb for at least 30 hours before the flattening became at all pronounced. With the soda-lime glass bulbs, in only one case was there any noticeable change in the mercury surface,

⁸ It should be noted that pressures of this magnitude were maintained in all of these experiments. No degree of wetting was ever obtainable where higher pressures were maintained.

and that took place only after the distillation had continued for 50 hours. In this one case the mercury surface was still slightly convex after the experiment had been run for 75 hours. At the conclusion of this run the train of bulbs while still evacuated was sealed off from the rest of the system, the mercury was then poured from one bulb to another and measurements upon the curvature of the mercury surface in each bulb were taken. By properly mounting the bulbs the vibration of the mercury was reduced to a minimum and this made it possible to take fairly accurate readings. These measurements, which were taken with a cathetometer, are given in Table I and represent the differences in height between the places where the mercury cut the glass of the container and the top portions of the meniscus. For comparative purposes, measurements were also taken upon mercury in a soda-glass container that was evacuated but had never been heat-treated.

Table I Wetting Measurements

Type of glass:	Soda-lime unheated	Soda lime	702-P	702-EJ	Quartz
Diff. in height, mm.:	1.6	0.6	0.3	0.0	sl. concave

The chemical compositions of the various types of glass used are given in Table II. Glass 702-EJ was a borosilicate glass containing no metal of the magnesium-lime-zinc group nor any heavy metals, and the quartz was of course practically pure silica.

TABLE II

Chemical Compositions of the Glasses Used					
Soda lime	702-P	s	oda lime	702-P

[&]quot; By difference.

These results would indicate that a parallelism exists between wetting and the chemical composition of the glass. It is interesting to note that in a previous paper⁶ on "Measurements of the Gases Evolved from Glasses of Known Chemical Composition," a similar parallelism was found to exist between the amount of gas evolved by a glass and its chemical composition.

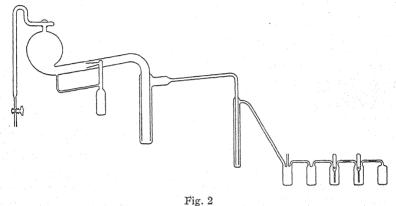

Fig. 2 shows diagrammatically the last type of apparatus worked with.

Here, as can be seen, capillary tubes were inserted in two of the bulbs; one made of soda-lime glass, the other of Pyrex. The small holes seen in the tubes just above the point where they become capillary, were to keep the pressure inside the capillary the same

⁶ Harris and Schumacher, Ind. Eng. Chem., 15, 174 (1923).

as in the outer bulb when the bottom of the capillary was closed by mercury. For denuding the glass of its adsorbed gas and for introducing the mercury into the apparatus, the methods employed in the preceding experiments were used.

Ten different runs were made with this type of apparatus. In one run a slight rise of the mercury in the capillary made of Pyrex glass was noted. In one other case there was neither a rise nor a depression in the Pyrex capillary. In 8 different runs the mercury was depressed in the Pyrex capillary. In no case was a rise observed in the soda-lime glass capillary.

Discussion

The results of the experiments that have just been described indicate that the chemical composition of the glass either directly or indirectly plays a part in determining whether or not mercury will wet the glass. The tendency of mercury to wet glass seems to decrease as the alkaline content of the glass increases. Similarly, as pointed out previously, the gas evolved from a glass increases as the alkaline content increases. A glass containing a high percentage of soda would be more easily hydrolyzed than one that contained a lower percentage, and the result of such an hydrolysis would be the formation on the surface of the glass of a thin film of sodium hydroxide, together with some amorphous silica. It is reasonable to assume, therefore, that mercury does not ordinarily wet a soda-glass surface because this film prevents it from ever touching the glass. On the other hand, such a film may have only an indirect effect on the wetting of glass by mercury due to the tenacious retention of large quantities of gas. If this alkaline film is either directly or indirectly responsible for the non-wetting of ordinary glass by mercury, then the results obtained in these experiments can be accounted for.

On the quartz surface, where there was no chance for an alkaline film to exist, a degree of wetting was always obtained. On the surface of Pyrex glass the alkaline film would surely be thinner than on the soda lime glass

and, as will be recalled, mercury seemed to show a greater tendency to wet Pyrex than it did soda-lime glass. That on two occasions a degree of wetting was noted when a soda glass was used can be accounted for by assuming that the specific conditions of washing and subsequent drying of the soda glass were such as to prevent any appreciable alkaline film formation. In the case of the capillary tubes, on the other hand, no marked wetting ever occurred in the capillaries because a longer period of time was required to remove the water from within these tubes than from surfaces outside, and this was favorable to the formation of alkaline films.

Summary

An attempt has been made to cause mercury to wet glass and quartz after their surfaces have been denuded of gas as far as it is possible with the present means at our command. The difficulty of this task appears to become greater as the alkaline content of the glass increases. Fairly good wetting can generally be obtained on quartz, while on Pyrex and sodalime glass it is obtained only occasionally.

LIESEGANG RINGS. III. THE EFFECT OF LIGHT AND HYDROGEN-ION CONCENTRATION ON THE FORMATION OF COLLOIDAL GOLD IN SILICIC ACID GEL. RHYTHMIC BANDS OF PURPLE OF CASSIUS

By Earl C. H. Davies RECEIVED JULY 2, 1923

Introduction.—In a previous paper¹ the author showed that light has a pronounced influence on the tendency for colored bands of colloidal gold to form in silicic acid gel. It was the purpose of the present work to make a more exhaustive study of this light effect. The following factors were investigated: the effect of light of different wave lengths; the relation between band formation and hydrogen-ion concentration; the variation of band formation with kind of acid used in making the silicic acid gel; the effect of variation of oxalic acid concentration; the result of using different strengths of gold chloride solution; the result of replacing the oxalic acid by other reducing agents.

The Effect of Light of Different Wave Lengths.—For the first series of experiments, glass cylinders, 18 × 5 cm., were fitted with large corks holding 2.5cm. test-tubes, within which were smaller tubes, containing the gel in which diffusion was to take place. Some of the gel was protected by

¹ Davies, This Journal, 44, 2700 (1922).

black glazed paper. Other tubes were protected by grids made by cutting horizontal, parallel slits 2mm, wide out of the black paper. These slits were 8 mm. apart. Other tubes were unprotected from the light rays, except by a total thickness of 5.1 mm. of nearly colorless glass, and the respective liquid, which was between the large test-tube and the wall of the cylinder. Tests were made in duplicate. Since the intensity of light varies inversely with the square of the distance, some samples were placed in the circumference of a circle of 30cm. radius at the center of which were 2 Edison Lamps "100 Watts, 115 Volts. P. S., 25 Mazda C." Other similar samples were put in the circumference of an outer concentric circle of 43.5cm. radius. Hence, the light intensity in the outer circle was to that in the inner circle as $(30)^2/(43.5)^2$ or about 1/2. The cylinders in the inner circle were spaced in such a way that they did not shut off the light from the farther cylinders. Solutions were so chosen that the light transmitted was of the different wave lengths present in the visible spectrum. The outer cylinders contained, respectively, air, water, 1 M cobalt nitrate, 0.001 M potassium permanganate, 0.01 M potassium permanganate, 1 M copper sulfate, 1 M nickel nitrate, and 1 M potassium dichromate solutions.

The silicic acid gel was made by slowly adding 500 cc. of water glass (d., 1.16) to a mixture of 500 cc. of 2.975 N sulfuric acid and 40 cc. of 1% gold chloride solution. The mixture was filtered before use. The water glass was of such composition that, with congo red as indicator, it was 1.564 N at d., 1.16 and 0.585 N at d., 1.06. Three days were allowed for the gel to set in the test-tubes. Five cc. of saturated oxalic acid solution was then added to each tube.

The experiment was run for 3 weeks without disturbing the lights or tubes. At the end of this time in no case did I find any evidence of bands in the gel samples which had been protected by black paper. Neither were there bands in the tubes protected only by the potassium dichromate solution. In all other cases of tubes exposed continuously to light some gold was reduced to the colloidal condition. The tubes with only air and glass as absorbent had at the top a purple region 7mm, wide, fading to a light green. There were faint, light green, double bands at 4.6, 5.6, 6.4, 7.7, 8.3 and 9.5 cm., respectively, from the top. These bands slanted toward the light and tended to be double, due to the fact that two bulbs were used instead of a point source of light. They were caused by irregularity of light intensity. The tubes with the grids showed, at each opening, reduction similar to the comparable position in an open tube. Behind the dark portions of the grids the results were very similar to the dark tubes at comparable depths but there appeared some effect of light due to reflection. Tubes more distant from the light showed less color than those in the inner circle. The order of decreasing reduction, that is, of decreasing tendency to form colloidal gold, was found to be: air, inner circle; air, outer circle; water, inner; water, outer; 1 M cobalt nitrate; $0.001\ M$ potassium permanganate; $0.01\ M$ potassium permanganate; $1\ M$ copper sulfate; $1\ M$ nickel nitrate; $1\ M$ potassium dichromate; and no light. However, $1\ M$ potassium dichromate and black paper protected the gold equally well.

This series of experiments shows conclusively that light of short wave length is responsible for catalyzing the formation of colloidal gold in silicic acid gel, when the experiment is carried out according to the directions of H. N. Holmes.² When the diffusion takes place in the dark only the larger particles of yellow gold crystals are produced. The beautiful, multicolored zones obtained by Holmes were not true Liesegang bands, for the latter would be formed in the dark and their distance apart would increase going from the top to the bottom of the gel. I have obtained these same colored zones but only in changing light, when Holmes' directions were followed. In connection with these bands, in his book on colloidal chemistry, Bancroft⁸ says, "He (Holmes) has put forward a theory of rhythmic banding which unfortunately does not account for the fact, recorded in the same paper, that colloidal gold gives three bands, red, purple and blue, before repeating." My present work plainly removes the only objection that Bancroft has offered to the theory advanced by Holmes. Whether Holmes' theory is general in its application is, of course, another matter.

Lecture or Laboratory Demonstration of the Effect of Light on Reduction of Gold.— To 25 cc. of 3 N hydrochloric acid add 2 cc. of a 1% solution of gold chloride. Shake this mixture while adding slowly 25 cc. of water glass (d., 1.16). Filter the liquid into 2 test-tubes and allow the gel to set for 3 days. Cover with black paper. Add to each tube 5 cc. of a saturated solution of oxalic acid. Place in a dark room and allow to diffuse for 3 weeks. Open a tube in bright sunlight and with a stopwatch record the time when color appears. When a tube is first opened only a few crystals of gold will be seen, but soon the color of colloidal gold will appear.

With such a tube I obtained a color flash in the upper part in 50 seconds. The time varies with light intensity. Hence the experiment may be used to measure the latter. The great rapidity, with which the color deepened, was very striking. After 3 minutes colloidal gold extended from a position 1.5 cm. from the top to the bottom of the tube. In the zone from 1.5 to 1.8 cm. it was a beautiful red; in the zone from 9.6–12 cm. the color shaded to purple. When 3 N sulfuric acid is used instead of the hydrochloric acid, the diffusion should not be allowed to continue for so long a time. Striking results may be obtained from the gel made with 3 N sulfuric acid by exposing it to light for a few minutes on the third day, and then each week until diffusion has reached the bottom of the tube. In this way the colored zones will be separated by nearly colorless ones.

Relation between Band Formation and Hydrogen-Ion Concentration.— This relation was studied in two ways, one direct, and the other more indirect. I used 76 tubes of gel for this phase of the work. Results, in Table I, are confined to shielded and open tubes. To make the gel, 6 cc. of 1% gold chloride solution were added to 75 cc. of the acid. To this

² Holmes, This Journal, 40, 1190 (1918).

³ Bancroft, "Applied Colloid Chemistry," McGraw-Hill Book Co., 1st ed., p. 259,

mixture were then added 75 cc. of filtered water-glass solution, and the product was quickly poured into test-tubes. After 3 days, gels with 0.67 N acidity were satisfactory. With the gels of lower hydrogen-ion concentrations setting occurred in less than 2 minutes.

TABLE I

RELATION BETWEEN HYDROGEN ION AND COLOR OF COLLOIDAL GOLD ⁴							
Acid	Acidity of mixture N	After standing in the dark 4 days	28 Cm. from lights	Exposed to sunlight after 3 days in dark			
HNO_3	0.67	Very light blue	Some blue to	In 50 sec. blue zone started at			
		to 2 cm.	2.1 cm.	4.3 cm. and reached 5.7 cm. in less than 5 min.			
HNO_3	0.045	Slight purple to 7.5 cm.	Purple to 8 cm.	In 1 min. 5 sec. a blue zone appeared between 6.4 and 7.4 cm.			
HNO_3	0.012^a	Very light purple	Green to violet	In 1 min. 40 sec. a light blue zone appeared at 5.7 cm.			
HC1	0.664	A few yellow crystals	Green, brown, yellow	In 43 sec. purple began at 0.7 cm. Final colors, blue, red, blue. Very pretty.			
HCI	0.034	Slight purple to 7.3 cm.	Purple to 8 cm.	Not observed in sunlight on third day.			
HCI	0.012^{a}	Slight purple to 6 cm.	Violet light, brown	In 28 sec. a purple zone came at 3.7-4.9 cm. In 3 min. 45 sec. light purple at 6.2-7.7 cm.

HC₂H₃O	2 0.67	Slight blue to 2.2 cm.	Slight green, blue to 2.1 cm.	In 28 sec. a purple zone began at 4 cm. After 3 min. 45 sec. it had extended to 4.7 cm.			
HC ₂ H ₃ O	0.047	Violet to 7.3 cm.	Purple to 8 cm.	No change in 10 minutes.			
HC ₂ H ₃ O	0.012^a	Wine color to 6.2 cm.	Wine color Very pretty	No change in 10 minutes. Very pretty.			

a Basic.

Conclusion in Regard to Hydrogen-effect in the Dark.—With the acids used, and at the concentration of these experiments, the decreasing order of hydrogen-ion concentration is nitric, hydrochloric, sulfuric, and acetic acids. The nitric and hydrochloric acids furnish nearly the same hydrogen-ion concentration. In keeping with this, I found that, with the final concentration of 0.67 N nitric and hydrochloric, scarcely any reduction took place in the dark. With sulfuric acid the reduction was to yellow

⁴ Red gold indicates small particles and hence also small "pockets." Blue gold indicates larger particles, and green still larger ones. A saturated solution of oxalic acid was used above the gel as the reducing agent.

crystals, and no colloid was formed in the dark. With acetic acid, in the dark, the reduction took place sufficiently rapidly to give the purple colloid. Similarly, when we consider the decreasing hydrogen-ion concentrations for each of the several acids, we find that there is a regular tendency for the reduction in the dark to take place more rapidly in the more basic gels. Take, for example, the concentrations of acetic acid recorded in Table I. With a final normality of 0.67, a slight blue developed to 2.2 cm. from the top. With a final acid normality of 0.047 the violet color extended to 7.3 cm. With the 0.012 N basic gel a wine color developed. So, also, in the other cases in the dark the most rapid reduction and hence the smallest colloidal particles occur where hydrogen-ion concentration is lowest.

In the Light.—When diffusion takes place in continuous, uniform light, we have the same relation between hydrogen-ion concentration and rapidity of reduction as we have in the dark. The difference is that in all cases the light hastens reduction, but it does not disturb the regularity of the hydrogen-ion relation. For example, in the case of acetic acid at $0.67\,N$ a slight green-blue was developed, showing that relatively large particles were present and hence reduction had occurred in large "pockets." With $0.047\,N$ acidity the color is purple. With $0.012\,N$ basic the color is like that of wine.

Hence, it appears from this series of experiments that where the hydrogen-ion concentration is relatively low we have reduction in small "pockets." I have spoken of this as "rapid" reduction. The effect of the light is comparable to a rapid decrease of hydrogen-ion concentration.

Besides the experiments recorded, I performed a series in which the final normality of the sulfuric acid in the gel was 2.1. With such a large hydrogen-ion concentration there was slightly more reduction to colloidal gold than with the $0.67\ N$ sulfuric acid; but, when exposed to the light, gels made with this acid gave very little further reduction, whereas a check tube of $0.67\ N$ excess acid gave reduction in the light in 42 seconds. Hence, we are driven to the conclusion that the influence of light shows up best at a final hydrogen-ion concentration of less than $2.1\ N$ and approximately $0.67\ N$.

The Variation of Band Formation with the Kind of Acid Used.—Hydrochloric acid and nitric acid give gels which behave quite similarly, but that from hydrochloric acid is better where the light effect on the gel is to be studied. In comparing similar hydrogen-ion concentrations it seems that the gel made with sulfuric acid shows a greater tendency for the reduction of gold than does that made with hydrochloric acid. Such differences are due to the presence of different salts which have an influence on the rate of peptization and hydration and hence help to govern

			portion	portion	
			brown, with bands	brown, with bands ^f	

^a 1 cc. for every 25 cc. of mixture, except with glucose where 0.1% means the percentage of solid glucose in the gel.

^b Later observations, after 3 weeks, on the duplicate tubes, showed that the results at 4 days were typical of the longer period.

^e These were present in all tubes in which phenylhydrazine was used. They were cleavage planes, of varying sizes up to 4.2 by 1.5 cm.

d These bands were light, reddish-brown, about 1 mm. wide. They were, starting

the size of the "pockets." However, the kind of acid is of far less importance than the concentration of hydrogen-ion present.

The Effect of Variation of the Concentration of Oxalic Acid.—My experiments show that in the case of the gel made with sulfuric acid the strength of oxalic acid solution may vary between saturated and 1/4 saturated, and perhaps may be even less, without effecting any great change in results. However, it is to be recommended that a saturated solution of oxalic acid be used.

The Results Obtained with Different Strengths of Gold Chloride Solution.—In Table II results are recorded of the effects of different reducing agents diffusing into gels, containing 1 cc. of 1 to 10% gold chloride in each 26 cc. There seems to be no advantage in having the gel contain more than 0.04% by weight, of gold chloride, while 0.4% gold chloride seems too concentrated for use.

The Effects of Replacing the Oxalic Acid by other Reducing Agents.— 136 Tubes of gel were made up in many different ways. The conditions governing the use of continuous light, grids, and control of the operations in the dark were observed also in these cases. The sulfuric acid used was 2.975 N and the hydrochloric acid was 2.967 N. The water glass was d. 1.16 and was 1.584 N. To 75 cc. of the acid was added 6 cc. of the gold chloride solution or the reducing agent (in the cases where the gold chloride was placed above the reducer); 75 cc. of filtered water glass (d., 1.16) was then added and the mixture constantly and vigorously shaken, and poured into 15mm. test-tubes to set. Three days were allowed for setting; after which some of the tubes were covered with grids or dark paper and all were put in the dark room at the same distance from the light, as described earlier in this paper. Illumination was continuous for three weeks.

Conclusion in Regard to Reducing Agents other than Oxalic Acid.—The most interesting set of experiments was with the formation of purple of Cassius. Formaldehyde and phenylhydrazine in alcohol are not suitable for this type of experiment. The results obtained when a 10% gold chloride solution diffused into a silica gel made with sulfuric acid and containing 0.1% glucose were remarkable in that regular bands were obtained but they were equally spaced, whereas the true Liesegang rings are at the top, at 3.7, 4.1, 4.45, 4.8, 5.1, 5.4, 5.7, 6.0, 6.25, 6.5, 6.8, 7.3, 7.7, 8.0 and 8.3 cm., respectively.

^e In the upper part of the tube the color was so intense that the bands were indistinct. In the lower part the purple bands were sharp. At 8 cm. they were 2.5 mm. apart, and they were true Liesegang bands.

f This was peculiar in that the concentrated AuCl₂ solution seemed to have dissolved the brown precipitate in the upper 2 cm. region. The bands in the brown portion were true Liesegang bands, but were difficult to see on account of the nature of the precipitate. At 4 cm. from the top, they were 1.5 mm., and at 9.7 cm. they were 5 mm. apart.

developed farther and farther apart. I shall refer to this striking phenomenon in a later paper.

Rhythmic Bands of Purple of Cassius.—Narrow but distinct rhythmic bands of purple of Cassius are obtained as follows. To 12.5 cc. of $3\ N$ hydrochloric acid add 1 cc. of 1% gold chloride solution. Shake the mixture vigorously while adding 12.5 cc. of water glass (d., 1.16). Allow the liquid to set in a test-tube for 3 days. Add 3 cc. of a mixture made from the equivalent of 10 g. of anhydrous stannous chloride and 0.1 g. of anhydrous stannic chloride in 90 g. of water. This mixture is turbid and, therefore, must be shaken vigorously before it is used. During the diffusion, the turbidity entirely disappears. When heavier bands are desired they may be obtained by using more concentrated solutions of gold chloride up to 10%; but when these more concentrated solutions are used the zones between the bands are not so free from residue.

Summary

- 1. Experiments have been performed which show that gels made with silicic acid and gold chloride are remarkably affected by light and that it is the light of short wave length which functions thus.
- 2. The results obtained remove Bancroft's objection to Holmes' diffusion theory of Liesegang band formation.
- 3. Another series of experiments has shown that there is a distinct relation between hydrogen-ion concentration and the size of "pockets" in which the gold is formed.
- 4. Directions are given for a striking lecture or laboratory experiment to show the influence of light on reduction.
 - 5. Purple of Cassius was obtained in true Liesegang bands.

THE TEMPERATURE COEFFICIENTS OF UNSATURATED WESTON CELLS

By Warren C. Vosburgh and Marion Eppley Received July 3, 1923

The unsaturated Weston cell, although not a true standard cell, is widely used as a secondary standard of electromotive force because of its low temperature coefficient. Jaeger¹ stated that the electromotive force of a cell of this type with a cadmium sulfate solution saturated at 4° as the electrolyte could be regarded as practically constant at all ordinary temperatures. Dearlove² found a temperature coefficient —0.00003 volts

¹ Jaeger, "Die Normalelemente," Wilhelm Knapp, Halle a.S., 1902, p. 86.

 $^{^2}$ Dearlove, *Electrician*, 31, 645 (1893). Dearlove does not state the concentration of cadmium sulfate in the electrolyte of his cells but the electromotive forces indicate that it was smaller than that of a solution saturated at 4° .

to —0.00007 volts per degree. The present investigation was undertaken to supply more definite information as to the magnitude of the temperature coefficient of unsaturated Weston cells.

Materials

Cadmium Sulfate.—A good grade of commercial cadmium sulfate was thrice recrystallized slowly at room temperature, or slightly above, the third time from redistilled water slightly acidified with sulfuric acid.

Mercurous Sulfate.—The mercurous sulfate designated as No. 1 was prepared electrolytically from mercury which had been purified by electrolysis. The apparatus was similar to that of Hulett, and the current density was 0.5 amp. per sq. dm. The amount of finely divided mercury in the mercurous sulfate was found to be dependent on the rate of stirring, a whiter product being obtained with more vigorous stirring. The

mercurous sulfate was allowed to stand for several months under 0.02 M sulfuric acid solution. It was then digested for 5 days at a temperature near the boiling point with 1.8 M sulfuric acid and kept under the acid solution in the dark until used.

Mercurous sulfate No. 2 was prepared by reducing mercuric sulfate with formaldehyde.⁴ Mercuric oxide of c. P. quality was added to a large excess of hot 4 M sulfuric acid solution, an excess of formaldehyde added and the solution maintained at 100° until precipitation was complete. The precipitate was washed and maintained at boiling temperature for several hours under 1.8 M sulfuric acid solution and kept under a 1.8 M acid solution in the dark.

Mercurous sulfate No. 3 was obtained by allowing a portion of the mercuric sulfate solution used in the preparation of No. 2 to stand at room temperature after addition of formaldehyde. It was washed and kept under $1.8\ M$ sulfuric acid solution in the dark.

Mercury.—Commercial redistilled mercury was purified by electrolysis as described by Wolff and Waters⁵ and twice redistilled by Hulett's method.⁶

Cadmium Amalgam.—Cadmium was deposited electrolytically from a concentrated solution of the purified cadmium sulfate, the cathode consisting of a weighed portion of the mercury described above. When sufficient cadmium had been deposited the amalgam was weighed, mercury added to bring the cadmium concentration to 12.5%, and the amalgam melted by gentle heating and well mixed.

Vessels.—Glass H-vessels of the type shown in Fig. 1 were used.

Apparatus

Potentiometer.—The potentiometer described by Eppley and Gray⁷ was used, the working battery consisting of 2 large capacity cadmium cells. Cell comparisons with this instrument were reproducible to 1 or 2 microvolts. For measuring Cells 56–60 and the normal cells at 45° a commercial potentiometer was used. It was calibrated over the range of the other potentiometer by making cell comparisons by means of both instruments. The correction at the upper limit of this range was assumed to apply to

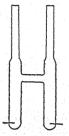

Fig. 1.— Type of Hvessel used. The length was about 13 cm. and the inside diameter of the lower parts of the legs 1 cm.

the readings of Cells 56-60, and that at the lower limit to to the readings of the normal cells. The corrected readings thus obtained must have been accurate to 0.00004 volt. The temperature coefficients should be more accurate than this, however, as readings could be duplicated to 0.00001 volt, and some errors must have been cancelled by the subtraction.

Both potentiometer systems were shielded as recommended by White.8

Standards.—Three well-aged, very constant, normal cells made at the National Physical Laboratory at Teddington, England, and furnished to this Laboratory through the kindness of Dr. F. E. Smith, were used as the reference standards. Their values were assumed to be such that the normal cells made in this investigation would have a value of 1.018054 volts at 25°.

Temperature Control.—Two oil thermostats, maintained constant within 0.02°, were used for regulation of the temperature. One was kept at 25° and contained the reference and working standards; the other contained the experimental cells, and its temperature was changed as desired. Temperatures were determined by means of a thermometer recently calibrated by the Bureau of Standards, and were accurate to 0.03°.

Preparation of the Cells

The platinum wires in the mercury legs of the vessels were amalgamated and the amalgam and mercury introduced as described by Wolff and Waters. A 0.015 M sulfuric acid solution, prepared from water redistilled from alkaline permanganate, was saturated with cadmium sulfate. Fifteen normal cells were prepared using this solution, 10 but otherwise as described by Wolff and Waters.9 Cells 1 to 5 were prepared with mercurous sulfate No. 1, Cells 6 to 10 with No. 2, and Cells 11 to 15 with No. 3. For the unsaturated cells, portions of the saturated solut on were diluted with from 2.5 cc. to 50 cc. of the 0.015 M acid solution to a liter, as shown in Table I. The mercurous sulfate, No. 1, was washed well with the cadmium sulfate solution to be used in the cells and introduced into the vessels by means of a pipet. Cadmium sulfate solution was then run in until the level was above the cross-arm. The air was displaced by nitrogen which had been washed with water and concentrated cadmium sulfate solution, and the upper ends of the glass tubes hermetically sealed. Special precautions were taken to prevent evapora-

- 9 Ref. 5, p. 30.

10 Hulett [(a) Trans. Am. Electrochem. Soc., 14, 89 (1908)] found that Weston cells with acid electrolytes were remarkably constant in electromotive force, and Smith [(b) Electrician, 75, 463 (1915)] and Obata [(c) Proc. Math. Phys. Soc. Japan, 2, 232 (1920)] found that Weston normal cells were more constant if the electrolytes were acid than if they were neutral. Obata determined the relation of the electromotive force to the acid concentration, and on the basis of his results it was calculated that an electrolyte containing 0.0115 moles of sulfuric acid in a liter (resulting from the saturation of 0.015 M sulfuric acid with hydrated cadmium sulfate) would give cells with an electromotive force 20 microvolts lower than that of the neutral cell. Obata's acid cells were all more acid than this, but some experiments in this Laboratory have shown that his relationship holds for low acidities also, contrary to the statement of Hulett (Ref. 9a, p. 80).

tion of the electrolyte. The cells were mounted on racks, copper connecting wires being soldered to the platinum wires and to short copper rods¹¹ inbedded in a hard rubber plate.

The concentration of cadmium sulfate in the various solutions was determined by evaporating 3 to 5 g. samples to dryness, with the addition of a little sulfuric acid. The residue was brought to constant weight by adding 1 or 2 drops of concd. sulfuric acid, heating with a medium flame, cooling, adding more acid, and heating with a low flame until the acid was completely expelled.¹² Three determinations were made on each solution, and the average results together with the average variations are given in Table I.

Table I

Composition of Cadmium Sulfate Solutions and Electromotive Forces of Cells

Solution no.	Cells	Dil. acid added Cc.	CdSO4	E.m.f. at 25° Average volts

Electromotive-force Measurements

The cells were allowed to age for over a month at 25° before the final measurements were made. Preliminary measurements showed that they changed very little during that time. Measurements were then made successively at 25°, 35°, 40°, 45°, 40°, 35°, 15°, and finally at 25° again. At each temperature measurements were made on successive days until it was shown that equilibrium had been attained. At the higher temperatures equilibrium was attained within less than a day after the temperature was changed. At equilibrium measurements nearly always agreed within 1 or 2 microvolts. The results are given in Tables I, II and III.

The first values at 25° for the unsaturated cells are given in Table I, each value being the average of a group of 5 cells. The figures for the average variation from the group averages give an idea as to the reproducibility of acid cells. In the case of the normal cells, in which there were no variations due to concentration differences, the average variation was

¹¹ The lead wires to the potentiometer were attached to these rods by means of spring clips.

¹² Preliminary experiments showed that weighing after the first heating gave erratic results, due doubtless to loss of sulfur trioxide. It was considered necessary, however, for the expulsion of all the water. See Baxter and Wilson, This Journal, 43, 1238 (1921).

considerably less, 0.000002_{9} volts at 25° . No cells were rejected for inconstancy or disagreement with the majority.¹⁸

TABLE II

		NORMAL CELLS

In Table II it is shown that the temperature formula of Wolff¹⁴ expresses the relationship between temperature and electromotive force of Cells 1 to 15.¹⁵ The practically negligible differences from the calculated values in Table II are in the direction of a smaller temperature coefficient. The results in Table II indicate that mercurous sulfate No. 1, which was used in the unsaturated cells, is a normal preparation, since

¹⁵ The values for Cells 11–15 are the results of the first measurements at 25°, 35°, 40° and 45°. Hysteresis interfered when the temperature was decreased. Cells 1 to 10 and the unsaturated cells showed very little hysteresis.

the saturated cells made with it agree with those made with the other mercurous sulfate preparations. 16

Temperature Coefficients of Unsaturated Cells

There is an average difference of 7 microvolts between the first and second results at 25° in Table III. Smaller differences are to be noticed between the two series of results at 35° and 40°, respectively. These differences may have been caused by a decrease in electromotive force of the cells due to the reaction, $Cd + 2Hg^+ \longrightarrow Cd^{++} + 2Hg$, at the surface of the amalgam, the mercurous ion being supplied by diffusion. ¹⁷ In view of the small size of the decrease and the order in which the measurements at the different temperatures were made, it was considered sufficient

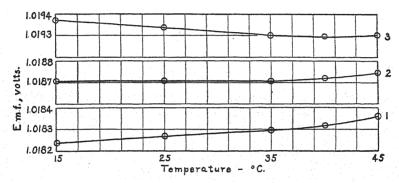

Fig. 2.—Variation of electromotive force with temperature

correction for this error to use the mean values at each temperature for the comparison. The results at 15° were obtained just previous to the final ones at 25°, and so were corrected for comparison with the others by adding half the differences between the two results at 25°. The relation between electromotive force and temperature is shown graphically in Fig. 2. Curve 1 represents the average electromotive force of cells 16–20, Curve 2 that of Cells 26–30, and Curve 3 that of Cells 45–50. Curves for the other groups were similar. The electromotive force is a linear function of the temperature 18° between 15° and 35°, but not between 35° and 45°.

Table IV shows that the temperature coefficient of the unsaturated

¹⁶ Lewis and Gibson [This Journal, **39**, 2575 (1917)] and Gerke [*ibid.*, **44**, 1702 (1922)] have called attention to the possibility of differences in free energy between salts prepared by chemical and electrolytic methods, respectively.

¹⁷ After the final measurements at 25° the unsaturated cells were kept at 25° for 3 months, at room temperature for 3 months more, and then measured at 25°. The average decrease was 23 microvolts, or 0.0023%. The normal cells decreased 6 microvolts during the first 2 months and remained constant for the next 4 months.

¹⁸ Callender and Barnes [*Proc. Roy. Soc.* (London) **62**, 117 (1898)] and Jaeger (Ref. 1, p. 69) found the electromotive force of the unsaturated form of the Clark cell to be a linear function of the temperature over a wide range.

cell is not only "negligible," but at a particular cadmium sulfate concentration is zero between 15° and 35°. This is illustrated in Fig. 3 in which the straight line, expressing the relation between the electromotive

force of the cell and its temperature coefficient, crosses the axis when the electromotive force is 1.01873 volts. The average variation of the temperature coefficients of the individual cells from the values given was about 0.1 microvolts per degree for the temperature coefficients between 15°

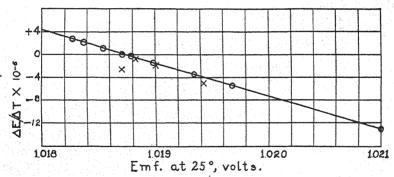

Fig. 3.—Variation of temperature coefficient with electromotive force. The circles represent the acid cells, and the crosses the neutral cells. (See below)

and 35° and about 0.2 mmv. per degree for the other temperature coefficients.

The temperature coefficients between 25° and 35° were measured again after the cells were about 8 months old. The electromotive forces had decreased 17 a little, but the temperature coefficients, in all cases but one, came within 0.2 microvolts per degree of the curve of Fig. 3. The average temperature coefficient of Cells 46–50 was —2.5 mmv. per degree instead of —3.3 as read from the curve, and the agreement among the individual cells was not as good as before. None of the unsaturated cells showed any appreciable hysteresis when the temperature was changed.

Cells with Neutral Electrolyte

Some unsaturated cells with neutral electrolytes were prepared in order to determine if possible how much effect acid in the electrolyte had on the temperature coefficient. The materials were the same as those used in the other cells. The acid in 4 of the cadmium sulfate solutions was neutralized by means of cadmium oxide precipitated from a cadmium sulfate solution by means of ammonium hydroxide, and well washed. Four groups of 5 cells each were prepared and the electromotive forces measured at 25° and at 35°. The temperature coefficients thus obtained did not lie on a straight line or on any regular curve when plotted against electromotive force, as seen in Fig. 3. The temperature coefficient of one group was practically on the curve for the acid cells, but the coefficients of the other groups were below it. Two determinations of the temperature coefficients about a month apart, and before the cells were 3 months old, gave closely agreeing values for 3 of the groups, but for the cells of the average electromotive force of 1.01870 volts the first determination gave —1.5 mmv, per degree, and the second -2.4 mmy, per degree. The latter cells showed considerable hysteresis when the temperature was reduced. Most of the other neutral cells showed some hysteresis. It seems likely that some disturbing factor, such as hydrolysis of the mercurous sulfate, was present in varying degree in the neutral cells and absent in the acid cells.

Electromotive Force and Cadmium Sulfate Concentration

The cadmium sulfate concentrations of the electrolytes of the unsaturated cells are given in Table I. When the concentrations are plotted against the electromotive force of the corresponding cells, all the points, except that for Solution 9, the most dilute one, lie on a straight line. The concentration in a cell having the electromotive force of the normal cell at a certain temperature gives the solubility of hydrated cadmium sulfate in a 0.015~M sulfuric acid solution at that temperature. By plotting the concentrations given in Table I against the electromotive forces at 15° , 18° and 25° , the solubilities calculated as percentages of anhydrous cadmium sulfate were found to be 43.08%, 43.14%, and 43.32%, respectively, the last value requiring a short extrapolation. These values are 0.13%, 0.13% and 0.12% lower, respectively, than the values given by Steinwehr¹⁹ for neutral solutions.

A cell with a zero temperature coefficient, which would have an electromotive force of 1.01873 volts, would require an electrolyte containing 42.93% cadmium sulfate. If the effect of acid on the solubility of cadmium sulfate is the same at lower temperatures as between 15° and 25° the electrolyte of the cell with zero temperature coefficient would be saturated at the same temperature as a 43.06% neutral solution, namely at about 4°.

¹⁹ Steinwehr, Z. physik. Chem., 94, 6 (1920).

Differential Heat of Solution of Cadmium Sulfate

The differential heat of solution of hydrated cadmium sulfate in its saturated solution, q', can be calculated by means of the equation²⁰

$$q' = 46148 \frac{m - 2.67}{m} T_0 \left[\frac{dE_1}{dT} - \frac{dE_2}{dT} \right]$$

where m is the number of moles of water per mole of cadmium sulfate in the saturated solution, E_1 is the electromotive force of the normal cell, E_2 that of a cell with saturated electrolyte but without crystals, and T_0 is the temperature. The results of this calculation are given in Table V. The temperature coefficients for the normal cell were obtained by differentiating Wolff's formula, 14 and those for the cells without crystals from curves similar to Fig. 3 drawn for the temperatures 15° , 18° and 25° . The values of m were calculated from the solubilities given above of hydrated cadmium sulfate in a 0.015 M sulfuric acid solution.

Table V

Differential Heat of Solution of Hydrated Cadmium Sulfate in a Saturated Solution Containing 0.012 Mole of Sulfuric Acid in a Liter

Temp.	m Moles	dE_1/dT Volts/deg.	dE_2/dT Volts/deg.	Cal./mole
15	15.27	-0.00003057	0.00000153	-352
18	15.23	00003686	.00000205	-431
25	15.12	00004945	.00000392	-605

If it is assumed that the temperature coefficient of neutral unsaturated cells is the same as for the acid ones of the same electromotive force, the heats of solution in Table V apply to neutral solutions as well as to the slightly acid ones for which they were calculated. For neutral solutions the values for dE_1/dT would be the same, since Wolff's formula, although derived for neutral cells, has been shown to hold for the acid cells. The values of m would be 3 to 4 parts in a thousand lower for neutral solutions, but an examination of the above equation shows that the values of q' would be in error by only a small part of this.

The differential heat of solution at 18° as determined in the above manner is less than half the value found by Steinwehr²¹ by a different method. The temperature coefficient of q' in the vicinity of 18° is -25 cal. per degree according to the above results while Steinwehr¹⁹ calculated -63 to -78 cal. per degree.

Summary

- 1. The electromotive force of unsaturated Weston cells increased in an approximately linear manner as the cadmium sulfate concentration decreased.
- 2. The electromotive forces were linear functions of the temperatures between 15° and 35° but were not linear functions between 35° and 45°.
 - ²⁰ Jaeger, Ref. 1, p. 36. Verhdl. Deutsch. Phys. Ges., 3, 50 (1901). Ref. 19, p. 14.
 ²¹ Steinwehr, Z. physik. Chem., 88, 245 (1914).

- 3. The temperature coefficient between 15° and 35° was found to be a linear function of the electromotive force. It decreased from 0.0000028 volts per degree for cells with an electromotive force of 1.01827 volts to —0.000013 volts per degree for cells with an electromotive force of 1.0210 volts, being zero for a cell with an electromotive force of 1.01873 volts.
- 4. Normal cells with electrolytes made by saturating a $0.015\ M$ sulfuric acid solution with hydrated cadmium sulfate behaved in accordance with Wolff's temperature formula.
- 5. Mercurous sulfate prepared by reduction of mercuric sulfate with formaldehyde at 100° was no different in its behavior in normal cells from the electroltyic salt.
- 6. The differential heat of solution of hydrated cadmium sulfate in a slightly acid saturated solution was calculated.

THE ENTROPY OF DIATOMIC GASES AND ROTATIONAL SPECIFIC HEAT

By Richard C. Tolman and Richard M. Badger Received July 3, 1923

I. Introduction

Assuming the rigid "dumb-bell" model, the entropy of a diatomic gas at temperatures high enough so that the specific heat at constant pressure has become $7/2\ R$, is given by the equation

$$S = \frac{7}{2} R \ln T - R \ln p + \frac{3}{2} R \ln M + R \ln J + S_2$$
 (1)

where T is the absolute temperature, p is the pressure, M the molecular weight, J the moment of inertia of the molecule and S_2 a constant which has the same value for all diatomic gases composed of molecules of the assumed model. This equation has been derived by Tetrode, Sackur and Schames on the basis of the quantum theory and by Tolman from the theory of similitude or relativity of size, and using kinetic-theory data for calculating moments of inertia, has been shown to agree with the available experimental data.

An important advance in the use of Equation 1 has been made by Urey.⁵ In the first place he has used moments of inertia obtained from spectral data instead of kinetic-theory data in testing the equation,⁶ and in the

second place he has obtained a theoretical value for the constant S_2 by making use of one of Reiche's equations for the rotational specific heat of diatomic gases. This latter possibility is of great interest since the work of Tetrode, Sackur and Schames did not make the theoretical value of this constant by any means certain, while the theory of the relativity of size gives no information as to the theoretical value of the constant.

Urey's method for determining the constant S_2 involved a laborious calculation of the whole rotational specific-heat curve from the absolute zero to a temperature where the rotational specific heat is approximately equal to R, followed by a graphical integration under this curve to determine the rotational entropy at the higher temperature, and was applied to only one of the several theoretical formulas for rotational specific heat which have been proposed. It is the purpose of the present article to show a simple mathematical method for obtaining the value of S_2 from various theoretical formulas for rotational specific heat, to apply the method to the 5 different formulas considered by Reiche⁷ and to the new formula based on half-quantum numbers recently considered by Tolman, and to compare the results obtained with the available experimental data.

II. The Additivity of Translational and other Forms of Entropy

The calculations presented in this article will be based on the assumption that the entropy of a gas can be calculated by putting it equal to the sum of the entropy given by the Sackur⁹ equation, which it would have as a perfect monatomic gas, plus the additional quantity of entropy which corresponds to the increase in the value of the specific heat C_p over 5/2 R as we proceed up from the absolute zero; in other words, that the total entropy is given by the equation

$$S = {}^{5}/{}_{2}R\ln T - R\ln p + {}^{3}/{}_{2}R\ln M + S_{1} + \int_{0}^{T} (C_{p} - {}^{5}/{}_{2}R) \frac{dT}{T}$$
 (2)

The above hypothesis was proposed by Tolman¹⁰ and found to be correct within the probable limits of experimental knowledge for the case of the entropy of diatomic hydrogen at 25° using actual specific-heat data for the evaluation of the last term in Equation 2. No claim is made as to the theoretical justification for this hypothesis. An equivalent hypothesis was earlier employed by Langen¹¹ for the calculation of Nernst's chemical constants, making use, however, of the theoretically incorrect Einstein-Stern equation for the specific heat of diatomic gases.

III. General Equation for Rotational Specific Heat

Except for the case of diatomic hydrogen, we have no experimental specific-heat data that would permit the direct evaluation of the last term in Equation 2 and must resort to some theoretical expression for calculating the excess specific heat due to the rotation of our "dumb-bell" molecules.

For convenience let us define the quantities Q and σ by the equations

$$Q = \sum p_m e^{-m^2 \sigma} \tag{3}$$

and

$$\sigma = \frac{h^2}{8\pi^2 JkT} \tag{4}$$

where p_m is the a-priori probability that a molecule will have the azimuthal quantum number m, J is the moment of inertia of the rigid "dumb-bell" molecule, h, k, and T have their usual significance and the summation Σ is to be taken over all the possible rotational states. It can then easily be shown that the rotational specific heat is given by the equation

$$C_R = R \sigma^2 \frac{d^2 \ln Q}{d \sigma^2} \tag{5}$$

IV. Integration between Zero and T

With the help of Equation 5 we obtain for the rotational entropy at temperature T the expression

$$S_R = \int\limits_0^T R \,\sigma^2 \frac{d^2 \ln Q}{d \,\sigma^2} \,d \ln T$$

Introducing the relation between σ and T given by Equation 4, we can transform the above expression as follows,

$$S_{R} = -\int_{0}^{T} R \sigma^{2} \frac{d^{2} \ln Q}{d \sigma^{2}} d \ln \sigma = R \left[\ln Q - \sigma \frac{d \ln Q}{d \sigma} \right]_{0}^{T}$$

$$= R \left(\ln Q_{T} - \sigma_{T} \frac{d \ln Q_{T}}{d \sigma} - \ln Q_{0} + \sigma_{0} \frac{d \ln Q_{0}}{d \sigma} \right)$$
(6)

Since the different theories of specific heat usually lead to simple expressions for $\ln Q$ at very low temperatures and at temperatures high enough so that the rotational specific heat has become R, the above expression for rotational entropy can easily be evaluated in the cases of interest without the necessity of determining the whole specific-heat curve.

V. Values of Q Given by Different Theories

Different hypotheses as to the value of the lowest possible azimuthal quantum number, and as to the relation between quantum number and a-priori probability have led to different expressions for Q. The following expressions for Q will be tested in this paper,—

I.
$$Q = \sum_{0}^{\infty} (2m+1)e^{-m^2\sigma}$$
 IV. $Q = \sum_{1}^{\infty} (m+1)e^{-m^2\sigma}$ II. $Q = \sum_{0}^{\infty} (m+1)e^{-m^2\sigma}$ V. $Q = \sum_{1}^{\infty} 2m e^{-m^2\sigma}$ III. $Q = \sum_{1}^{\infty} (2m+1)e^{-m^2\sigma}$ VI. $Q = \sum_{1}^{\infty} 2n e^{-(n-1/2)^2\sigma}$

The first five of these expressions are the ones which were derived by Reiche⁷ on the basis of the first form of quantum theory and different assumptions as to the lowest quantum number and as to a-priori probabilities, and the sixth is the one discussed by Tolman8 derived on the new assumption that the lowest possible azimuthal quantum number is 1/2. A statement of the hypotheses which have led to these different expressions for Q will be found in the paper of Tolman.8 The expressions I and II are intrinsically not very probable since they lead to specific-heat curves with maxima at temperatures lower than the final asymptotic approach to the value R.

Evaluation of Rotational Entropy

We may now evaluate the rotational entropy as given by Equation 6 for the above six cases.

Case I. $Q = \sum_{n=0}^{\infty} (2m+1)e^{-m^2\sigma}$. At high temperatures we may evidently write the approximations

$$Q_T = \int_0^\infty (2 m + 1)e^{-m^2\sigma} dm = \frac{1}{\sigma_T} \left(1 + \frac{1}{2} \sqrt{\pi \sigma_T} \right)$$

$$\ln Q_T = -\ln \sigma_T + \frac{1}{2} \sqrt{\pi \sigma_T}, \text{ and } \frac{d \ln Q_T}{d \sigma} = -\frac{1}{\sigma_T} + \frac{1}{4} \sqrt{\frac{\pi}{\sigma_T}}$$

and at low temperatures the approximations

$$Q_0 = 1 + 3 e^{-\sigma_0}$$
, $\ln Q_0 = 3 e^{-\sigma_0}$ and $\frac{d \ln Q_0}{d \sigma} = -3 e^{-\sigma_0}$

Substituting into Equation 6, for the rotational entropy at temperature T, we obtain

$$S_R = R(-\ln \sigma_T + \frac{1}{2}\sqrt{\pi\sigma_T} + 1 - \frac{1}{4}\sqrt{\pi\sigma_T} - 3e^{-\sigma_0} - 3\sigma_0e^{-\sigma_0})$$

Returning now to Equation 4 by which σ was defined $\sigma = \frac{h^2}{8\pi^2 T h T}$

$$\sigma = \frac{h^2}{8\pi^2 Ik7}$$

we see that σ approaches zero at high temperatures and infinity at low temperatures so that for the case in which we are interested we have

$$S_R = R \ln T + R \ln J + R \ln \frac{8 \pi^2 k}{h^2} + R$$
 (7)

and substituting S_R for $\int_0^1 (C_p - \frac{5}{2}R) d \ln T$ in Equation 2 we obtain for the total entropy of our diatomic gas

$$S = {}^{7}/{}_{2}R\ln T - R\ln p + {}^{3}/{}_{2}R\ln M + R\ln J + \left(S_{1} + R\ln \frac{8\pi^{2}k}{h^{2}} + R\right)$$
 (8)
where
$$S_{2} = S_{1} + R\ln \frac{8\pi^{2}k}{h^{2}} + R$$
 (9)

is the constant of the entropy equation.

Since Reiche⁷ and Tolman⁸ have given simple values for In Q at high and low temperatures for the other theories of rotational specific heat,

an entirely similar method of calculation can be used for evaluating the constants, using the other forms of Q that have been proposed. The results are given in Table I.

The second column gives the form of Q that has been considered and the third column the form found for S_2 . Expressing entropies in calories per degree per mole, pressure in atmospheres, molecular weight in grams per mole, moment of inertia in grams cm. squared per mole, and using Lewis'12 value, -2.63, for S_1 , we have calculated the numerical values of S_2 given in the fourth column.

Since we shall generally be interested in the value for the entropy of gases at 1 atmosphere pressure and 25° C. = 298.1° K., we may substitute these values of pressure and temperature in Equation 1 and rewrite it in the form

$$S_{298.1}^{\circ} = \sqrt[3]{2R \ln M} + R \ln J + C_{298.1}$$
 (10)

Numerical values of C_{298-1} are given in the last column of Table I.

TABLE I

	Sum	mary of Results		
Case	Form of Q	Form of S_2	S_2	C298.1
Ι	$\sum_{0}^{\infty} (2 m + 1)e^{-m^2\sigma}$	$S_1 + R \ln \frac{8 \pi^2 k}{h^2} + R$	66.30	105.95
II	$\sum_{0}^{\infty} (m+1)e^{-m^2\sigma}$	$S_1 + R \ln \frac{8 \pi^2 k}{h^2} + R - R \ln 2$	64.92	104.57
III	$\sum_{1}^{\infty} (2 m + 1)e^{-m^2\sigma}$	$S_1 + R \ln \frac{8 \pi^2 k}{h^2} + R - R \ln 3$	64.12	103.77
IV	$\sum_{1}^{\infty} (m+1)e^{-m^2\sigma}$	$S_1 + R \ln \frac{8\pi^2 k}{h^2} + R - 2R \ln 2$	63.54	103.19
V	$\sum_{1}^{\infty} 2 m e^{-m^2 \sigma}$	$S_1 + R \ln \frac{8 \pi^2 k}{h^2} + R - R \ln 2$	64.92	104.57
vi	$\sum_{1}^{\infty} 2 n e^{-(n-1/2)^2 \sigma}$	$S_1 + R \ln \frac{8 \pi^2 k}{h^2} + R - R \ln 2$	64.92	104.57

VII. Discussion of the Different Values of S2

It will be noticed that three of the proposed theories of specific heat (II, V and VI) have led to the same value of S_2 . Of these, Theory II is not entirely probable since it is based on the assumption that a-priori probabilities are to be calculated by counting positive and negative rotations only once, which does not agree with the Bohr correspondence principle. Theory V is perhaps as probable as any of those based on the assumption that the lowest possible azimuthal quantum number is unity, and Theory VI is the one based on the assumption that the lowest possible azimuthal quantum number is $^{1}/_{2}$.

Theory V is the one selected by Urey⁵ for determining S₂ by graphical ¹² Lewis, *Phys. Rev.*, **18**, 121 (1921). See also Lewis and Randall, "Thermodynamics," McGraw-Hill Book Co., New York, **1923**, p. 457.

integration under the specific-heat curve. Urey obtained in this way a value which, using our method of expression, 13 gives $S_2 = 64.93$, while we have obtained by a more direct mathematical treatment the practically identical value, $S_2 = 64.92$.

Since the different theoretical values for S_2 differ among themselves by a maximum of less than 3 cal./mole deg., an experimental decision as to the correct value for S_2 is difficult. Accurate values for the entropy and moment of inertia are both needed, the possible deviation from the assumed rigid "dumb-bell" model must be considered, and the assumption that the specific-heat curve has already reached the value $C_p = 7/2$ R must be scrutinized.

Moments of inertia calculated from the *classical* formula for the wave lengths of the maxima of infra-red double bands

$$J = kT \left\{ \frac{\lambda_1 \lambda_2}{\pi c (\lambda_2 - \lambda_1)} \right\}^2$$

are evidently less suitable for exact tests than those calculated on the basis of the quantum theory from a complete knowledge of the rotation spectrum, and moments of inertia calculated on the basis of the quantum theory from band or many-lined spectra in the visible or ultraviolet are not completely satisfactory since they presumably correspond to the molecule in an excited condition rather than in the normal condition which contributes to specific heat at moderate temperatures.

The following table presents all the figures for the calculated and experimental values of the entropy of diatomic gases at $25\,^{\circ}$ C. and 1 atmosphere that we have felt justified in including. The data upon which some of the figures are based are far from satisfactory, as will be indicated in the discussion that follows. Hydrogen has been omitted since the specific heat is still considerably below 7/2 R at $25\,^{\circ}$, and the moment of inertia would have to be obtained from the many-lined spectrum that corresponds to an excited condition of the molecule. Carbon dioxide and hydrogen cyanide have been included since the spectral data for these substances indicate that the structure of the molecule is linear and that they behave like rigid diatomic molecules.

The first column of the table gives the formula of the substance, the second column the value of the moment of inertia in grams cm. squared which was used for the calculation, the third column the experimental value of the entropy as determined by thermodynamic methods, and the remaining columns the values of the calculated entropies using the six different formulas developed in this paper, together with the deviations from the experimental values. The values of entropy calculated by the three formulas II, V and VI which agree have been put in a single column.

¹³ Urey used volumes instead of pressures in his entropy equation. It is easy to show that the constants for the two methods of expression differ by $R \ln R$.

The values of the moments of inertia for the first four gases in Table II are the ones used by Urey.⁵ The value for hydrogen chloride is based on Ime's data for the infra-red bands and hence is very accurate. The value for nitrogen is from the constant 2B for the 3883 cyanogen band as given by Kratzer, and hence suffers from the grave doubt as to whether this band is due to nitrogen or cyanogen. The values for carbon monoxide and nitric oxide are calculated by the classical formula from the separation of the maxima of infra-red bands and hence are not exact.

S	ubstance	J×1040	S exptl.	$\mathcal{S}_{\mathtt{I}}$	Dev.	$\mathcal{S}_{ ext{III}}$	Dev.	S_{IV}	Dev.	SII, V, VI Dev.
	HCl -	2.594	43.3	44.3	1.0	42.1	1.2	41.6	1.7	42.9 0.4
	N_2	14.4	45.6	46.9	1.3	44.8	0.8	44.2	1.4	45.6 0.0
	CO	14.7	45.6	47.0	1.4	44.8	0.8	44.2	1.4	45.6 0.0
	NO	14.3	49.3	47.1	2.2	45.0	4.3	44.4	4.9	45.8 3.5
	CO ₂	50	49.4	50.8	1.4	48.6	0.8	48.0	1.4	49.4 0.0
	HCN	33	49.1	48.9	0.2	46.3	2.8	45.7	3.4	47.1 2.0

The treatment of carbon dioxide is based on the assumption that this behaves like a diatomic gas with the carbon atom in the middle between the oxygen atoms. The moment of inertia is that obtained by Barker¹⁴ from infra-red spectra, who concludes from the spectral data that the molecule is linear in structure rather than triangular. It is a matter of great interest that the inverse calculation of the moment of inertia of carbon dioxide from thermodynamic data was made by Eucken,¹⁵ before Barker's results were known. Eucken in his calculations used the language of Nernst's chemical constants rather than that of entropy and used what was equivalent to an empirical rather than a theoretical value for the constant S_2 . He obtained the value for carbon-dioxide $J=50\times 10^{-40}$ g. cm. squared in complete agreement with the later spectral work of Barker who was himself unfamiliar with Eucken's work, which had appeared only a few months earlier.

Hydrogen cyanide is also treated as a rigid linear structure. The moment of inertia has been calculated from the separation between the maxima $\lambda_1=13.60\mu$, and $\lambda_2=14.33\,\mu$ measured by Burmeister. The spectral data now available show no evidence of a third moment of inertia. If we assume radii for the atoms that are consistent with those found for these same atoms in other gases, it seems necessary to assume that the hydrogen atom is between the carbon and nitrogen atoms in order to account for the large moment of inertia, $J=33\times13^{-40}$. The assumption of such a structure is undoubtedly bizarre but finds some support from the theory of hydrogen bonds proposed by Latimer and Rodebush. ¹⁷

¹⁴ Barker, Astrophys. J., 55, 391 (1922).

¹⁵ Eucken, Z. physik. Chem., 100, 159 (1922).

¹⁶ Burmeister, Verh. D. phys. Geo., 15, 589 (1913).

¹⁷ Latimer and Rodebush, This Journal, 42, 1431 (1920).

The experimental values of the entropies of the diatomic gases are those given by Eastman.¹⁸ The experimental values for the triatomic gases have been calculated from the free-energy data of Lewis and Randall.¹⁹ The values for nitric oxide and hydrogen cyanide may be greatly in error owing to the insufficiency of the thermodynamic data.

It would be dangerous to draw from the figures in Table II an absolutely definite conclusion as to the correct theory of rotational specific heat and rotational entropy. The derivations assumed are (1) a rigid dumb-bell molecule whose moment of inertia does not change with speed of rotation, (2) rotational energy for the molecule but no vibrational energy, (3) a specific-heat curve that has already reached 7/2 R at the temperature in question. Our spectral knowledge of hydrogen chloride is enough to tell us that Conditions 1 and 2 will be nearly met by this molecule, but the assumption that the specific heat is already 7/2 R is not justified for this gas at 25°C., owing to the small value of J. Nitrogen must be excluded for an exact test owing to the probability that the bands used belong to evanogen rather than nitrogen. Carbon monoxide and nitric oxide are unsuitable for exact tests since their moments of inertia had to be calculated from the classical formula. Furthermore, the experimental value for the entropy of nitric oxide may be greatly in error. Carbon dioxide is not suitable since the value of the specific heat is apparently already greater than 7/2 R at 25°. Finally, in the case of hydrogen cyanide both the spectral data and the thermodynamic data are unsatisfactory.

In spite of these difficulties, we feel that the tentative conclusion may be drawn in favor of the rotational entropy given alike by Theories II, V and VI. If we eliminate nitric oxide and hydrogen cyanide where the experimental values of the entropy may be greatly in error, we note an almost perfect correspondence between the experimental entropy and the value given by Theories II, V and VI. Under all the circumstances it would seem best to use for the present the values of S_2 and C_{298-1} , given by these theories.

VIII. Summary

1. A direct mathematical method has been developed for determining the theoretical values of the constants S_2 and C_{298-1} in the equations for the entropy of diatomic gases,

$$S = \frac{7}{2} R \ln T - R \ln p + \frac{3}{2} R \ln M + R \ln J + S_2$$

$$S(298.1^{\circ}, 1 \text{ atm.}), = \frac{3}{2} R \ln M + R \ln J C_{298.1}$$

- 2. Six different theories which have been proposed for rotational specific heat all based on the first form of quantum theory, but based on different theories as to a-priori probabilities and as to the lowest possible
 - 18 Eastman, This Journal, 45, 80 (1923).
- ¹⁹ Lewis and Randall, "Thermodynamics," McGraw-Hill Book Co., New York, 1923.

azimuthal quantum number, have been used to determine the theoretical values of S_2 and $C_{298.1}$ and the results compared with experimental values.

3. In the absence of further evidence, the best values for S_2 and $C_{298.1}$ are 64.92 and 104.57, respectively. (Entropy in calories, temperature in degrees centigrade absolute, pressure in atmospheres, molecular weight in grams per mole, moment of inertia in gram cm. squared per mole.)

THE TEMPERATURE COEFFICIENT OF PHOTOCHEMICAL REACTION RATE

By Richard C. Tolman Received July 9, 1923

I. Introduction

Let us consider a photochemical reaction, $aA + bB + \ldots \longrightarrow Products$, taking place at some given temperature T, under the influence of radiation from an external source, the frequency of the radiation being ν , and its energy density throughout the reacting mixture being u_{ν} . If we confine our attention to cases where the rate of reaction is proportional to the energy density u_{ν} and where the law of Guldberg and Waage is followed, we may write for the rate of the above reaction the expression,

$$-\frac{\mathrm{d}C_{\mathrm{A}}}{\mathrm{d}t}=k_{\nu}u_{\nu}C_{\mathrm{A}}^{\mathrm{a}}C_{\mathrm{B}}^{\mathrm{b}}\ldots \tag{1}$$

The quantity k_{ν} occurring in Equation 1 may be called the *specific photochemical reaction rate*. It is the rate at which the reaction would proceed if the reacting substances were present at *unit concentration* and subjected to radiant energy of frequency ν and *unit energy density*. The quantity k_{ν} is a parameter, independent of the concentration and energy density, but dependent on the temperature T and frequency ν . The temperature T is to be taken as that which would exist if the illumination from the external source were cut off. It is the purpose of the following article to present a theoretical treatment of the change in k_{ν} with T.

In an earlier article, ¹ the writer has already shown that for a monomolecular photochemical reaction, the temperature coefficient of photochemical reaction rate will be given by the equation

$$\frac{\partial \ln k_{\nu}}{\partial T} = \frac{\bar{\epsilon} - \bar{\epsilon}}{kT^2} \tag{2}$$

where $\bar{\epsilon}$ is the average energy of the molecules which pick up radiant energy and react, $\bar{\epsilon}$ is the average energy of all the molecules and k is Boltzmann's constant. In the article referred to, the above equation

¹ Tolman, This Journal, 42, 2506 (1920).

was obtained as a result which was incidental to a treatment of thermal reaction rates, and the methods employed were those of the classical statistical mechanics.

In this article we shall present a simple and direct proof of Equation 2, using the methods of the quantum theory instead of those of the classical statistical mechanics. Consideration will also be given to the temperature coefficient of bimolecular reactions, attention will be paid to the nature of the quantity $\frac{\partial}{\partial \nu} \left(\frac{\partial \ln k_{\nu}}{\partial T} \right)$, an interpretation of existing data on photochemical temperature coefficients will be given, a criticism will be made of Plotnikow's attempted classification of photochemical temperature coefficients into three groups, and some discussion of Einstein's

We may now proceed to our theoretical treatment.

law of photochemical equivalence will be presented.

II. The Number of Molecules in a Given Quantum State

The chance that a molecule will pick up radiant energy and hence undergo a monomolecular change, or in the case of bimolecular reactions arrive in an activated state such as to facilitate reaction upon collision, will evidently depend not only upon the frequency and density of the radiant energy involved but also upon the internal condition or quantum state of the molecule at the time it is subjected to the radiant energy.

For the number of molecules N_i in the i^{th} quantum state we shall use the expression

$$N_{i} = N \frac{p_{i} e^{-\epsilon_{i}/kT}}{\sum_{i} p_{i} e^{-\epsilon_{i}/kT}}$$
(3)

where N is the total number of molecules present, p_i is the a-priori probability that a molecule will be in the i^{th} quantum state, ϵ_i is the energy corresponding to the i^{th} quantum state, k and T have their usual significance and the summation \sum_{0}^{∞} is to be carried out over all possible quantum states of the kind in question.

The justification for this equation rests at the present time largely upon its correspondence with the Maxwell-Boltzmann distribution law, familiar in the classical statistical mechanics, which may be written in the form

$$d N = N \frac{e^{-\epsilon/kT} d\sigma}{\oint e^{-\epsilon/kT} d\sigma}$$
(4)

where ϵ is the energy of a molecule whose coördinates and momenta have values falling in the region $d\sigma$ and the integration \mathcal{I} is to be taken over the whole of the generalized space σ . Equation 4 may be regarded as the limit approached by Equation 3 in the regions of generalized space corresponding to high quantum numbers where the successive energy levels

are near together, the a-priori probabilities p_i occurring in Equation 3 and the size of the infinitesimal regions $d\sigma$ occurring in (4) being chosen so as to secure correspondence between (3) and (4) at the limit, thus satisfying the Bohr correspondence principle. The simplest procedure is to choose the a-priori probabilities as equal to the number of ways² in which a given quantum state can occur, and then adjust the size of $d\sigma$ so as to secure the desired correspondence.

III. Rate of a Monomolecular Photochemical Reaction

We may now proceed directly to obtain an expression for the rate of a monomolecular photochemical reaction. The mechanism of such a reaction may be pictured as consisting in the absorption of a quantum of radiant energy of magnitude $h\nu$ which raises the molecule to such an energy level that the monomolecular change can take place.

Let $\alpha_{i\nu}$ be the chance in unit time that a molecule in the i^{th} quantum state surrounded by radiant energy of frequency ν and unit density will absorb a quantum of energy $h\nu$, and $s_{i\nu}$ be the chance that such an activated molecule will undergo the monomolecular transformation in question. The quantity $s_{i\nu}$ will be unity only in case every activated molecule reacts without losing its activation before reaction by re-emission. Making use of Equation 3 for the number of molecules in the i^{th} quantum state we may then evidently write for the rate at which molecules are reacting under the influence of radiant energy of frequency ν and density u_{ν} the expression,

$$-\frac{\mathrm{d}N}{\mathrm{d}t} = u_{\nu} N \frac{\sum_{i}^{\infty} \alpha_{i\nu} \, p_{i} \, e^{-\epsilon_{i}/kT}}{\sum_{i}^{\infty} p_{i} \, e^{-\epsilon_{i}/kT}}$$
(5)

where the summation \sum_{0}^{∞} is to be taken over all possible states. Noting that $(-dN/dt)/(u_{\nu}N)$ is the quantity which we have called the specific photochemical reaction rate k_{ν} , we may now write,

$$k_{\nu} = \frac{\sum_{i=0}^{\infty} \alpha_{i\nu} s_{i\nu} p_{i} e^{-\epsilon_{i}/kT}}{\sum_{i=0}^{\infty} p_{i} e^{-\epsilon_{i}/kT}}$$
(6)

The above expression for photochemical reaction rate would permit a relatively complete solution of the whole problem of monomolecular photochemical reaction rate if we had sufficient knowledge of the values of $\alpha_{i\nu}$, $s_{i\nu}$, p_i and ϵ_i . At the present stage of scientific development, however, such knowledge is largely lacking. Moreover, at the present time we

² For example, in the case of a rotating molecule of the dumb-bell model this would mean the number of possible distinguishable orientations having the same azimuthal quantum number, as determined from the theory of quantization in space.

have little knowledge of the absolute values of k_{ν} since few photochemical experiments have been made with *monochromatic* light of *known intensity*. For both these reasons we shall find it advisable to turn our main attention to the percentage temperature coefficient of k_{ν} rather than its absolute value, since the theoretical treatment of the temperature coefficient does away for the most part with the necessity of detailed knowledge of the quantities in Equation 6, and there is furthermore a considerable body of data on photochemical temperature coefficients.

IV. Temperature Coefficient of Monomolecular Photochemical Reaction Rate

Assuming the quantities $\alpha_{i\nu}$, $s_{i\nu}$ and p_i independent of the temperature, which is certainly justifiable as a first approximation, we may carry out a logarithmic differentiation of Equation 6 and obtain

$$\frac{\partial \ln k_{\nu}}{\partial T} = \frac{1}{k_{\nu}} \frac{\partial k_{\tau}}{\partial T} = \frac{1}{k_{\nu}} \frac{\sum_{0}^{\infty} \alpha_{i\nu} s_{i\nu} p_{i} e^{-\epsilon_{i}/kT}}{\sum_{0}^{\infty} p_{i} e^{-\epsilon_{i}/kT}} - \frac{\sum_{0}^{\infty} p_{i} e^{-\epsilon_{i}/kT} \frac{\epsilon_{i}}{kT^{2}}}{\sum_{0}^{\infty} p_{i} e^{-\epsilon_{i}/kT}}$$

An examination of the first term on the right hand side of the above equation will show that it is equal to the average energy before activation of the molecules which actually pick up radiant energy and react, divided by kT^2 . The second term is obviously the average energy of all the molecules divided by kT^2 . Hence we may rewrite the above equation in the form

$$\frac{\partial \ln k_{\nu}}{\partial T} = \frac{\overline{\epsilon} - \overline{\epsilon}}{kT^2} \tag{7}$$

where the symbols $\bar{\epsilon}$ and $\bar{\epsilon}$ have the significance explained above.³

Before proceeding to a consideration of the interpretation of experimental facts with the help of this very simple equation, we shall first show that a slightly modified form of Equation 7 will also apply to dimolecular reactions.

V. Rate of a Bimolecular Photochemical Reaction

The mechanism of a bimolecular photochemical reaction may be pictured as consisting in the activation of one or both of the molecules entering into the reaction followed by collision and reaction. Let the reaction in question be $A + B \longrightarrow Products$ and let us consider the case in which only the molecules of A are activated by the extraneous radiation. For

³ The similarity of this equation in form to that for thermal reactions should be noted. In the case of thermal reactions, however, the quantity $\frac{1}{\epsilon} - \frac{1}{\epsilon}$ must be replaced by the whole energy of activation. See Tolman, Ref. 1.

the number of such activated molecules $N_{i\nu}$ present at any given time with the energy

$$\epsilon_{i\nu} = \epsilon_i + h\nu \tag{8}$$

we may evidently write

$$N_{i\nu} = N_{\rm A} \frac{u_{\nu} \alpha_{i\nu} \tau_{i\nu} p_{i} e^{-\epsilon_{i}/kT}}{\sum_{i} p_{i} e^{-\epsilon_{i}/kT}}.$$
(9)

where $N_{\rm A}$ is the total number of molecules of A, $\alpha_{i\nu}$ is the chance per unit time that a molecule in the $i^{\rm th}$ quantum state will pick up a quantum when surrounded by unit energy density of frequency ν , and $\tau_{i\nu}$ is the average life that such an activated molecule exists without reëmission. Furthermore, for the number of molecules of B in the $j^{\rm th}$ quantum state we may write,⁴

$$N_{i} = N_{\rm B} \frac{p_{i} e^{-\epsilon_{i}/kT}}{\sum\limits_{0}^{\infty} p_{i} e^{-\epsilon_{i}/kT}}$$
(10)

The chance that a molecule of A in the quantum state iv will collide with a molecule of B in the quantum state j will evidently be proportional to the product of the concentrations of molecules in these states, and in the case of gases as a first approximation to the square root of the absolute temperature. Hence if we denote by s_{ivj} the chance that reaction will take place on a collision between molecules in these states, we may evidently write with the help of Equations 9 and 10 for the rate of the dimolecular reaction the expression,

$$-\frac{1}{v}\frac{\mathrm{d}N_{\mathrm{A}}}{\mathrm{d}T} = k_{c}T^{1/2}\frac{N_{\mathrm{A}}}{v}\frac{N_{\mathrm{B}}}{v}u_{\nu}\frac{\sum\limits_{0}^{\infty}\sum\limits_{0}^{\infty}\alpha_{i\nu}\tau_{i\nu}s_{i\nu j}p_{i}e^{-\epsilon_{i}/kT}p_{j}e^{-\epsilon_{j}/kT}}{\left(\sum\limits_{0}^{\infty}p_{i}e^{-\epsilon_{i}/kT}\right)\left(\sum\limits_{0}^{\infty}p_{j}e^{-\epsilon_{j}/kT}\right)}$$

where v is the volume of the container, k_c is a constant which determines the number of collisions when the temperature is given, and the summation in the numerator is to be taken over all states i and j. If we again define k_r as the rate of reaction at unit concentrations under the influence of unit energy density we may write

$$k_{\nu} = k_{c} T^{i/2} \frac{\sum_{i=1}^{\infty} \sum_{i=1}^{\infty} \alpha_{i\nu} s_{i\nu j} p_{i} e^{-\epsilon_{i}/kT} p_{j} e^{-\epsilon_{j}/kT}}{\left(\sum_{i=1}^{\infty} p_{i} e^{-\epsilon_{i}/kT}\right) \left(\sum_{i=1}^{\infty} p_{i} e^{-\epsilon_{i}/kT}\right)}$$
(11)

As in the case of monomolecular reactions, we shall find it more informing to consider the temperature coefficient of reaction rate rather than its absolute value and shall proceed to obtain its value.

4 In obtaining Formulas 9 and 10 we assume that the values of $N_{i\nu}$ and $N_{j\nu}$ are not appreciably affected by losses through reaction.

VI. Temperature Coefficient of Bimolecular Photochemical Reaction Rate

Carrying out a logarithmic differentiation of Equation 11 we obtain

$$\frac{\partial \ln k_{\nu}}{\partial T} = \frac{1}{k_{\nu}} \frac{\partial k_{\nu}}{\partial T} = \frac{1}{2T} + \frac{1}{k_{\nu}} k_{c} T^{1/2} \frac{\sum\limits_{0}^{\infty} \sum\limits_{0}^{\infty} \alpha_{i\nu} \tau_{i\nu} s_{i\nu j} p_{i} e^{-\epsilon_{i}/kT} \frac{\epsilon_{i}}{kT^{2}} p_{j} e^{-\epsilon_{j}/kT}}{\binom{\sum\limits_{0}^{\infty} p_{i} e^{-\epsilon_{i}/kT} \binom{\sum\limits_{0}^{\infty} p_{i} e^{-\epsilon_{j}/kT}}{\binom{\sum\limits_{0}^{\infty} p_{i} e^{-\epsilon_{j}/kT} \binom{\sum\limits_{0}^{\infty} p_{i} e^{-\epsilon_{j}/kT}}}$$

$$+ \frac{1}{k_{\nu}} k_{c} T^{1/2} \frac{0}{0} \frac{\sum\limits_{0}^{\infty} \sum\limits_{0}^{\infty} \alpha_{i\nu} \tau_{i\nu} s_{ij\nu} p_{i} e^{-\epsilon_{j}/kT} p_{j} e^{-\epsilon_{j}/kT} \frac{\epsilon_{j}}{kT^{2}}}{\binom{\sum\limits_{0}^{\infty} p_{i} e^{-\epsilon_{j}/kT} \binom{\sum\limits_{0}^{\infty} p_{j} e^{-\epsilon_{j}/kT}}{\binom{\sum\limits_{0}^{\infty} p_{j} e^{-\epsilon_{j}/kT}}{\binom{\sum\limits_{0}^{\infty} p_{j} e^{-\epsilon_{j}/kT}}}$$

$$- \frac{\sum\limits_{0}^{\infty} p_{i} e^{-\epsilon_{i}/kT} \frac{\epsilon_{i}}{kT^{2}}}{\sum\limits_{0}^{\infty} p_{j} e^{-\epsilon_{j}/kT}} \frac{\sum\limits_{0}^{\infty} p_{j} e^{-\epsilon_{j}/kT}}{\sum\limits_{0}^{\infty} p_{j} e^{-\epsilon_{j}/kT}}$$

An examination of the terms in the above equation shows that it may be rewritten in the form

$$\frac{\partial \ln k_{\nu}}{\partial T} = \frac{1}{2T} + \frac{\tilde{\epsilon}_{A} + \tilde{\epsilon}_{B} - \tilde{\epsilon}_{A} - \tilde{\epsilon}_{B}}{kT^{2}}$$
(12)

where $\tilde{\epsilon}_A$ is the average energy before activation of the molecules of A which pick up radiant energy and then react, $\tilde{\epsilon}_B$ is the average energy of the molecules of B which enter into the reaction and $\tilde{\epsilon}_A$ and $\tilde{\epsilon}_B$ are the average energies of all the molecules present. If it is desired, Equation 12 can be rewritten in the form

$$\frac{\partial \ln k_{\nu}}{\partial T} = \frac{1}{2T} + \frac{\tilde{\epsilon} - \tilde{\epsilon}}{kT^2} \tag{12a}$$

where $\bar{\epsilon}$ is the average energy of the pairs of molecules of A and B that actually enter into the photochemical reaction and $\bar{\epsilon}$ is the average energy of any pair of molecules of A and B. Except for the negligible term 1/(2T) Equation 12a has the same form as Equation 7 for monomolecular reactions. It should be noted that the term 1/(2T) arises from the assumption that the number of collisions of the molecules of the gas is proportional to the square root of the absolute temperature. In the case of reactions taking place in a liquid medium, the decrease in the viscosity of the liquid with rise of temperature might be accompanied by a considerable increase in the chance of collision, so that a larger but probably roughly calculable term would have to be introduced.

Equations 12 and 12a were derived for a bimolecular reaction in which only one of the reacting substances was activated by the radiant energy in question. In case activation of both substances were involved the rate of reaction would no longer be proportional simply to the first power of the energy density and a somewhat more complicated treatment is necessary which is hardly worth considering at the present stage of experimental

knowledge. Even in the case of a polymerization such as that of anthracene, it is not probable that both anthracene molecules are activated in an appreciable fraction of the collisions which lead to reaction, while in the case of reactions between unlike molecules one of the components is very often photo-active in the region of the spectrum used and the other inactive.

No treatment will be given at the present time of reactions of higher order than the second, since higher order collisions are of very improbable occurrence, and total changes of higher order than the second probably take place in many cases as the result of a series of changes of lower order.

VII. The Quantity
$$\frac{\partial}{\partial \nu} \left(\frac{\partial \ln k_{\nu}}{\partial T} \right)$$

Before proceeding to an interpretation of experimental data let us consider the change in temperature coefficient with frequency. It is evident that the differentiation of either of the equations, 7 or 12a, for the two cases we have treated will lead to the same result, namely,

$$\frac{\partial}{\partial \nu} \left(\frac{\partial \ln k_{\nu}}{\partial T} \right) = \frac{1}{kT^{2}} \frac{\delta \tilde{\epsilon}}{\delta \nu} \tag{13}$$

VIII. Relation between Two Methods of Expressing Temperature Coefficients

Temperature coefficients for rate of reaction are unfortunately usually expressed as the ratio r between the rates of reaction at temperatures separated by an interval of 10 °C., in accordance with the expression

$$r = \frac{k_{T+10}}{k_T} \tag{14}$$

Expressing temperature coefficients in the more rational way adopted in this article, it is evident that we may write as a rough approximation

$$\frac{\partial \ln k_{\nu}}{\partial T} = \frac{k_{T+10} - k_T}{10 (k_{T+10} + k_T)/2} = \frac{r - 1}{5(r + 1)} \,, \tag{15}$$

We may now proceed to the interpretation of existing experimental data.

IX. Interpretation of Experimental Values of Temperature Coefficients

The most striking fact concerning the temperature coefficients of photochemical reaction rates is the extremely great number of reactions for which the value of r is unity or only slightly greater than unity. Plotnikow, in his admirable collection of existing information on photochemistry, lists 21 photochemical reactions for which the maximum value of r is 1.08.

The existence of such a group of reactions is readily understood on the basis of the developments presented in this article. The value unity for r means, in accordance with Equation 15, the value zero for $\partial \ln k_{\nu}/\partial T$.

⁵ Plotnikow, "Lehrbuch der Photochemie," de Gruyter and Co., Berlin and Leipzig, 1920, p. 62.

Hence, in accordance with Equation 7 for monomolecular reactions, and also in accordance with Equation 12a for bimolecular reactions, provided we neglect the small term arising from increased frequency of collision, we may write

$$\frac{\partial \ln k_{\nu}}{\partial T} = \frac{\bar{\epsilon} - \bar{\epsilon}}{kT^2} = 0 \tag{16}$$

and may conclude that for this great group of well-known photochemical reactions the average energy of the molecules which enter into the reaction is practically the same as the average energy of all the molecules. This result is entirely understandable, since it merely means that the average molecule has as good a chance of picking up energy and becoming activated as the molecules in some special quantum state far removed in energy content from the average. For reactions of this group, preliminary partial activation of the molecule is not necessary in order that the molecule may absorb its quantum and react.

The above discussion also makes it clear that we ought to expect to find cases in which preliminary activation of the molecules is advantageous in promoting reaction. This may arise either because molecules in the lower quantum states are not in a condition to absorb radiant energy of the frequency used, or because the energy level which they attain after the absorption is not high enough to lead to chemical reaction. In such cases the average energy $\bar{\epsilon}$ of the molecules which enter into the reaction will be greater than the average energy $\bar{\epsilon}$ of all the molecules and we shall find

$$\frac{\partial \ln k_{\nu}}{\partial T} = \frac{\bar{\epsilon} - \bar{\epsilon}}{kT^2} > 0$$
, and $r = \frac{k_{T+10}}{k_T} > 1$ (17)

As a matter of fact, Plotnikow⁵ lists 17 reactions in which the ratio r varies from 1.17 to 1.50. Plotnikow believes that these reactions can be divided into two sub-groups having the approximate values for the ratio r of 1.20 and 1.40, and is also inclined to believe that the value 1.20 should be ascribed to the increase with temperature in the velocity of some diffusion process involved in the reaction, so that there would be only two true photochemical temperature coefficients, corresponding to r = 1.00 and r = 1.40.

On the basis of the theoretical developments presented in this article, there seems to be no ground for the point of view of Plotnikow. The most significant term in determining the value of the temperature coefficient will be $\bar{\epsilon} - \bar{\epsilon}$ which is the difference between the average energy of the molecules which actually react and the average energy of all the molecules. This quantity will depend on the energy levels for the different quantized states of the particular substances involved and there is no reason why different substances should all have the same value of $\bar{\epsilon} - \bar{\epsilon}$. The value zero for $\bar{\epsilon} - \bar{\epsilon}$ is a very natural one to expect and this accounts

for the large group of photochemical reactions with zero temperature coefficient, but there is no reason to suppose that when $\tilde{\epsilon} - \tilde{\epsilon}$ is greater than zero it will be the same for different kinds of molecules as would be necessary to account for a unique value r=1.40.

In the case of second order reactions, in addition to the effect of the term $\bar{\epsilon} - \bar{\epsilon}$ in determining temperature coefficients, we shall also have to consider, as pointed out above, the effect of temperature in increasing the number of collisions between the reacting molecules. In gaseous systems the number of collisions will be roughly proportional to the square root of the absolute temperature and this will produce a negligible increase in reaction velocity with increasing temperature. In liquid systems the decrease in viscosity with rising temperature may be large enough to produce a measurable effect on reaction velocity. Similar considerations will apply to heterogeneous reactions where diffusion of the reacting substances to a catalytic surface is necessary for reaction. Since the viscosity of water at room temperature decreases about 20% for a 10° rise. this might account in some cases as suggested by Plotnikow for a value r = 1.20. It should be noted, however, that of the 7 reactions which Plotnikow lists as belonging to the group with the value 1.20, 3 are gaseous reactions, so that his explanation can hardly be a general one.

Further evidence as to the tenability of the theory of temperature coefficient here presented, is afforded by a calculation of the magnitude of $\bar{\epsilon} - \bar{\epsilon}$. If in accordance with Equations 7 and 15 we write

$$\frac{\partial \ln k_v}{\partial T} = \frac{\bar{\epsilon} - \bar{\epsilon}}{kT^2} = \frac{r - 1}{5(r + 1)},$$

and take r=1.40 and $T=300^\circ$, as typical, we obtain for $\bar{\epsilon}-\bar{\epsilon}$ the value 6000 cal. per mol. This corresponds to a value of 0.26 volts per molecule which is an entirely reasonable figure for the difference in energy contents between successive quantum levels in a molecule.

A monomolecular photochemical reaction taking place at room temperature in a homogeneous system with a temperature coefficient corresponding to r=1.40 might be very reasonably interpreted by assuming that the molecules in the lowest quantum state were not photo-active, and that molecules had to be in the next highest quantum state with a preliminary activation corresponding to 0.26 volts in order to absorb light and react. The relative numbers of molecules in the first and second quantum states would be given in accordance with Equation 3 by the expression

$$\frac{N_1}{N_2} = \frac{p_1 \ e^{-\epsilon_1/kT}}{p_2 \ e^{-\epsilon_2/kT}}$$

Since the ratio of the a-priori probabilities p_1/p_2 is certainly small, we may temporarily take it as unity; substituting the value of $\bar{\epsilon} - \bar{\epsilon}$ corresponding to 0.26 volts we then obtain for our particular case the ratio,

 $N_1/N_2=22,000$. We thus see that practically all the molecules will be in the lowest quantum state⁶ and that the difference, $\bar{\epsilon}-\bar{\epsilon}$, between the average energy of the molecules which react and the average energy of all the molecules will be approximately, as assumed above, the difference between the energy levels in the lowest and next to the lowest quantum states. The process of reaction itself will consist in the picking up of a quantum $h\nu$ by molecules in the next to the lowest quantum state followed by reaction. If the photo-active light has the wave length $500\mu\mu$ this denotes a further increase in energy level corresponding to an activation of 2.5 volts per molecule, again an entirely reasonable figure.

Before leaving the subject of temperature coefficients, the question naturally arises whether negative temperature coefficients might be possible, owing to the fact that molecules in the lowest quantum state could pick up radiant energy of the frequency employed and molecules in the second quantum state not be able to do this. It will be seen from the above discussion, however, that at room temperature with probable values of the difference in energy between the first and second quantum states, nearly all the molecules in any case would be in the lowest quantum state, and negative temperature coefficients would not be probable since a lowering of the temperature would not appreciably increase the percentage of molecules in the lowest quantum state.

X. Interpretation of Experimental Values of $\frac{\partial}{\partial \nu} \left(\frac{\partial \ln k_{\nu}}{\partial T} \right)$

In Section VII we showed that the change in temperature coefficient with frequency for a photochemical reaction is given by the equation

$$\frac{\partial}{\partial \nu} \left(\frac{\partial \ln k_{\nu}}{\partial T} \right) = \frac{1}{kT^2} \frac{\partial \bar{\tilde{\epsilon}}}{\partial \nu}$$

Since $\bar{\epsilon}$ is the average energy of the molecules that actually react, this quantity may decrease with frequency, for at higher frequencies the magnitude of the quantum $h\nu$ is increased and molecules from a lower quantum state may be raised to a level where reaction is possible. This means that we may expect to find cases where the second derivative in question is negative, provided $(\partial \ln k_{\nu}/\partial T)$ is not already zero.

Experimental data of the kind in question are not numerous nor certain. Nevertheless, referring once more to Plotnikow's treatise, we find that silver citrate paper has the temperature coefficient r = 1.19 in the blue and 1.07 in the ultraviolet; the phototropic substance salicylidene- β -

⁶ We exclude the possibility of an appreciable number of molecules in quantum states higher than the second owing to the still greater energy of these states, and the increased volume which would accompany the higher states. For the case of monatomic hydrogen, the distribution of atoms in the different quantum states, allowing for the increased volume of the atom in the higher quantum states, has been treated by Urey in an article which will probably appear in the Astrophysical Journal.

naphthylamine has the values 1.8 in the green, 1.45 in the blue and 1.39 in the violet; and the reaction between chlorine and hydrogen has the values 1.50 for green light (550–530 $\mu\mu$), 1.31 for blue light (490–470 $\mu\mu$) and 1.21 for violet light (400–350 $\mu\mu$). These results if reliable are in complete agreement with the theory here presented.

XI. Remarks on Einstein's Law of Photochemical Equivalence

Although the main purpose of this article has been to consider the temperature coefficient of photochemical rate of reaction, a few words concerning Einstein's law of photochemical equivalence will not be out of place. According to this law the number of molecules that enter into a photochemical reaction should be equal to the number of quanta of radiant energy absorbed. It is evident from the discussion presented in this paper, however, that molecules may sometimes absorb a quantum of energy and then lose it by re-emission before reacting. This would be true in the case of monomolecular reactions unless the quantity sin occurring in Equation 6 should be unity, and in the case of bimolecular reactions unless the product $\tau_{i\nu}$ $s_{i\nu}$, occurring in Equation 11 should be great enough to assure reaction for every molecule activated. Thus we should expect to find many reactions in which the actual amount of reaction falls below that predicted by an over simplified statement of Einstein's law, and this agrees with the experimental facts.7 Cases might also occur in which the primary photochemical reaction is followed by secondary reactions which would make the total change greater than that predicted. case apparently occurs under certain conditions in the reaction between hydrogen and chlorine and has been discussed by Nernst.⁸ The situation may be summed up by stating that although Einstein's law of photochemical equivalence presumably holds for individual molecular changes it may not hold for the total end result of a photochemical reaction as macroscopically determined.

XII. Conclusion and Summary

- 1. A simple equation for the temperature coefficient of photochemical reaction rate has been derived on the basis of the quantum theory. The equation agrees with that previously obtained by the author using the methods of the classical statistical mechanics.
- 2. Existing data on temperature coefficients of photochemical reactions have been successfully interpreted with the help of the equation. It has been shown that Plotnikow's division of photochemical temperature coefficients into three distinct classes is apparently not tenable.
- ⁷ For the best work in this field see Warburg's papers in the Berichte der Berliner Akadamie.
 - 8 Nernst, Z. Elektrochem., 24, 335 (1918).

- 3. An equation for change in temperature coefficient with frequency has been derived and successfully used in interpreting existing data.
- 4. The causes for apparent deviations from Einstein's law of photochemical equivalence have been discussed.
- 5. Experimental work in this Laboratory is now in progress for further testing the ideas presented in this article.

THE ADSORPTION OF GASES BY COPPER

By Robert N. Pease¹ Received July 11, 1923

During a recent investigation of the combination of ethylene and hydrogen in the presence of metallic copper,² a considerable amount of data on the adsorption isotherms of hydrogen, ethylene, ethane and carbon monoxide on copper was accumulated. As these results show many points of special interest, it has seemed worth while to devote a separate paper to them.

The apparatus, procedure and method of preparation of the copper and the gases have already been described² and need not be repeated here in detail. Suffice it to say that adsorptions at a series of pressures between 0 and 760 mm. were determined by admitting the gases in small quantities to an evacuated bulb containing the copper and measuring the pressure after equilibrium had been established. The dead space in the bulb and connecting tubes was determined by the use of helium, which was assumed not to be adsorbed.

The absorbent consisted of about 100 g. of copper granules prepared by reduction of copper oxide by hydrogen at 200° in its original position.

Adsorption Isotherms on Active Copper at 0°

The adsorption isotherms at 0° in the presence of active copper are shown graphically in Fig. 1. Ethane was not actually run on this sample but its comparative behavior is known from two other series on similar samples of copper. An isotherm has been sketched in for completeness. Nitrogen was also run on this sample but the variability of the results indicated the presence of varying but small quantities (less than 0.5%) of some strongly adsorbed impurity. The nitrogen was prepared from ammonium chloride and sodium nitrite and was purified by passage through sulfuric acid, phosphorus pentoxide and a tube cooled in a mixture of solid carbon dioxide

¹ The work represented by this paper was performed while the author was National Research Fellow at Princeton University.

² Pease, This Journal, 45, 1196 (1923).

and alcohol. A curve corresponding to the least adsorption noted for nitrogen has been sketched in. From the form of this particular curve, it would appear that this particular sample of nitrogen contained negligible amounts of impurity.

The marked specificity of the adsorption is conclusively demonstrated by the results of these measurements; for the order of adsorption not only bears no simple relation to the order of boiling points (that is, condensa-

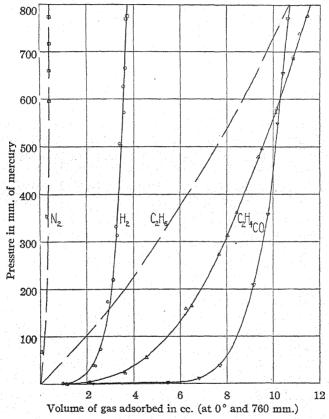

Fig. 1.—Adsorptions of N₂, H₂, C₂H₆, C₂H₄ and CO on active copper at 0°. Weight of copper catalyst: 117.0 g. Volume of dead space: 58.50 cc.

bility) but in addition depends upon the pressure at which comparison is made. Thus, at 10 mm. pressure the order of adsorptions is N₂, C₂H₆, H₂, C₂H₄, CO; while at 760 mm., the order is N₂, H₂, C₂H₆, CO, C₂H₄; and from the slopes of the curves it is evident that at still higher pressures the order will be N₂, H₂, CO, C₂H₄, C₂H₆. The order of boiling points is H₂, N₂, CO, C₂H₄, C₂H₆. The marked difference in the behavior of nitrogen and carbon monoxide toward copper is especially to be emphasized in view of the similarity in many physical properties of these two gases.

Leaving nitrogen out of account for the moment, certain interesting relationships among the adsorptions are clear. It is plain that the curves for hydrogen, carbon monoxide and ethylene are similar in form.3 There is a portion representing adsorption at a pressure of less than 0.2 mm. which amounts to about 1 cc. for hydrogen, 2 cc. for ethylene and 4 cc. for carbon monoxide, a second portion pronouncedly concave to the pressure axis and a third portion which is nearly rectilinear. The curve for ethane differs from the above in showing no marked low-pressure adsorption and being slightly concave to the pressure axis over the whole range. It is of interest that the slopes of the curves at 1 atm. for the four gases stand in the order of boiling points, that of hydrogen (expressed in cc. per 10 mm.) being 0.010, of carbon monoxide 0.020, of ethylene 0.065 and of ethane 0.092. If it were not for the fact that the slope of the nitrogen curve is certainly much less than that of hydrogen, one might be inclined to say that the adsorption at the higher pressures was due to the "physical" forces of capillarity. There would still be the difficulty that this implied the liquefaction of the gases in the capillaries of the copper at temperatures which for hydrogen and carbon monoxide are much higher than the critical, though not for ethylene and ethane ($t_c = 9.5^{\circ}$ and 32.1°, respectively).

Much time was spent in attempting to fit the data to various adsorption equations to be found in the literature, but it was found that none reproduced satisfactorily the values for the concave portions of the curves, that is the adsorptions up to about 0.5 atm. The best fit was obtained with a modification of Langmuir's equation for adsorption on a single type of elementary space. The simple equation may be written, $V_{\rm ads.} = [ap/(1+ap)]V_{\rm sat.}$, in which a and $V_{\rm sat.}$ are constants.

According to this equation, when ap is large compared to unity, $V_{\rm ads.} = V_{\rm sat.} = a$ constant, and when ap is small compared to unity, $V_{\rm ads.} = ap$ $V_{\rm sat.} = {\rm const.} \times p$. The coefficient, a, may be taken as a measure of the strength of the adsorption. It is probable that with an adsorbent such as the copper granules used in the work, elementary spaces or active adsorbing centers of all degrees of activity are scattered over the surface and that before Langmuir's equation can be properly applied, the "distribution curve" for activity must be known.⁴ We may assume, however, that over the range of pressure considered these activities may be grouped around three average values corresponding to (1) a high activity and large value of a (for which $V_{\rm ads.} = V_{\rm sat.}$); (2) a medium activity and medium value of a (for which $V_{\rm ads.} = [ap/(1+ap)]V_{\rm sat.}$) and a low activity and low value of a (for which $V_{\rm ads.} = [ap/(1+ap)]V_{\rm sat.}$). We may then write $V_{\rm ads.} = apV_{\rm sat.}$).

Adsorption curves for CO on copper like those here reported had been previously obtained by H. A. Jones and H. S. Taylor in the Laboratory of Princeton University.
 Langmuir, This Journal, 40, 1361 (1918).

 $V_1+V_2+V_3=V_{\rm lsat.}+\frac{a_2p}{1+a_2p}\,V_{\rm 2sat.}+a_3V_{\rm 3sat.}\,p.$ This equation can be made to fit the experimental values for hydrogen, carbon monoxide and ethylene within the experimental error. Considering that it is a four-constant equation, which may be written $V_{\rm ads.}=A+\frac{Bp}{1+Bp}\cdot C+Dp$, this is not strange. As it may be considered to have some theoretical basis, this equation has been preferred to others, however. It may be noted that the three terms correspond in a way to the three portions of the characteristic adsorption isotherms. The best values of the four constants for hydrogen, carbon monoxide and ethylene are given in Table I.

Table I
Values of Constants in Adsorption Equation

The Effect of Poisoning the Copper with Mercury

Since previous experiments had demonstrated that mercury was a very powerful catalyst poison in the ethylene-hydrogen combination and that adsorption runs approximately parallel to catalytic activity, it was of interest to investigate further the influence of poisoning on the latter property. Accordingly, with the sample of copper used in the experiments just described, the influence of mercury on the adsorptions of hydrogen, ethylene and carbon monoxide at 0.° was determined.

A small quantity of mercury, estimated at 0.015 cc., was forced into the adsorption bulb with hydrogen, after which the bulb was evacuated and heated to 200°. During the heating a few small globules of mercury condensed out on the cool portions of the connecting tube but the bulk of the mercury remained in the bulb. After heating, the mercury was found to have completely disappeared and there was no visual evidence of a change in the copper. Adsorption measurements revealed a marked decrease in activity, however.

The character of the effect of mercury poisoning is made clear by an examination of the curves in Fig. 2. (Broken curves, before poisoning; solid curves, after poisoning). It will be noted that the curves have been moved nearly parallel to themselves toward the pressure axis, corresponding to decreases of different magnitudes mainly in the strong (low pressure) adsorption. The amounts of these decreases in adsorption at 1 atmosphere are 4.85 for carbon monoxide, 3.40 for hydrogen and 1.60 for ethylene; at 100 mm. the decreases are 5.00, 2.70 and 1.90, respectively.

It is not clear why these decreases should vary so much among themselves, if the effect of mercury is to saturate permanently a certain number of elementary spaces. In particular, the result seems to be at odds with a conclusion arrived at in another paper.² There it was shown that when a mixture of ethylene and hydrogen was let into the bulb containing copper catalyst, the initial pressure (obtained by extrapolation) was what would be expected if the total amount of gas adsorbed were equal to the amount of ethylene alone which would have been adsorbed if it alone were present. This did not necessarily mean that no hydrogen was adsorbed under these conditions. In fact, quite the opposite was indicated by the results of

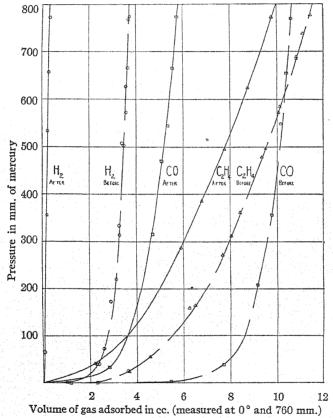

Fig. 2.—Adsorptions of H₂, C₂H₄ and CO on copper before and after poisoning with mercury. Broken curves: before poisoning. Solid curves: after poisoning. Weight of copper catalyst: 117.0 g. Volume of dead space: 58.50 cc.

the research as a whole. Rather the result was interpreted to mean that those active centers on the catalyst surface which could hold hydrogen molecules were also among those which could hold ethylene molecules, so that any hydrogen adsorbed from a mixture of the two simply displaced an equivalent amount of ethylene from the surface, one molecule of hydrogen replacing one of ethylene. The writer would have been inclined

to predict from this that the mercury would have decreased the adsorptions of the two gases by like amounts, whereas it actually decreases that of hydrogen about twice as much as that of ethylene. It would seem that de-activation of the active centers could proceed in steps, so that while a given active center was completely prevented from adsorbing molecules of hydrogen, it could still adsorb ethylene strongly. Carbon monoxide, which is the most strongly adsorbed of the three, is also most affected by the mercury, its adsorption being decreased about three times as much as that of ethylene. The fact that the decrease for ethylene is both absolutely and relatively the least of the three may be connected with its relative ease of condensation.

It may be mentioned that the decreases in adsorptive capacity were accompanied by a decrease in catalytic activity toward ethylene-hydrogen combination in the ratio of more than 200:1. It is only at very low pressures that the decreases in adsorption approach this ratio. This would seem to be conclusive evidence that the strongest adsorbing centers are responsible for the main part of the catalytic activity of the preparation.

Effect of De-activation by Heat Treatment

In the course of the experiments on the catalytic combination of ethylene and hydrogen, the effect on both catalytic activity and adsorptive capacity of partially de-activating a copper catalyst by heating it to 450° in a vacuum was determined.⁵ As this gave results which differ somewhat from those obtained by de-activation with mercury, they are also included.

The results of measurements of adsorption of ethylene and hydrogen before and after heating the copper adsorbent to 450° are shown graphically in Fig. 3. It will be seen that the effect of de-activating this sample of copper by heating was in a general way similar to the effect of de-activating the other sample by poisoning it with mercury. The curves have been moved over toward the pressure axis to nearly parallel positions, at the higher pressures at least. The heating has, however, decreased the hy-

⁵ Interesting results on the effects of heating active copper to successively higher temperatures have been obtained in the course of this investigation. In the present instance, the catalyst had been prepared at 200°, and heated to 300° after reduction. It had not thereafter been taken above 200°. After the experiments on the active material so obtained had been carried out, the catalyst was heated first to 350° for an hour and then to 400° for ¹/₂ hour without a marked change in activity resulting. It was then heated to 450° for one hour after which it was found to have decreased in activity as will be shown. Further heating at 450° for ¹/₂ hour was without noticeable effect, however. Similar results were obtained with another catalyst which was eventually heated to 550° to produce a very inactive material. For each rise in temperature a noticeable decrease in activity occurred but further heating at the same temperature was without marked effect. There seems, therefore, to be a stable condition of the surface corresponding to the highest temperature to which it has been heated. All the heatings described above were carried out in a vacuum.

drogen adsorption relatively less than the poisoning and the ethylene adsorption relatively more. Thus, at one atmosphere the decrease in hydrogen adsorption amounts to 70%, while the decrease in ethylene adsorption amounts to 22%. These are to be compared with decreases of

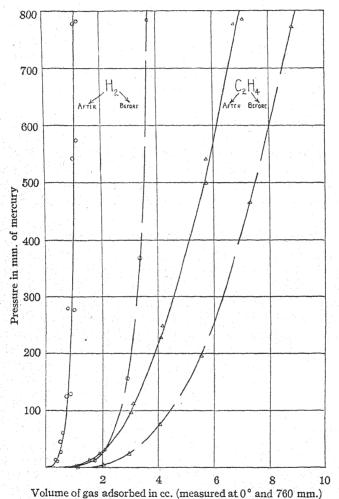

Fig. 3.—Adsorptions of H_2 and C_2H_4 on copper at 0° before and after de-activation by heating to 450° in a vacuum. Broken curves: before heating. Solid curves: after heating. Weight of copper catalyst: 94.9 g. Volume of dead space: 47.05 cc.

92% for hydrogen and 14% for ethylene caused by mercury poisoning. The absolute decreases at one atmosphere are 2.60 for hydrogen and 1.95 for ethylene. It will be seen that these figures are much more nearly of the same order than in the case of copper poisoned with mercury.

The decrease in catalytic activity in the ethylene-hydrogen combination accompanying these decreases in adsorption amounted to 85%. Just as in the case of the poisoning by mercury, one must go to very low pressures to find a corresponding decrease in adsorption, indicating again that it is the strong (low-pressure) adsorption which is mainly responsible for catalytic activity.

Seat of the Adsorptive Action of Active Copper

It is clear from the relative adsorptions of the different gases by active copper that we may at once conclude that ordinary condensation in capillaries is not a sufficient explanation of the results, although it may account for the adsorption of ethane and partially for that of ethylene. The action seems rather to be a specific one between the copper surface and the particular gas. It seems probable, however, that any copper surface will not do but that the surface must be in a special condition. 6 From the evidence here presented, taken in conjunction with previous experience in the Princeton Laboratories, it would seem that an active copper surface is one which has scattered over it regions containing atoms whose fields are highly unsaturated. This follows from the fact that heating active copper to temperatures as low as 450° caused appreciable sintering besides decreasing the surface activity. Sintering at so low temperatures points to the pre-existence on the surface of atoms of high mobility and therefore in a state of unsaturation. The process of sintering is the process of saturation of these atoms and since the agency which causes the sintering also decreases the surface activity, it is reasonable to look upon these unsaturated atoms as the cause of this activity. One would look for atoms of this character in surfaces of high degree of curvature—in "peaks," that is to say, on the copper surface—rather than in the "valleys," or capillaries.

It seems probable that each of these "peaks" can attach more than one molecule of adsorbed gas. Otherwise it is difficult to see how combination of ethylene and hydrogen, for example, can take place as a result of adsorption. As already pointed out, since each hydrogen molecule that is adsorbed apparently displaces an ethylene molecule, the same point on the copper surface cannot hold a molecule of both. The two must, however, be in close juxtaposition if combination is to occur. This can be true only if a given peak possesses more than one possible point of attachment. The activity is, therefore, not due to isolated active atoms scattered over the surface but to groups of these atoms.

It has sometimes been assumed that catalysts owe their activity to the presence of an allotropic form. While this cannot be rated very highly as an explanation, still it appeared to be of interest to find whether active

⁶ See Taylor and Burns [This Journal, 43, 1273 (1921)], Gauger and Taylor [ibid., 45, 920 (1923)] and Benton, [ibid., 45, 887, 900 (1923)] on the effect of method of preparation and of heat treatment on adsorptive capacity.

copper had the same crystalline structure as inactive. Accordingly, at the suggestion of Dr. A. W. Hull, the General Electric Research Laboratory was requested to make an X-ray analysis of a sample of active copper and very kindly consented to do so. The analysis proved that active copper has the same arrangement and spacing of atoms as ordinary massive copper, thus disposing of the assumption of a different allotropic form. This result also indicates that amorphous metal does not exist in any quantity on the surface. The discovery by Scheerer that metals preserve their characteristic crystalline arrangement and spacing of atoms even when in the colloidal state would render the existence of amorphous copper in the material used still more doubtful.

The peculiar appearance of active copper (it usually has a dull, reddish-brown surface) may be laid to its fine state of subdivision rather than to the presence of another form. Platinum black and precipitated silver behave similarly. Wood⁹ has suggested that the phenomenon is probably due to the "trapping" of the incident light in the pores of the substance by multiple reflection and consequent abnormally large adsorption.¹⁰

Apparent Density of the Copper Adsorbent

As a check on the determination of the dead space with helium on one sample of copper, determinations were also carried out by filling the exhausted bulb with water after the experiments were concluded. The value obtained with helium was 47.05 and with water was 47.13 after correction had been made for the volumes of the connecting tubes. The volume of the empty bulb was also determined and was found to be 58.00 cc., after applying the above correction. From these data the apparent density of the copper can be calculated. The average of the two values for the dead space, 47.09 cc., will be used.

	Vol. cc.	
Empty bulb		Wt. of copper = 94.925 g.
Dead space	47.09	wt. 94.93
Copper	10.91	Dens. of copper = $\frac{\text{wt.}}{\text{vol.}} = \frac{94.93}{10.91} = 8.70$
		Dens. of massive copper ¹¹ = 8.935

⁷ This request was made by Dr. Arthur F. Benton who prepared the sample and sent it in for investigation.

⁸ Scheerer, Appendix to Zsigmondy's "Kolloidchemie," 4th Edition, 1922, p. 387.

⁹ Wood, "Physical Optics," Macmillan Co., 1921, p. 449.

¹⁰ A sample of active copper recently prepared in the writer's laboratory has the characteristic appearance of ordinary copper and yet possesses high activity both as a catalyst and as an adsorbent with this exception, namely, that the adsorption of ethylene is almost the same as that of hydrogen instead of being two or three times as great. Accepting Wood's explanation, the appearance of this sample indicates that it is non-porous. The absence of large adsorption of ethylene at higher pressures is a strong indication that such adsorption is due to capillary condensation.

¹¹ Landolt-Börnstein "Tabellen," Julius Springer, 1905, p. 226.

The active copper is seen to have an apparent density lower by about 2.5% than that of massive copper. Since the X-ray analysis of a sample of active copper just mentioned showed that the copper had the normal arrangement and spacing of atoms, it is evident that the low density is probably due to the presence of cavities within the mass into which neither helium nor water penetrated.

Summary

- 1. The adsorption isotherms of hydrogen, ethylene, ethane, carbon-monoxide and nitrogen at 0° and up to one atmosphere have been measured. The results are discussed and the specific nature of the adsorption emphasized.
- 2. The effect of poisoning the copper with mercury on the adsorptions of hydrogen, ethylene and carbon monoxide and the effect of partially deactivating copper by heating on the adsorptions of hydrogen and ethylene have been determined. In both cases it has been found that the strong adsorption at low pressures has been markedly decreased while the additional adsorption at higher pressures has suffered little or not at all.
- 3. From these results and certain incidental observations it has been concluded that the adsorption is due to specific adsorbing centers on the copper surface rather than to the surface as a whole. These centers, it seems most reasonable to suppose, are regions of high curvature or "peaks" on the surface.

THE CATALYTIC OXIDATION OF CARBON MONOXIDE. I. EFFICIENCY OF THE CATALYSTS, MANGANESE DIOXIDE, CUPRIC OXIDE AND MIXTURES OF THESE OXIDES

By J. A. Almquist and William C. Bray Received July 18, 1923

In connection with the work of the Defense Research Section, C. W. S., it was discovered 1,2,3,4 that specially prepared mixtures of certain oxides catalyzed the combustion of carbon monoxide at low concentration in air. The catalyst composed of 60% of manganese dioxide and 40% of copper oxide furnished a striking example of the "mixture effect" in contact ca-

talysis, since with dry gas it had been made to operate at high efficiency at a temperature as low as 0°, although each of its components was active only at a much higher temperature.

In 1920, an investigation of the mixture effect was begun in this Laboratory, and the manganese dioxide-copper oxide catalysts for the combustion of carbon monoxide were chosen for study. It was planned to obtain as complete data as possible for several series of catalysts, varying in composition from pure manganese dioxide to pure copper oxide, rather than to attempt to prepare especially active catalysts. In order that the results for each series might give comparable data on the mixture effect, all of the catalysts of one series were prepared from the same moist samples of the individual oxides, and were dried under similar conditions. The program included the study of catalytic activity, adsorption and desorption of the gases involved, and the pore volume of the catalysts.

Since the completion of our work the results of a related investigation by Benton⁶ have been published, in which special attention was paid to the adsorption of gases by several oxide catalysts, including manganese dioxide, cupric oxide, and one mixture of these oxides. The experimental details differ greatly in these two independent investigations, and each will be a useful supplement to the other.
